CASE REPORTS

GONORRHEAL SEPTICEMIA AND ERYTHEMA NODOSUM*

By HENRY J BAKST, M D, JOHN A FOLEY, M D, and MARION E LAMB,
Boston, Massachusetts

SINCE the report of two cases of gonococcal septicemia by Hewes¹ in 1894 the publishing of sporadic cases has increased that number to about 150. Only 37 of this number, however, have had as fortunate an outcome as the two cases described by Hewes. We have recently had the opportunity of observing a case of gonococcal septicemia complicated by the presence of erythema nodosum. The fact that this patient was still entirely well when seen 14 months after his discharge from the hospital is, we believe, a source of added interest.

CASE REPORT

A 42 year old colored porter was admitted to the Boston City Hospital on December 30, 1933, complaining of pain in both legs of about two weeks' duration.

Two weeks before admission to the hospital he noticed the onset of symptoms which were suggestive of an acute upper respiratory infection. On the following day he awoke with aching pains in both legs, and became aware of the presence of large, red, painful areas on both legs. He also complained of fever, chills, nausea, frequency and nocturia.

The family and social histories were essentially irrelevant.

The patient was a widower, his wife having died in 1929. There had been no pregnancies, and the cause of her death was unknown to the patient.

His past history was not remarkable as far as childhood diseases were concerned. He had no knowledge of having had chorea or rheumatism, and had had no known contact with tuberculosis. In 1923 a bullet was removed from his left thigh, and in 1930 he was admitted to the Boston City Hospital for four days because of an acute gastritis following an alcoholic debauch.

Symptoms referable to the cardiorespiratory or gastrointestinal systems were not elicited. He gave a history of gonorrheal infection in 1926, but denied lues by name and symptoms. He weighed 148 lbs. on admission to the hospital, and his best weight had been 154 lbs. six months previously.

Physical examination revealed a well developed and well nourished adult negro, lying quietly and comfortably in bed. The skull, scalp and hair were negative. The ears and eyes were normal. The pupils reacted equally and well to light and distance. A slight painless swelling of the right side of the upper lip was noted in addition to the presence of a small scar on the left side of the forehead. The mouth and throat were not remarkable. The neck was negative save for the presence of slight painless adenopathy.

The thorax was symmetrical and expanded equally and well on both sides. The

*Received for publication July 3, 1935.

From the Fifth Medical Service, Boston City Hospital, the Department of Medicine, Boston University Medical School, and the Mallory Institute of Pathology, Boston.

apex impulse was plainly visible at the fifth interspace in the midclavicular line. The heart sounds were regular and of good quality. No thrills or murmurs were made out. The aortic second sound was slightly more pronounced than the pulmonic second sound. The lung fields were clear and resonant throughout with no râles. The radial pulses were regular, equal, and synchronous with a rate of 76 per minute. The blood pressure was recorded as 128 mm of Hg systolic and 76 mm diastolic.

Examination of the abdomen was negative. No tenderness, masses or spasm were made out. The liver, spleen, kidneys and gall-bladder were not palpable. The genitalia were normal. Rectal examination revealed the presence of a slightly enlarged boggy prostate which was moderately tender on digital palpation. Many pus cells were seen in a smear of the prostatic secretion, but no organisms were noted.

Small, non-tender, firm glands were palpated in both axillae and both posterior cervical chains.

The reflexes and upper extremities were normal. The lower extremities were negative except for the presence of a two-inch scar on the upper and inner aspect of the left thigh, which was the result of an old bullet wound. Two round, red, painful, indurated and symmetrical lesions about two inches in diameter were noted on the anterior surface of both legs midway between the knees and ankles.

The hemoglobin was 80 per cent (Sahli). The leukocyte count, which was 3,600 on admission, rose steadily until January 17, when it reached a peak of 20,500. It then slowly declined, and was 8,500 at the time of discharge from the hospital. The erythrocyte average count was 4,000,000. The differential smear was not remarkable, and no malarial parasites were seen.

Twenty-seven urine specimens showed a variable reaction with a specific gravity ranging from 1.003 to 1.027. Albumin in small amounts was present on four occasions, but sugar was never noted. Microscopic examination of the sediment revealed occasional white cells, rare red cells, and no casts.

The non-protein nitrogen was reported as 42 mg. The Kahn test of his blood was negative. The Widal test was negative. The first blood culture showed a *Staphylococcus albus* contamination. On January 16 the second blood culture was reported as having been positive for *Micrococcus gonorrhoeae*. The next two cultures on January 19 and 20 showed no growth, but on January 24 a second culture positive for *Micrococcus gonorrhoeae* was obtained. On January 29 no growth was again reported, but on January 31 a third culture positive for *Micrococcus gonorrhoeae* was obtained. The eighth blood culture, taken on February 1, was sterile, and on February 6, *Micrococcus gonorrhoeae* was grown from the blood for the fourth time. The next three blood cultures taken on February 11, March 5, and March 8 showed no growth.

All blood cultures were incubated in blood broth. The four positive cultures showed a moderate degree of hemolysis at the end of 48 hours. When grown on a blood agar plate, these organisms were recognized as raised, gray or colorless, glistening, moderate sized, non-hemolytic colonies. On direct smear, the organisms were found to be gram negative, biscuit-shaped diplococci of irregular size and variable staining. Agglutination reactions gave a positive result with antigenococcus serum in a dilution of 1:400, the same organisms agglutinating with antimeningococcus serum in a dilution of 1:200. Sugar fermentations on ascitic agar with the addition of hormone broth showed the invariable ability of this organism to form acid with dextrose and no change with maltose. On the basis of these findings the organism was considered to be *Micrococcus gonorrhoeae*.

On February 9 a skin biopsy taken from one of the nodes on the left leg was cultured in blood broth. This culture, after 144 hours of incubation, showed no growth.

Examination of the spinal fluid revealed no abnormal findings. The stools were negative.

An electrocardiogram taken on January 30 was reported as showing normal sinus rhythm with a rate of 77 per minute. The PR interval was 0.15 second. The QRS interval was 0.08 second. T_1 and T_2 were upright. T_3 was low. Left ventricular predominance was present.

Roentgenoscopic examinations of the abdomen and chest were negative.

The patient received very little treatment other than salicylates by mouth, prostatic massage, and an increased fluid intake. His frequent chills were accompanied by a septic temperature which persisted for eight weeks. His spleen was never palpable nor did he, at any time, develop audible cardiac murmurs.

By February 22, the fever had subsided, and the skin lesions had cleared entirely. He was discharged well on March 14, 1934.

The patient was admitted to the hospital again on April 1935 for the purpose of checking his physical condition. As far as could be determined, he was perfectly well at this time, and the complement fixation reaction, which unfortunately had been omitted during his previous admission, was now negative.

DISCUSSION

With Faure-Beaulieu's² review of 34 cases in 1906, Thayer's³ review of 20 cases at the Johns Hopkins Hospital in 1922, and the more recent surveys by McCants,⁴ Newman,⁵ and Solomon et al.,⁶ it is seen that the question of gonococcal endocarditis has received periodic and thorough attention. McCant noted 100 published cases in the literature up to 1912. Solomon, Hurwitz, Woodall, and Lamb found an additional 48 cases since then. With few exceptions, these cases have all been of fatal issue. Of the total number of cases reported, there are 10 instances in which the patient survived despite the presence of cardiac involvement,^{5, 7-15} a mortality rate of approximately 93 per cent.

It is reassuring to consider that the presence of the gonococcus in the blood stream does not always imply so high a mortality rate. Thomas¹⁶ and Irons⁸ believe that instances of mild gonococcal sepsis, which ordinarily recover, are considerably more common than is usually recognized. Its infrequent demonstration is ascribed to the difficulty in culturing the organism, the relatively small number of organisms in the blood stream in any given case, the ill-defined clinical picture, and the failure to recognize a metastatic lesion as evidence of a possibly demonstrable septicemia.⁸ More recently it has been suggested that an intermittent bacteremia makes the isolation of the gonococcus from the blood stream more difficult.^{17, 18}

A review of the literature reveals 27 reported cases of non-fatal gonococcemia without demonstrable endocarditis.^{1, 17-19, 20-38} These cases, in addition to our own, exhibit certain features which are worthy of note. Without exception they all represent instances of protracted fever. In several cases the presence of an enlarged spleen and of a suggestive rash obscured the true diagnosis for a time because of the obvious possibility of typhoid fever.^{13, 31}

Of the 28 recovered cases, 18 patients (including our own) had skin manifestations. These skin lesions demonstrate with admirable accuracy the skin manifestations of gonorrhea noted by Leon Perrin³⁹ and Buschke.⁴⁰ Eight patients had a maculo-papular rash,^{23, 24, 26, 27, 30, 31, 38} and two of these had additional pustular lesions.²⁴ Three (including our own) had erythema nodosum,^{21, 29} and three patients had a pustular eruption.^{22, 25, 28} Siegal described a pleomorphic papulo-pustular rash with associated hemorrhagic areas.³⁷ In the

remaining three cases one patient had a macular rash,¹⁸ another had a purpuric eruption¹⁷ and the third had an urticarial type of skin lesion³⁴

The simultaneous occurrence of gonococcal septicemia and erythema nodosum in our patient led us to a consideration of the presence of the latter condition. Early observers such as Trousseau,⁴¹ and later, Lendon,⁴² and others,^{43, 44} recognized these skin lesions as a specific infectious disease of unknown etiology. MacKenzie⁴⁵ noted that many of his cases of erythema nodosum exhibited characteristics of the rheumatic state. Others observed that erythema nodosum was often associated with tuberculosis,^{46, 47, 48} and the presence of acid fast bacilli was actually noted in histological sections of the nodes.^{49, 50} These three conflicting points of view in addition to the well supported concept that this disease is due to streptococcal infection^{51, 52} still have staunch adherents.

Ernberg^{53, 54} looks upon erythema nodosum as an early manifestation of tuberculosis and considers it to be an autogenous tuberculin reaction. Wallgren^{55, 56} adheres strongly to the possibility of a tuberculous etiology and has pointed out the occurrence of epidemics of erythema nodosum in tuberculous families. Collis^{57, 58} recognizes erythema nodosum as a type of hyperactive response to different bacterial allergens, and believes that in London, at least, it is most commonly due to tuberculous and hemolytic streptococcus endotoxins. Yet, in a not far-removed clinic, Forman and Whitwell,⁵⁹ although accepting erythema nodosum as a reaction of bacterial allergy, insist that the evidence is in favor of the tubercle bacillus. Symes,^{60, 61, 62} another British observer, recognizes two forms of the disease: an acute specific fever of essentially unknown etiology, and an allergic form of nodular rash which may be associated with rheumatic fever and tuberculosis. In this country, Hess and Berman⁶³ have demonstrated cases of both the tuberculous and rheumatic variety.

The obvious fact that erythema nodosum has been reported in association with at least 13 other conditions has gone almost wholly unrecognized.

As early as 1887, Bradley⁶⁴ noted the occurrence of erythema nodosum as a manifestation of iodism. This was later supported by Perrin⁶⁵ in 1892. Subsequently these skin lesions were noted in association with syphilis,^{66, 67} smallpox,⁶⁸ phlebitis,⁶⁹ meningococcal,^{70, 71, 72} gonococcal^{21, 29} and pneumococcal septicemia,⁷³ leprosy,⁷⁴ septic sore throat,^{75, 76, 77} scarlet fever,⁷⁸ the post-influenzal state,⁷⁹ chronic ulcerative colitis,⁸⁰ lympho-granuloma inguinale,⁸¹ ultra-violet rays,⁸² and rat-bite fever.⁸³

In view of this imposing array of infectious, chemical, and mechanical factors it seems unreasonable to accept, without qualification, any narrow concept of the etiology of erythema nodosum. The evidence in hand seems to agree with the recent views of Goldberg-Curth⁸⁴ who recognizes an idiopathic type of erythema nodosum, the pathogenic organism of which is unknown, and a symptomatic type which may develop in the course of a wide variety of infectious diseases, and as a cutaneous reaction to toxic substances.

In a recent publication Elwell⁸⁵ gives an excellent review of the various theories regarding the etiology of erythema nodosum. He also presents an interesting case of erythema nodosum in which the recurrence of the skin lesions was associated with axillary lymphadenitis and dental sepsis. It is his view that the syndrome of erythema nodosum expresses a reaction to various bacterial allergens, the most important of which is tuberculosis.

SUMMARY AND CONCLUSIONS

1 A case of gonococcal septicemia complicated by erythema nodosum-like lesions with eventual recovery of the patient is presented

2 The literature on gonococcal septicemia is reviewed A study of the recovered cases reveals an estimated mortality rate of 93 per cent in those cases of septicemia suffering from endocardial damage The presence or absence of cardiac damage is an important factor in determining the prognosis

3 Skin manifestations of various types in association with gonococcal septicemia are seen with sufficient frequency to be regarded as an important diagnostic factor Although the most common type is a maculo-papular lesion, any of the skin manifestations of gonorrhea may occur such as urticaria, hyperemia, purpura, and erythema nodosum

4 It is probable that the so-called idiopathic type represents a large group of patients with symptomatic erythema nodosum in whom the causative factors have been overlooked Any patient presenting the symptom complex of erythema nodosum requires careful study and investigation, for the lesions may occur in the course of a wide variety of infectious, chemical, and mechanical processes

ENTERIC CYSTS *

By O B MAYER, M D, F A C P, *Columbia, South Carolina*

ENTERIC cysts, sometimes called enterogenous or developmental cysts, are structurally similar to the intestines. Their cavity, containing a mucoid substance, is usually lined by epithelial cells with an underlying layer of lymphoid tissue and smooth muscle. Increasing internal pressure and consequent impairment of blood supply may cause localized atrophy or other structural changes. According to Ewing,¹ their origin is from some bud or pouch along the intestinal tract, and Evans² believes them to be related to the more common diverticula of childhood. The usual location in the ileocecal area may be explained by the fact that there is a remnant here of the vitelline duct or yolk sac. When the proximal end of this pouch remains patent, the result is the typical Meckel's diverticulum.

Since the first description of Fraenkel³ in 1882, Drennen,⁴ Haggard,⁵ and Bradley and Hoke⁶ have brought the total number of reported ileocecal cysts to twenty-eight. Occurrences elsewhere along the intestinal tract have been reported. Slesinger⁷ found an ileal cyst eight feet from the ileocecal valve, Aitken⁸ another ileal cyst, McLanahan and Stone⁹ two cysts in the rectal area, and Jackson and Ewell¹⁰ one in the mesentery of the transverse colon. These structures have been found even in the thorax (Salvin,¹¹ Poncher and Milles¹²) where they probably arise from mediastinal alimentary tract rests. Hughes-Jones¹³ reviews 55 cases.

The majority of cases have been in childhood, although cysts have been reported in both extremes of life. There is no predilection for either sex and

* Received for publication February 28, 1935

there is usually no other developmental defect. Many of the reported ileocecal cysts have been small, the larger ones are rarely more than 10 cm in diameter.

In the local hospital records of over 80,000 patients no enteric cysts have been recorded. In spite of the rarity their clinical importance must be recognized. They may produce confusing symptoms which simulate intussusception, abdominal tumors, cysts of other kinds, appendiceal abscess, and intestinal obstruction. Infantile pyloric stenosis by its projectile vomiting can usually be differentiated from other forms of obstruction. The clinical picture in adults may be vague and misleading. In general, the symptoms are those due to mechanical pressure, such as pain and obstipation. Other symptoms, however, may arise from intracystic infection, or from hemorrhage, or from the weight of a larger mass. In spite of clinical experience, laboratory studies and roentgenography, after the discovery of an abdominal tumor the final diagnosis is frequently deferred until operative exposure, or even until microscopic studies have been made.

CASE REPORT

A 12 year old white boy was first seen in April 1934, complaining of abdominal soreness and swelling of two days' duration. Eighteen months earlier and again two weeks earlier he had fallen, causing abdominal pain for a few hours. Both falls were considered inconsequential. On examination his doctor had found a large protuberance from a tumor in the left upper abdomen. Otherwise, the history was that of a sound, hardy boy.

Examination showed a normal, healthy, afebrile, athletic appearing child, who had walked into the hospital. Nothing of significance was found except a tumor mass in the left hypochondriac and epigastric regions, which extended to the umbilicus. This was smooth and round, tense, slightly tender and immovable.

The blood cell counts were normal. The urine contained a trace of albumin, and a scant number of hyaline casts.

Roentgen-ray report by Dr T. A. Pitts: "Fluoroscopic examination of the chest is negative. The filled stomach is pressed upward by a palpable mass. The stomach and duodenal cap are negative. The remainder of the duodenum which partially encircles the mass is extremely narrow and assumes an unusual course. The jejunum runs anteriorly and is flattened. The practically empty colon is not outlined. The mass is fixed and the distorted outline of the duodenum makes it typical of a pancreatic tumor, probably a cyst." (Figure 6)

Glucose tolerance test, with 70 grams of glucose

Time	Blood Sugar	Urine Sugar
Fasting	100 mg	0
30 min	154 mg	+++
60 min	156 mg	++
120 min	114 mg	0

The pre-operative clinical diagnosis of probable pancreatic cyst was based on the history of abdominal injury, the location and the apparently rapid development of the tumor, roentgen-ray studies and glucose tolerance test findings.

At the operation, performed by Dr G. H. Bunch, there was found attached to the upper surface of the transverse mesocolon and situated well under the cardiac end of the stomach, an irregular, large, cystic mass (figure 1), not adherent, pushing the stomach upward and the transverse colon downward into the pelvis. Its size

and position mechanically widened the duodenal curve, but caused no apparent obstruction. The attachment of the mass to the transverse mesocolon was separated and the tumor removed intact (figure 2), without disturbing the relationship of the viscera and without resection of the gut.

FIG 1 Anterior view of intact cyst (Inch scale)

The pathological report by Dr H H Plowden is as follows. Gross description "The specimen was a cystic tumor weighing 1,563 grams and measuring 20 by 14 by 11 cm. Its outer surface was smooth, glistening, and studded with occasional dense nodules, about 0.5 cm in diameter. The tumor was quite tense, giving the impression of considerable pressure within.

"When the cyst was opened a great quantity of thick, stringy, tenacious mucus of a pale, bluish color with occasional white streaks was seen. The inner walls conformed in shape to the general outside shape, except that toward the point of mesenteric attachment a number of low ridges terminated in sharp edges as if they had at one time divided the large cyst into a number of smaller ones. This finding suggested an originally loculated cyst" (Figure 3).

Microscopic description "Sections made from various parts of the cyst wall show varying structures, apparently depending on the amount of stretching to which the wall has been subjected. The outer surface covering is of flat, pavement-like endothelial cells, which correspond to the peritoneal covering. Beneath this is a layer of thin, loose connective tissue in which are a few small lymphocytes and small

blood vessels The greatest variation of structure is seen in the type of lining cells and in the amount of smooth muscle present In some areas the lining epithelium is a single layer of low cuboidal cells, in others there are several layers of columnar cells, in still others there is a layer of tall columnar cells of the mucus-forming type (figure 4) The latter type of cells predominates In the thinner parts there are

FIG 2 Showing mesenteric attachment (Inch scale)

merely fragments of muscle tissue In some of the thicker areas there is a well developed muscle layer made up of inner circular fibers and outer longitudinal fibers (figure 5) The histological resemblance to intestine is quite striking Diagnosis Enteric cyst"

Convalescence was uneventful and during the 10 months since the operation the boy has been entirely well .

FIG 3 Interior of cyst Atrophic ridges suggest a loculated-type tumor

SUMMARY

Enteric cysts are rare developmental abnormalities which occur anywhere along the alimentary tract although usually in the region of the terminal ileum. Symptoms are usually manifested in early childhood.

This example was found in a 12 year old boy after symptoms of a few days' duration, and the correct diagnosis was made only after microscopic study. The unusual features were (1) its unusual location in the transverse mesocolon, (2) its large size, about one-twenty-fifth of the body weight, and (3) its at-

FIG 4 Section of cyst wall showing single layer of tall columnar cells, many of a goblet type (High power)

FIG 5 Section of entire cyst wall showing similarity to intestinal structure (Low power)

FIG 6 Retouched film showing site of cyst

tachment which permitted intact removal without disturbing the adjacent intestine

EDITORIAL

THE MOVEMENT AND DISTRIBUTION OF BODY WATER

It is now fairly well established that sodium and potassium, the two principal basic ions present in the body fluids, have a preponderant influence upon the volume and distribution of body water, as well as upon the regulation of osmotic pressure. Approximately nine-tenths of the total osmotic pressure of the body fluids, under normal conditions, is contributed by the dissolved electrolytes. Proteins, urea and other organic substances usually play a distinctly subordinate role. As the contribution of the anions to the total osmotic pressure is about equal to that furnished by the bases, and varies with them, fluctuations in the concentration and excretion of sodium and potassium are of particular significance.

About 70 per cent of the mass of the body is composed of water, which may be separated into two principal divisions from a chemical point of view—the fluid within the cells, and that which bathes the interstitial spaces and comprises the various extracellular fluids, including the blood plasma, lymph and other bodily humors. Owing to the fact that potassium exists in the fluids of the interior of most cells almost to the exclusion of sodium, and that sodium, calculated on the basis of its chemical combining power, or equivalence, accounts for nearly 90 per cent of the bases of the fluids outside of the cells, it is often possible to identify the origin of water discharged from the body by means of the concentrations of these basic electrolytes which are dissolved in it. There is good evidence at the present time, although most of it is indirect, that under ordinary circumstances potassium does not diffuse freely out of the cells and that sodium and chloride do not diffuse into them. The exact amounts of sodium and chloride which are actually present in the intracellular fluids are unknown, but there is reason to believe that at least in many types of cells very little of these electrolytes occur, if indeed they are actually present at all.

In contrast to the relative immobility of the electrolytes, the body water is believed to pass freely in and out of the cell membranes, as required, so as to maintain an equilibrium of the osmotic pressure throughout the body fluids. The pattern of the dissolved substances is fairly constant, but their proper concentrations are stabilized by this shift of water. For the same reason, an excretion of one or both of these ions must necessarily be followed by the excretion of water in order that the concentrations in the body fluids may be maintained at precise level. By studies of the base content of the excreta in disease states, or following the use of diuretic agents, the origin can therefore be surmised. In this manner it has been learned that the dehydration of diabetic acidosis, of severe infantile diarrhea, and following the use of diuretin are all due to a loss of both extracellular and intracellular water. On the other hand, the type present in the condition of heat

cramps, as well as that following the use of thyroxin in myxedema, appears to be due chiefly to a loss of extracellular water

Fluid, however, does not necessarily follow the movement of electrolytes, or at least it may not move in the same direction. Mackay and Butler have recently reported a disproportionate retention of sodium relative to water during the onset of an acute upper respiratory tract infection, and similar retention of sodium, analogous to the well known retention of chloride, has been reported in pneumonia by Sunderman. Darrow and Yannet, by means of ingenious experiments with intraperitoneal glucose, have removed a large portion of the electrolytes of the extracellular fluids without any gain or loss of water from the body, and have demonstrated the profound dehydration and hemoconcentration which results, due to the passage of water into the cells to equalize the osmotic relationships.

A recently studied type of dehydration and resultant hemoconcentration and shock, that following the withdrawal of the adrenal cortical hormone from adrenalectomized animals, is analogous to the type last mentioned. Here a loss of sodium and chloride in the urine is accompanied by a retention of potassium, and the loss of water by way of the kidney may be almost negligible. In this case, in order to maintain the necessary equality of osmotic pressure both inside and outside of the cellular membranes, water penetrates from the interstitial fluids into the cells, lowering the electrolyte concentration within, while at the same time raising that of the interstitial fluids. The consequence, however, is a hemoconcentration, and the symptoms of dehydration and shock which result are practically identical with those seen when actual losses of fluids occur from the body. The observation is of practical interest, since it illustrates anew, the fact that the clinical phenomena which are observed as a result of hemoconcentration, dehydration, and shock, follow chiefly the loss of extracellular fluids. The intracellular fluid, as in this case, may actually be augmented in amount, but this has no effect upon the dehydration. The body does not lose a significant amount of water, but its displacement into the cells renders it ineffective. The fact that the volume of extracellular fluids, as estimated on theoretical grounds, and as measured by means of the sulphocyanate method introduced by Crandell, or by the sucrose and sulphate distribution studies of Leviates, is not large, as compared to the volume of intracellular fluids, may make more significant the loss of smaller amounts of the former than have hitherto been appreciated. These measurements would indicate that the volume of the interstitial fluids is about 20 to 25 per cent of the body weight, while the fluid within the cells themselves may be twice or even three times as much.

BOOK REVIEWS

Poliomyelitis, a Handbook for Physicians and Medical Students By JOHN F LONDON, M D, and LAWRENCE W SMITH M + 275 pages, 14 5 × 22 5 cm Macmillan Company, New York 1934 Price, \$3 00

This monograph is a very timely addition to the subject of poliomyelitis. It is short and concise and yet is inclusive enough to answer any pertinent question concerning the disease. The opening chapter gives a short historical review of the subject, with especial reference to Heine and Medin, whose names the disease carries. Our present knowledge concerning etiology and pathogenesis is briefly outlined in the second chapter.

The pathology of the disease is especially well covered. This presentation is based on 96 autopsied cases in the Willard Parker Hospital. About 40 pages are devoted to this analysis. The pathology of the reticulo-endothelial system, general systemic pathology, and pathology of the central nervous system are discussed under separate headings. The interesting work of Burrows on the reticulo-endothelial system in poliomyelitis has been more or less corroborated in the authors' series. They agree to "the initial restriction of the infection to the reticulo-endothelial system." The pathological changes in the nervous system are discussed in detail with ample illustrations.

The epidemiology of the disease is fully covered. Such factors as geographic distribution, climate, incidence, effect of season, and the current theories concerning the modes of dissemination are briefly described.

The chapters on symptomatology, paralysis, laboratory aids, and diagnosis are amplified with valuable illustrative cases. The treatment of the disease is discussed at length. All methods currently employed are critically analyzed. The opinion of the authors is that serum therapy is of little or no value in preventing paralysis. The consensus of opinion both for and against serum therapy, however, is discussed. The last chapter gives a valuable short outline on the after care of paralysis, and was written by an orthopedist, Dr Garry de N Hough. A short appendix concludes the book. There is an ample bibliography at the end of each chapter, covering 236 titles.

This book can be highly recommended to anyone desiring a concise, authoritative source of information concerning poliomyelitis.

J G A, Jr

Recent Advances in Allergy By GEORGE W BRAY, M B, Ch M, M R C P V + 503 pages, 14 5 × 20 5 cm P Blakiston's Son and Co, Inc, Philadelphia 1934

The title "Recent Advances in Allergy" applied to this work to make it uniform with the other members of the "Recent Advances" series, does not express its completeness, as it presents a good general historical review of the study of allergic disease. The author states that his aim is "to provide in a handy and inexpensive form a resume of our present state of knowledge and the trend of modern research in allergy in general, and its individual manifestations in particular."

The book is divided into two parts, the first discussing the nature of hypersensitiveness, the mechanisms of its manifestations in animals and man, and the general factors involved in allergic diseases. The second division takes up the individual manifestations of allergy: asthma, hayfever, allergic rhinitis, skin diseases, cerebral and gastrointestinal symptoms, bacterial, physical and drug allergies, serum reactions, and hypersensitiveness to animal parasites, fungi, and insects.

The most serious adverse criticism that might be advanced is that the author, in the more practical parts of the book, has written specifically for the English, rather

than the American, practitioner In such a subject, the geographic distribution of offending plants, with their pollinating periods, is of prime importance, and American flora have been largely neglected The author states that he has made no effort to present this phase of the subject due to its excellent study in American publications

In general, "Recent Advances in Allergy" is quite complete, very well documented, and, with the above exception, practical It should provide a useful and interesting general view of the subject

T N C

Diseases of the Thyroid Gland By ARTHUR E HERTZLER, M D 348 pages, 17 × 25 cm C V Mosby Co, St Louis 1935 Price, \$7 50

This monograph is described by its author as an expression of his own experiences and impressions in dealing with affections of the thyroid gland The background is further described as a small country hospital whose isolation makes the investigators more free to follow their own ideas uninfluenced by the opinion of associates It is, therefore, not intended to be either complete or authoritative, and what is lost in encyclopedic quality is gained in freshness, originality and interest

There are disadvantages in this approach to the subject Opinions may be confused with accepted facts, and important recent contributions seem to have limited acceptance by the author The author, for example, is disinclined to use the classification of the Society for the Study of Goiter, yet much of his discussion elsewhere is argument for this same classification, and his reasons cited for non-acceptance apply nearly as aptly to his own classification

One may differ with many statements and conclusions, but this difference of opinion is stimulating, and reminds us that many convictions are, after all, only opinions which may be weakened or strengthened by a good argument

It is to be regretted that one's enjoyment of the book is somewhat marred by occasional lapses from acceptable English

In spite of certain handicaps the book will be keenly enjoyed by all those interested in diseases of the thyroid gland

E M H, JR

Objective and Experimental Psychiatry By D EWEN CAMERON 271 pages, 15 × 22 cm Macmillan Co, New York 1935 Price, \$3 00

Feeling a "growing distrust of purely descriptive and intuitive concepts of human behavior" and finding it "more and more difficult to content (himself) with facts or assertions save where they will withstand experimentation and will not fail us on prediction," Dr Cameron points out some of the pitfalls of our usual psychiatric records He begins by sketching the development of science in general, from a collection of animistic myths to a more or less precise array of formulae buttressed by objectively demonstrable facts, and stresses the need for a study of human behavior from a more detached point of view, affording more demonstrable behavior items in the patient and less injection of the observer's own personality traits Observational errors, projectionism ("the attempt to ascribe to the patient the feelings and thinking which we consider from our experience he should be entertaining on being exposed to a given situation") and conventionalization (the tendency to make the history of the reaction conform with already delineated concepts) are the greatest defects This thesis, and possible points of attack for experimental methods, are developed in the first two chapters

The next 15 chapters survey impartially the literature on Tests of Intelligence, Introversion—Extraversion, Word Association Tests Conditional Reflexes; Heredity, Statistics Blood Sugar Tests, Response to Ephedrin and Adrenalin, Hemoclastic Crisis, Respiratory Center and Schizophrenia, Epilepsy, Basal Metabolism,

Blood Pressure, Sedimentation Rate Hemo-Encephalic Barrier and pH Relations to Personality, Constitution, and Pathology, in their relation to the problems of abnormal behavior

The field is thoroughly covered, with references from 300 odd writers on the various subjects. The final chapter is a brief presentation of simple statistical methods. It is a well written book of value to psychiatrists because of the validity of the writer's views and the assembled review of material, and to other physicians who may be interested in current experimentation on the objective aspects of personality.

H M M

Russell A Hibbs By GEORGE M GOODWIN 136 pages, 15 × 22 cm Columbia University Press, New York, N Y 1935 Price, \$2.00

Everyone who had the good fortune to know Dr Hibbs will realize how well the author of this treatise has portrayed his character.

Dr Hibbs was a most striking figure at all times, he spoke with a decisiveness that carried conviction, not only by reason of his deep voice and strong face, but also because he would "back-up" his statements with figures that carried authority. He was keenly interested in developing young surgeons and was always ready to offer counsel, to open pathways for advancement, and to stick by his man, he was a stimulating personality by example as well as by suggestion. Only a very few knew Dr Hibbs in his lighter moments and it is gratifying to know that he had some real fun from extra-curricular activities, as he was usually seen working hard, early and late.

Some of the original surgical procedures that Dr Hibbs instituted have become standard throughout the world and have revolutionized the treatment of certain conditions. Thousands of patients are indebted to him for these contributions to surgery as well as to his own personal efforts for them, as individuals.

The New York Orthopedic Hospital with its Country Branch is a lasting monument to Dr Hibbs and will forever bear witness to his indomitable spirit, wisdom, foresight, perseverance and capability.

The author has written about Dr Hibbs in a style which flows easily and which gives a clear impression of the striking personality about whom he is writing.

The collection of original papers in the appendix makes the book valuable also as a reference book, and it might well be added to any surgeon's library. The two tributes preceding the appendix express the feelings of the many who have come into intimate contact with this outstanding orthopedic surgeon.

A F V

Synopsis of Regional Anatomy By T B JOHNSTON, M B, Ch B, Professor of Anatomy, University of London, Guy's Hospital Medical School 3rd Edition Lea and Febiger, Philadelphia 1935 Price, \$4.50

This book is intended to be used side by side with prepared or recently-dissected specimens, and presupposes a fairly accurate knowledge of each region described. Written in concise but distinctly readable form it gives one the impression of a dissecting manual from which the technical instruction and minute detail have been omitted. Added are occasional practical points which serve to stimulate the student's interest in an otherwise rather abstract study.

Except for that part devoted to the central nervous system it is devoid of illustrations, an acceptable omission in a book of this type, especially as mental pictures are best created from the dissected cadaver itself.

The nomenclature is the English adaptation of the B N A, eliminating many of the flaws of the previously-used English terminology and including many new self-

explanatory terms which should with few exceptions find their way into the fuller textbooks. Proper names have been properly excluded.

This book is especially for the student of gross anatomy. It is not a practitioner's book of reference. Put to the purpose for which it is intended it will be a useful adjunct to the student's other books of anatomical instruction.

M R

Diseases of the Mouth and Their Treatment. By HERMAN PRINZ, M D, and SIGMUND S GREENBAUM, M D. xiv + 602 pages, 16 × 24 cm. Lea and Febiger, Philadelphia. 1935. Price, \$9.00.

This is a well written and splendidly arranged text dealing with oral disease. The introductory chapters give a comprehensive description of the embryology, anatomy and physiology of the oral cavity. Mouth examination is described, including clinical, roentgenographic and microscopic methods. Oral hygiene and dental prophylaxis are discussed.

Oral manifestations of local origin, as well as those due to metabolic disturbances, blood dyscrasias, avitaminoses, endocrine diseases, infectious diseases, tropical diseases, parasites, skin diseases, drug eruptions, etc. are all well classified, and described in a systematic and thorough manner. Congenital anomalies, and acquired diseases of the tongue, lips, cheek, palate, salivary glands and floor of the mouth receive adequate consideration. There is a comprehensive classification and description of oral tumors and cysts with methods of diagnosis and treatment.

There is also an interesting discussion of the oral manifestations in functional and organic neurologic conditions: dysarthria, tics, local paralyses, neuralgias, etc.

The closing chapter concerns therapeutic suggestions, such as mouth washes, tooth pastes, ointments and anesthetics.

The book throughout is profusely illustrated with photographs and colored drawings. The method of approach, the completeness of description, and wide range of references make this book authoritative in its field.

STATE MEETINGS OF COLLEGE MEMBERS

Connecticut

The first meeting of the Connecticut members of the American College of Physicians was held at the Hartford Hospital, Hartford, Conn, on October 12, 1935. The meeting was held under the chairmanship of Dr Henry F Stoll, Governor of the College for the State of Connecticut. Fifty members of the College were in attendance, as were also the College Governors for the New England States, including New Hampshire, Maine, Massachusetts and Rhode Island, and also Dr James Alex Miller of New York City, President of the College. A program of clinics was given at the Hartford Hospital, beginning at 11 a m and lasting until 4 30 p m. Dr James H Means, Regent of the College from Boston, conducted a clinical pathological conference in the morning, and Dr A M Burgess, Governor for Rhode Island, conducted a similar conference in the afternoon. The social aspects of the meeting included a luncheon through the courtesy of the Avery Convalescent Hospital, a tea through the courtesy of the Neuro-Psychiatric Institute and Hospital and a dinner at the Hartford Club. Dr O G Kiedman was toastmaster at the dinner. Dr James Alex Miller, President of the College, delivered an address on College affairs, and Dr Louis Casamajor of New York City delivered an address on "Interesting Types of Psychoneuroses Met with During the Current Industrial Depression". The meeting as a whole was one of the most successful ones that has been conducted on behalf of the College.

Virginia

During the Virginia State Medical meeting held in Norfolk, October 15 to 17, a dinner was held with 33 Virginia members of the American College of Physicians present at the Monticello Hotel, for the purpose of organizing a more consolidated

unit of the Virginia members of the American College of Physicians. At this meeting Dr J Morrison Hutcheson, Governor of the College for Virginia, was elected President and Dr Frederick C Rinker of Norfolk was elected Secretary. During the meeting a motion was carried appointing a committee of three, including the President and Secretary, to formulate plans to be presented next autumn at a similar dinner during the state medical meeting.

Members of the Medical Club of Philadelphia and graduates of the University of Pennsylvania recently honored one of the distinguished members of the American College of Physicians, Major General Charles Ransom Reynolds, who has recently been raised to the highest rank, that of the Surgeon General, in the medical service of the U S Army. General Reynolds graduated from the University of Pennsylvania School of Medicine in 1899, and has been in the Medical Corps of the U S Army for 34 years, being promoted to his present post last June, when he succeeded Major General Robert U Patterson, who is also a Fellow of this College. General Reynolds will be responsible for the health and welfare of the men of the Army wherever stationed and also for the youths of the CCC who have come under the care of the Army. General Reynolds was born in Elmira, N Y, in 1877, receiving his medical degree at the age of 22, and interned at "Blockley," the Philadelphia General Hospital. Shortly after entering the Army, he went to the Philippine Islands, where he participated in several battles. After returning to the United States for a short period, he returned to the Philippines again, where he won the Silver Star for gallantry in action in aiding the wounded in a battle on the Island of Jolo. At the opening of the World War he advanced to the rank of Lieutenant Colonel. He went overseas as Division Surgeon of the 77th Division of the American Expeditionary Forces, and participated in the offensives at Aisne-Marne, St Mihiel and Meuse-Argonne. He was awarded the Distinguished Service Medal for his service in the field and hospitals. Since the war, he was in charge of the School of Instruction at Carlisle Barracks, in Pennsylvania.

General Reynolds' first assistant in the Surgeon General's office is another Fellow of the College, Brigadier General Matthew A DeLaney, also a graduate of the University of Pennsylvania School of Medicine, Class of 1898. General DeLaney also has a distinguished record in the Army, having served in the Philippine Islands, on the Mexican border and in the World War. He was decorated by the Prince of Wales and cited for gallant and distinguished service by Field Marshal Haig. His entire professional career has been devoted to the Army, except for a few years during the Taft administration when he was the White House physician.

Dr John N Simpson (Fellow and Governor of the College for West Virginia), Morgantown, W Va, has been made Dean Emeritus of the West Virginia University School of Medicine.

Dr D O N Lindberg (Fellow), medical director and superintendent of the Macon County Tuberculosis Sanatorium, Decatur, Ill, has been reelected (third term) as Secretary of the Mississippi Valley Sanatorium Association for 1935-36.

The New York Academy of Medicine is conducting its tenth series of Friday afternoon lectures, starting at 4 30 o'clock. The following Fellows are participating: November 15 Dr Thomas T Mackie, Research Associate, Cornell University.

Medical College "The Diagnosis and Treatment of Intestinal Infections Occurring in New York City",

November 22 Dr Emanuel Libman, Consulting Physician, The Mount Sinai Hospital "Points in Medical Diagnosis",

December 20 Dr Ralph Pemberton, Professor of Medicine, Graduate School of Medicine, University of Pennsylvania "The Present Status of Arthritis and the Treatment of It",

January 3 Dr Harlow Brooks, Attending Physician, Bellevue Hospital "Evaluation of Focal Infections from the Internist's Viewpoint",

January 10 Dr A S Blumgarten, Associate Attending Physician, Lenox Hill Hospital "Recent Advances in Endocrine Research and Their Value in Clinical Practice",

March 6 Dr Irving S Wright, Chief of the Vascular Clinic, New York Post-Graduate Hospital "Diagnosis and Treatment of Peripheral Vascular Disease"

The following Fellows of the College were appointed by the Department of State of the United States as delegates to the International Congress on Gastro-Enterology, held in Brussels, Belgium, during last August

Dr Henry L Bockus, Philadelphia, Dr Russell S Boles, Philadelphia, Dr Max Einhorn, New York, Dr Sara M Jordan, Boston, Dr B B Vincent Lyon, Philadelphia, Dr William Gerry Morgan, Washington, D C, and Dr Franklin W White, Boston Among other members of the College who were present at the Congress were Dr Samuel Weiss (Fellow) and Dr Anthony Bassler (Fellow), New York, Dr William A Swalm (Fellow) and Dr Harry M Eberhard (Associate), Philadelphia The 1937 Congress will be held in Paris

Dr David P Bair (Fellow), St Louis, was appointed during September to membership on the Council on Pharmacy and Chemistry of the American Medical Association Dr A J Carlson (Fellow), Dr G W McCoy (Fellow), Dr A C Ivy (Fellow) and Dr William J Kerr (Fellow) are members of the Committee for the Protection of Medical Research of the American Medical Association

Dr Willard R Wirth (Associate) has been appointed assistant professor of medicine at the Graduate School of Medicine, Tulane University of Louisiana

Dr Dwight O'Hara, professor of preventive medicine, Tufts College Medical School, Boston, has been appointed by Governor Curley of Massachusetts as a member of a public health commission to codify the health laws of the State of Massachusetts, eliminating those which are obsolete and revising others

The Medical Society of Virginia held its sixty-sixth Annual Session at Norfolk, October 15 to 17, under the presidency of Dr Francis H Smith (Fellow), Abingdon Dr Arthur C Christie (Fellow), Washington, D C, and Dr James E Paullin (Fellow and Regent), Atlanta, Ga, were the two guest speakers, whose subjects were "The Answer of the Medical Profession to State Medicine" and "The Significance and Diagnostic Importance of Pain in Disease," respectively Dr J Morrison

Hutcheson (Fellow and Governor for Virginia) was elected President-Elect and Dr C Lydon Harrell (Fellow), Norfolk, was elected one of the Vice-Presidents Dr Walter B Martin (Fellow), Norfolk, was elected a delegate to the American Medical Association

Dr Hugh S Cumming (Fellow), Surgeon General of the U S Public Health Service, recently gave the dedicatory address of the newly opened isolation pavilion of the Gallinger Municipal Hospital in Washington, D C

Dr Alfred Stengel (Master), Professor of Medicine and Vice-President of the University of Pennsylvania, and Dr Paul Dudley White (Fellow), Assistant Professor of Medicine at Harvard University Medical School, were the two invited guests on the occasion of the second annual Postgraduate Day of the Medical Institute of the University of Toledo, November 8, on the subject of cardiovascular renal disease

Dr George R Maxwell (Fellow), Morgantown, has been reelected President of the West Virginia Tuberculosis Association for 1935-36

Dr Benjamin H Orndoff (Fellow), Chicago, is the general secretary for the fifth International Congress of Radiology, to be held in Chicago during September, 1937

Dr Bernard T McGhie (Fellow), Toronto, is acting deputy minister of health of the division of hospitals and the department of health of Ontario

At the opening exercises of the University of Michigan Medical School at Ann Arbor, Dr Andrew P Biddle (Fellow), Detroit, was the recipient of the honorary degree of Master of Arts, "in recognition of a life devoted to the advancement of education and ethics in the medical profession"

Dr Lowell S Selling (Associate), Detroit, has been appointed psychiatrist in the recorder's court of Detroit, to succeed Dr Isaac L Polozker (Fellow), deceased

Dr William J Stapleton (Fellow), Detroit, has been appointed acting Dean of the Wayne University College of Medicine

Dr Joseph F Bredeck (Fellow), St Louis, is President of the Missouri Public Health Association

Dr Arthur Jackson Patek (Fellow), Milwaukee, founder and for several years editor of the *Wisconsin Medical Journal*, was the recipient of an award for distinguished service by the State Medical Society of Wisconsin at its annual session during

the past autumn Dr Patek is a former president of the Medical Society of Milwaukee County and also of the State Medical Society of Wisconsin

Dr Charles M Griffith (Fellow), Washington, D C, has been elected President of the Association of Military Surgeons of the United States

Dr Roscoe L Sensenich (Fellow), South Bend, has been installed as President of the Indiana State Medical Association for 1936

Dr Edwin W Gehring (Fellow and Governor for Maine) has been named editor of the *Maine Medical Journal*

Dr David P Barr (Fellow), St Louis, has been chosen as a representative of the St Louis Medical Society on the newly created Medical-Dental Service Bureau

A new building for the care of acute cases at the Suffolk Sanatorium, Holtsville, N Y, has been named for Dr William H Ross (Fellow), first president of the county board of health

Dr Ralph R Hendershott (Associate), Tiffin, Ohio, was installed as President of the Ohio State Medical Association at its annual meeting in Cincinnati during October

Dr David Riesman (Fellow), Philadelphia, was installed as President of the Inter-State Postgraduate Medical Association at its annual session in Detroit, October 18

Major Raymond O Dart (Fellow), Washington, D C, is acting curator of the Army Medical Museum, succeeding Major Virgil H Cornell (Fellow)

Dr Wallace M Yater (Fellow and Governor for the District of Columbia) is President of the Washington Society of Pathologists

Dr C C Carpenter (Fellow), professor of pathology at Wake Forest (N C) College of Medicine, has been appointed assistant dean of the College

Dr Nathaniel B Heyward (Associate), Columbia, S C, has been appointed a member of the State Board of Medical Examiners for a four-year term

OBITUARIES

DR AUGUST CAILLÉ

Dr August Caille (Fellow), New York City, died October 10, 1935, of cerebral hemorrhage at the Lenox Hill Hospital, aged, 81 years

Dr Caillé was born in Madison, Indiana, attended the New York College of Pharmacy, graduating in 1873 with highest honors, and then went abroad for the study of medicine at the University of Wurzburg, where he graduated in 1877 Dr Caillé then returned to America and established himself in the private practice of medicine in New York City, in 1879 He resolved to take an American degree in medicine and enrolled in the College of Physicians and Surgeons of Columbia University, and in 1881 received the degree of medicine from that institution

Dr Caillé pursued the study and practice of medicine with much ability and enthusiasm, and was indefatigable in research, especially in the line of children's diseases, on which subject he had become a recognized authority He was appointed Professor of Medicine and Children's Diseases at the New York Post-Graduate Medical School and Hospital in 1888, an appointment he held for nearly fifty years At the time of his death, he was Emeritus Professor of Medicine and Pediatrics and Consulting Physician to the Babies' Wards of the New York Post-Graduate Medical School and Hospital, Consulting Physician to the Lenox Hill Hospital, the Sea Cliff Convalescent Home for Babies and Isabella Home His connections with the Lenox Hill Hospital and the Isabella Home endured for over fifty years

In the proceedings of many important medical bodies, Dr Caille's name appears prominently, for he was elected to many responsible offices He was an ex-President of the American Pediatric Society, a member of his county medical society, the New York State Medical Society and a Fellow of the American Medical Association, in addition to being an honorary member of the German Medical Society in New York City In the earliest annals of the American College of Physicians, Dr Caille's name appears as a member of its Council It is further disclosed that he was elected the second Treasurer of the College at the end of 1916, serving for some years thereafter

Dr Caille was deputed as the American delegate to the International Medical Congress in Berlin He substantially contributed to the medical literature of this country, having published many articles and monographs, the majority of which appeared in leading medical periodicals He introduced Soxhlet's home sterilization of milk and bottle food for infants to the American profession in 1887 He was one of the first in this country to practice and teach spinal puncture and stomach washing He gave the first demonstration of O'Dwyer's method of intubation for croup in Germany at Frankfort in 1887 He devised a perforated trocar for abdominal puncture and an automatic tracheal retractor for facilitating tracheotomy for

membranous croup. He suggested permanent drainage for certain forms of dioppsy, and devised a scratch test for the detection of individuals sensitized to animal sera.

He was the author of a comprehensive work on "Differential Diagnosis and Treatment of Disease," published in 1906, and also of a presentation of postgraduate teaching entitled, "Prevention and Treatment of Disease."

DR. PEDRO GUTIERREZ IGARAVIDEZ

Dr. Pedro Gutierrez Igaravidez (Fellow), San Juan, Puerto Rico, died May 24, 1935, aged, 64 years.

Dr. Igaravidez was born in San Juan, Puerto Rico, August 24, 1871. He held the degree of Bachelor of Arts from the Instituto Civil, the degree of Bachelor of Science from the Instituto Ensenanza, Cadiz, Spain, and his medical degree from the University of Sevilla, Spain, 1896. He was formerly Visiting Physician to the Municipal Hospital of San Juan, Medical Director of the Anti-tuberculosis Sanatorium and Member of the Anemia Commission (1904), Chairman of the Puerto Rico Anemia Commission, 1906-10, Director of the Tropical and Transmissible Diseases Service of Puerto Rico, 1910-12, Director of the Institute of Tropical Medicine and Hygiene and Chief of the Laboratory Service of the U. S. Base Hospital in San Juan. He had done postgraduate work at the Polyclinic Hospital of Philadelphia and at the London School of Tropical Medicine in England. He was the author of many published papers.

Dr. Igaravidez was a member of the Royal Society of Tropical Medicine, London, American Society of Tropical Medicine, American Medical Association, American Public Health Association, National Tuberculosis Association, Puerto Rico Medical Association, and had been a Fellow of the American College of Physicians since 1924. He was formerly Clinical Professor of Tropical Medicine in the School of Tropical Medicine of Puerto Rico, conducted under the auspices of Columbia University. At the time of his death, he was Chief of the Division of Roentgenology of the Puerto Rico Department of Health.

Dr. Igaravidez was one of the most prominent clinicians of Puerto Rico and for many years was a close friend and associate of the late Dr. Bailey K. Ashford.

DR. MORGAN SMITH

In the death of Morgan Smith, September 14, 1935, the State of Arkansas lost not only an outstanding leader of the medical profession, but a man who had devoted a large part of his time to the public advancement. Although a general practitioner, Dr. Smith gained his reputation in the field of pediatrics and had done much to further this branch of medicine in the state.

A graduate of the medical departments of the University of Arkansas and Tulane, he began his practice in Little Rock in 1904. Shortly thereafter, Dr. Smith became the state director of the Rockefeller Sanitary Commission for the eradication of hookworm in the South. Out of this commission evolved the Arkansas State Board of Health, and Dr. Smith was its first superintendent.

In 1913, he was appointed Dean of the medical department of the state university and held this position until 1927 when he resigned to resume his private practice. It was under Dr. Smith's regime that the school attained its Grade "A" rating. The pediatric instruction was under his supervision from the time of its introduction in the school until his resignation. He was a member of the American Academy of Pediatrics.

During his lifetime, Dr. Smith had many honors accorded him. He was a past president of the Arkansas Medical Association. He had served on the Council of the Southern Medical Association, and at the time of his death, he was the president of the Arkansas Pediatric Society. He was a Fellow of the College since 1928.

Entering politics in 1929, Dr. Smith was elected to the Arkansas State Senate, and was returned to his seat there for the two following sessions of that body. It was while in the Legislature that he sponsored the Basic Science Law which is now active in medical licensure in Arkansas.

The last two years of his life were spent chiefly at his country home not far from Little Rock. His health had been impaired by cardiac disease, but he was still able to enjoy his many friends and to work among his flowers and vegetables. Death came suddenly as he was enjoying his favorite avocation, reading.

A man of imposing personal appearance, jovial disposition, attractive personality, a peerless raconteur, a skillful and sympathetic physician and a true friend, Morgan Smith made a lasting imprint on the pages of Arkansas medicine.

OLIVER C. MELSON, M.D., F.A.C.P.,
Governor for Arkansas

DR. HARRY WARDWELL CAREY

Dr. Harry Wardwell Carey (Fellow), Troy, New York, died August 14, 1935, of coronary thrombosis, aged 60 years.

Dr. Carey was born in Stamford, Conn., April 15, 1875. He attended the schools of his native State and was graduated from Yale University with the degree of Bachelor of Arts in 1897 and from Johns Hopkins University School of Medicine with the degree of Doctor of Medicine in 1901. He became assistant bacteriologist and assistant pathologist to the Bender Laboratory for a period of two years. He pursued postgraduate study in dermatology at the University of Munich and at the University of Berlin during 1903, returning to Troy to engage in private practice and to act as

instructor in histology at the Albany Medical College In 1904 he became instructor in surgical pathology and in 1905 instructor in physical diagnosis He was pathologist to the Samaritan Hospital from 1904 to 1930, he organized the Society for the Relief of Tuberculosis in 1907, he was bacteriologist for the City of Troy from 1907 to 1926, physician-in-charge of the Lakeview Sanatorium, 1912 to 1916, director of the Social Hygiene Clinic (municipal) from 1919 to 1931, pathologist to the Troy Hospital, 1925 to 1927, and to the Cohoes Hospital from 1927 to 1930 He was attending physician to the Samaritan Hospital from 1930 to the time of his death As a matter of fact, his death occurred while he was making his rounds at the Samaritan Hospital

Dr Carey was a member of the Rensselaer County Medical Society and the New York State Medical Society He was a Fellow of the American College of Physicians since 1931, and a Fellow of the American Medical Association He was the author of many published articles and of a book entitled "Bacteriology for Nurses"

Dr Carey's whole career was marked by an enthusiastic interest in preventive medicine One of his earliest efforts in Troy was to build up a campaign against tuberculosis He succeeded in establishing an institution for the treatment of tuberculosis and was named its first supervising physician As a result of this, the Pawling Sanitarium was later established It was said that the death rate in Troy from tuberculosis is but a small fraction of that of thirty years ago Dr Carey exerted wide influence in other preventive measures such as cancer control, milk inspection, etc In spite of his varied public activities, he conducted an extensive private practice, until his health compelled him to confine it largely to office and hospital work

ISAAC LOUIS POLOZKER

Isaac Louis Polozker (Fellow) was born in Grodno, Russia, October 24, 1873 At the early age of five he determined to become a physician, being influenced by four uncles—all members of the medical profession In 1889 he came to the United States, completed a course at the City College of New York and then moved to Detroit—graduating from the Detroit College of Medicine in 1897 He returned twice to Europe to study, doing postgraduate work in psychiatry at the University of Vienna

Dr Polozker was early interested in pediatrics and contributed numerous published articles in that specialty Later he became interested in psychiatry and became Psychiatrist to the Recorder's Court, Detroit His long experience in general practice brought to his work in the Psychopathic Clinic a rich equipment of experience, particularly useful in the evaluation of criminality

Dr Polozker was a Professor of Clinical Psychiatry at Wayne University and College of Medicine, Detroit, Psychiatrist at the Eloise Hospital

for Mental Diseases, Director of the Psychopathic Clinic of the Recorder's Court, Neuropsychiatrist at St Mary's Hospital, Member of the Wayne County Medical Society, Detroit Medical Group, Detroit Neurological Society, Michigan State Medical Society, Fellow of the American Medical Association, the American Psychiatric Society, American Teacher's Society and the American College of Physicians

On August 21, 1935, he passed away suddenly with coronary thrombosis. He is survived by his widow, the former Florence Higer, whom he married in 1919

J FRANK KILROY, M D

DR ADOLPH H NAHMAN

Dr Adolph H Nahman (Fellow), San Francisco, Calif, died September 21, 1935, aged 58 years

Dr Nahman was born in Poland, and received his preliminary college education at the University of Warsaw. He then entered Northwestern University Medical School, Chicago, from which he received his medical degree in 1909. After graduation, he went to San Francisco, interned at the Southern Pacific Hospital and thereafter became associated with the Mount Zion Hospital, where he attained the position of senior associate of the medical department and chief of the outpatient department. He was a member of the San Francisco County Medical Society, California Medical Association and the American Medical Association, and had been a Fellow of the American College of Physicians since 1926.

Dr Norman Epstein, in the Bulletin of the San Francisco County Medical Society, has written "A great doctor has passed. A kindly, pleasant, cheerful soul who knew no hours, no creeds, no caste when the sick called. He gave of his remarkable ability and rich store of knowledge to poor and wealthy alike.

Dr Nahman truly typified the family physician. He entered the homes of his patients as a friend and advisor. He thoroughly knew and understood his people and their peculiarities. He personally supervised and attended upon every technical procedure done upon his patients.

As an exponent of the sadly neglected art, bedside medicine, he had no equal. His personal and detailed close observation, combined with comforting and rational therapy based on an alert understanding of every advance in modern medicine, instilled confidence. He spent his life in study and work and attained a perfection in clinical medicine which is rarely reached.

Dr Nahman's interests were not exclusively confined to medicine. His devotion to his family was a prominent feature of his life. He loved music, and his hobbies were photography and gardening. He traveled widely and was much interested in general human affairs. To those who knew him his memory will ever endure."

H LISSER, M D, F A C P,
Governor for northern California

DR EMIL JOSEPH SUSSLIN

Dr Emil Joseph Susslin (Associate), Bridgeport Conn , died July 9, 1935, of subacute bacterial endocarditis , aged, 37 years

Dr Susslin was a graduate of the University of Vermont, 1921 His internship was at the Bridgeport (Conn) Hospital At the time of his death, he was Attending Physician to the Englewood Hospital and Assistant Physician at the Bridgeport Hospital He was a member of the Bridgeport Medical Society, the Fairfield County Medical Society, the Connecticut State Medical Society and the American Medical Association He became an Associate of the American College of Physicians during 1928

CHEMICAL STUDIES IN MYASTHENIA GRAVIS *

By MILDRED ADAMS, PH D, MARSCHELLE H POWER, PH D, and
WALTER M BOOTHBY, M D, F A C P, *Rochester, Minnesota*

PREVIOUS metabolic studies of subjects with myasthenia gravis have dealt chiefly with the inorganic metabolism, particularly that of calcium and magnesium, and with the metabolism of nitrogen, creatine, creatinine, and carbohydrate. The results have been more or less contradictory. Marburg¹ reported a high blood magnesium in one case, but Hellich,² and Hellich and Tessenow³ found that the values for the magnesium of the blood were normal (three cases). Bayha⁴ reported a low blood calcium in one case, in contrast to normal values found by Hellich, Hellich and Tessenow, Marburg, Berglund, Medes and Lohmann⁵ and Reuter.⁶ Laurent and Walther⁷ have recently determined values for the potassium of the plasma of six patients with myasthenia gravis. The values appeared to be rather low, but for several reasons, particularly the fact that normal subjects exhibited similar low values, these writers were not inclined to attach great importance to their observations. Keschner and Strauss⁸ determined the sugar, uric acid, creatinine, urea, nonprotein nitrogen, and cholesterol in the blood of two patients with myasthenia gravis, and the values obtained for all of these constituents were normal. From more detailed studies of the inorganic metabolism, Pemberton,⁹ and Diller and Rosenbloom¹⁰ found negative calcium balances in their cases, and noted that improvement occurred as the result of treatment with calcium lactate. Bookman and Epstein,¹¹ on the other hand, found the calcium balances of their patients to be slightly positive, and that the administration of calcium lactate caused no improvement. In similar studies, Halpern¹² reported a more marked retention of calcium than that observed by Bookman and Epstein. The results of studies of the nitrogen balance in cases of myasthenia gravis have been of a similar nature. Kauffmann¹³ observed a positive nitrogen balance in one subject on a high protein diet during rest and a decrease in this balance as the condition became worse as a result of exercise. Pemberton reported a retention of nitrogen, while Diller and Rosenbloom reported a negative

* Submitted for publication September 6, 1935

From the Section on Clinical Metabolism, The Mayo Clinic, Rochester, Minnesota

nitrogen balance Halpern¹² reported a marked retention of nitrogen and phosphorus, and Bookman and Epstein generally noted a retention of nitrogen, sulphur and phosphorus

The excretion of creatine and creatinine by patients with myasthenia gravis has received considerable attention Berglund, Medes and Lohmann, and Remen¹⁴ reported a definite creatinuria in the cases which they had under observation Williams and Dyke,¹⁵ and Bernhardt and Simpson¹⁶ observed a creatinuria only in cases in which the condition was severe, while in the cases of Hellich and Tessenow, Gibson, Martin and Buell,¹⁷ and McCrudden and Sargent,¹⁸ no creatinuria was present Diller and Rosenbloom found low values for the excretion in the urine of creatinine, uric acid, and neutral sulphur, and suggested that the disease is accompanied by a low endogenous metabolism In addition, Spriggs,¹⁹ Pemberton, and also Bookman and Epstein, reported a low excretion of preformed creatinine On the other hand, the excretion of creatinine by the patients observed by Curschmann,²⁰ and of those studied by Hellich and Tessenow, was reported to be normal It is obviously impossible to draw any definite conclusions from the results reported to date, as to abnormalities in the metabolism of patients with myasthenia gravis

In a series (Boothby's²¹) of 71 cases we have had the opportunity to study carefully the excretion of creatine and creatinine of 35 subjects with myasthenia gravis, both before treatment and after the beginning of treatment with glycine Some of the results have been briefly referred to elsewhere,²² but in connection with a general discussion of the effect of the administration of glycine on the excretion of creatine and creatinine and in the papers dealing essentially with the clinical side of the problem The more comprehensive data concerning the excretion of creatinine and of creatine in myasthenia gravis will be included in this paper, together with several illustrative case histories

In addition, we have obtained data for the concentrations of several constituents of the blood of 10 patients with myasthenia gravis These patients, with one exception, had severe myasthenia gravis The group included four females and six males, and the ages of these patients ranged from 17 to 69 years The results are shown in table 1 It is apparent from these data that there is nothing abnormal in the composition of the blood of this group of patients The values obtained for calcium, magnesium, sodium, potassium, inorganic phosphorus, creatinine, uric acid, amino acid, urea, and sugar were found to be well within normal limits

The results of our studies on the excretion of creatinine and creatine in cases of myasthenia gravis are summarized in table 2 In general, control periods of two to five days, during which glycine was not administered, were obtained, except in a few cases in which the patients were already taking glycine at the time of their admission to the clinic After beginning treatment with glycine, data on the daily excretion of creatine and creatinine for periods of usually three weeks or longer were obtained The daily results

for periods of, usually, seven days were averaged, the range of these averages for the time during which glycine was administered is recorded in the table. Throughout the observations the subjects were allowed to take their customary mixed diets. The constant average daily excretion of creatinine and creatine observed after equilibrium had been established on any one regimen suggests that the influence of the intake of food was approximately constant. A few of the subjects were taking ephedrine before the administration of glycine was started, but the response to the administration of glycine appeared to be much the same in these cases as it was in the cases in which ephedrine was not administered.

It is evident from table 2 that the excretion of creatinine and creatine in the untreated patient is not usually abnormal. As a means of comparing different individuals Shaffer²³ has suggested the use of the creatinine coefficient, that is, the milligrams of creatinine, or preferably creatinine nitrogen, excreted per kilogram of body weight in 24 hours. Shaffer presented data which indicated that the creatinine nitrogen coefficient for normal individuals ranges from 5.4 to 11.7, but believed that if inactive, elderly, or obese individuals were excluded, the limits for normal individuals would be approximately from 7 to 11. The creatinine nitrogen coefficients of our male patients ranged from 4.5 to 9.8. If the first five patients, who were

* Creatinine was determined by the colorimetric method of Folin. Creatine was converted to creatinine by boiling with picric acid, and determined according to the method of Folin.

** The coefficients for certain subjects who were already receiving glycine, or to whom glycine was administered immediately, appear in parentheses.

† Patients were taking ephedrine before treatment with glycine was started.

all 65 years of age or more, and obese, are excluded from consideration, the coefficients of the remaining patients will be found to vary from 6.6 to 9.7. This range is somewhat lower than that considered normal for active individuals by Shaffer, and would probably have been still lower if the patients had been on a strictly meat-free diet. On the other hand, there was no such striking deviation from the normal, as has been suggested occasionally for this disease, particularly in view of the fact that the patients were forced to be relatively inactive. The creatinine nitrogen coefficients of the female patients varied from 5.1 to 7.9, a range which is somewhat lower than that observed for the male patients. However, the range of the coefficients for normal women has frequently been considered to be lower than that for men, so that our values do not seem to differ strikingly from the normal.

The occurrence of a creatinuria in our patients before treatment with glycine was started was observed less frequently than might be expected from previous reports. In only two of 18 males who were under observation before the administration of glycine was begun was the excretion of creatine nitrogen greater than 0.04 gm per day, and in the other patients the excretion of creatine was at most a questionable trace. There was a greater tendency toward creatinuria among the females than among males, five of the 12 female patients on whom control periods were obtained excreted more than 0.04 gm creatine nitrogen per day. This tendency, as is well recognized, has been frequently noted for normal women. The extent of the creatinuria in the group as a whole showed little correlation with the severity of the disease.

The effect of the administration of glycine on the excretion of creatinine and creatine in cases of myasthenia gravis is shown in table 2. So far as creatinine is concerned, little change usually was observed in the excretion after beginning the administration of glycine. In a few cases a slow, gradual increase in excretion of creatinine occurred, which was accompanied by a definite improvement in the condition of the patient. In many other cases improvement occurred without any change in the excretion of creatinine. In four cases the excretion of creatinine gradually decreased during the administration of glycine, in one of these cases, in which the excretion of creatinine was only slightly reduced, the condition was definitely improved, in the other three cases in which the reduction of excretion of creatinine was more marked, the condition became progressively worse in spite of any type of treatment that could be given. There was, therefore, no clear-cut correlation between the condition of the patients and the changes in excretion of creatinine during the periods in which glycine was administered. In no case was there encountered any abrupt, sudden alteration in the excretion of creatinine.

As regards creatine, the excretion of this substance was almost always increased after the administration of glycine and in several cases it was markedly increased. Harris and Brand,²¹ likewise, observed a slight increase in the creatine excretion in a case of myasthenia gravis in which 22

gm of glycine were administered per day. Milhorat²⁵ also has observed that the administration of glycine in cases of myasthenia gravis may increase an existing creatinuria, or provoke one where none existed previously. Some other investigators, who studied only a few cases,^{11 26 27} have failed to note an increase in the excretion of creatine following the administration of glycine. We have found that the type of change in the excretion of creatine incident to the administration of glycine may vary considerably. Some subjects exhibited an immediate and marked increase in the excretion of creatine, others responded more slowly and gradually, while still others exhibited no response. Because of the slow rate of change observed for many of the subjects, it seems likely that the few who were in this last group would have exhibited some change if they had been under observation for a longer period.

The following reports of cases illustrate these points in somewhat greater detail than the data in table 2.

CASE REPORTS

Case 9. A man, aged 37 years, who weighed 73.1 kg and whose height was 5 feet and 7 inches (170.2 cm), had had myasthenia gravis for four months before he registered at the clinic. He had not received any treatment during this period. There was marked weakness of the muscles of the arms, legs, neck, and eyelids, and of the muscles of mastication and deglutition. The patient was so weak that he could barely walk one block, even with help. Improvement, which occurred after the administration of glycine, was approximately 25 per cent in the first two weeks, and approximately 50 per cent at the end of six weeks. At the end of three or four months his condition was still further improved. This improvement has been maintained, and during the last year medication has not been required. He now has been employed at full-time work on the railroad for more than a year. This is the only patient in this series of cases who apparently has been able to maintain his strength completely after medication has been discontinued. The effect of the administration of glycine on the excretion of creatinine and creatine by this patient is shown in table 3. It may be noted that a small but definite increase in the excretion of both

creatinine and creatine occurred. The decrease in the excretion of creatine in the last period may have been caused by the ephedrine, which was administered during this time.

Case 16 A man, aged 42 years, who weighed 73.9 kg, and whose height was 5 feet and 10½ inches (179 cm), had had myasthenia gravis for three or four weeks before he came to the clinic. The condition had progressed rapidly. There was moderate weakness of the muscles of the arms and legs, and of the muscles of mastication and deglutition. He was able to walk several blocks and could eat food without great difficulty. He improved slowly but definitely after the administration of glycine was started, during the two months he remained at the clinic. The daily excretion of creatine increased from a trace to 0.26 gm, and there also was a progressive and definite increase in the daily excretion of preformed creatinine (table 4).

* Periods of observation were consecutive.

Further improvement occurred for some time after he left our immediate observation. Then, following a slight relapse, he apparently became discouraged and adopted other treatment. He gradually failed and died about 13 months after he first was seen at the clinic.

Case 25 A man, aged 40 years, who weighed 81.1 kg and whose height was 5 feet and 9¾ inches (177.2 cm), had had myasthenia gravis for four months before he came to the clinic. He had not received any treatment during this period. There was moderate weakness of the muscles of the arms, legs, neck, and eyelids, and of the muscles of mastication and deglutition. He was able to walk fairly well, and before he came to the clinic he had been able to work part of each day as a contractor. Definite improvement occurred after the administration of glycine. The improvement was accelerated by the additional administration of ephedrine. He is back at full-time work at present, two and a half years after he first came to the clinic. It has been possible to reduce the dosage of the glycine somewhat, but he notices a weakness when the administration of the drug is discontinued. There was an increase in the excretion of creatine and a slight increase in the excretion of preformed creatinine after the administration of glycine (table 5). The slight decrease in the excretion of creatine observed in periods 6 and 7 may be due to the administration of ephedrine.

Case 20 A man, aged 24 years, who weighed 67 kg and whose height was 5 feet and 8¾ inches (174.6 cm), had had myasthenia gravis for nine years before he came to the clinic. There had been partial remissions during this period. Ephedrine 3/8 grain (0.024 gm), had been administered four times daily for five weeks before he came to the clinic, but had not produced any improvement. At the clinic, the

§ Nine months after period 6

administration of ephedrine was reduced to 3/8 grain (0.024 gm) twice daily. A constant intake of food was employed, and food, urine, and feces were analyzed. The nitrogen balance was markedly negative. The additional administration of 15 gm of glycine, twice daily, improved the nitrogen balance only slightly. The excretion of creatine increased rather rapidly after the administration of glycine and maintained a fairly constant level, except in the ten days during which creatine was administered (table 6). The extra creatine given during this time (period 9) was

† One gm of creatine is equivalent to 0.28 gm of nitrogen. The extra creatine was quantitatively excreted.

quantitatively excreted. There was a progressive and marked decrease in the excretion of preformed creatinine. The administration of glycine never produced any consistent or material clinical improvement. The patient could not walk and was barely able to turn over in bed. All of his muscles were very weak and he could not raise his head. There was marked difficulty in swallowing which made it necessary to abandon the balance studies and resort to nasal feeding. During the following

five months there was only slight fluctuation in the clinical condition. He never was able to walk more than 20 or 30 steps. He was troubled greatly with mucus in the pharynx. The administration of insulin or eschatin for short periods did not produce any change in the clinical condition, although there were periods in which the intensity of the condition varied. In July 1935, approximately five months after he came to the clinic, he was able to be out of doors in a wheel chair, but he never regained the ability to swallow. He returned home the same month, where he continued to follow about the same treatment as was employed at the clinic. He caught cold, probably pneumonia developed, and he died in the latter part of September.

The changes in the excretion of creatine which followed the administration of glycine are not necessarily characteristic of myasthenia gravis, as we have obtained similar results in many other conditions, such as chronic fatigability, various types of muscular disturbances, and arthritic and rheumatic-like conditions.²²

Complete balance studies have been obtained in two cases of myasthenia gravis. The detailed results will be reported shortly. In general, the results indicated that the type of balance found depended on the condition of the patient at the time of the investigation. The two patients observed both had very severe myasthenia gravis. Both subjects were taking 3/8 grain (0.024 gm) of ephedrine sulphate, twice daily, when the studies were started and the administration of ephedrine was continued throughout. One subject, although unable to get around to any great extent without the aid of a wheel chair, had been showing a slow, gradual improvement partly as a result of the administration of ephedrine for several years. She was found to be in nitrogen balance before glycine was administered and maintained this balance when 40 gm of glycine per day were administered. Nothing abnormal was seen in the sodium, potassium, calcium, magnesium, phosphorus, or sulphur balances, either before or after the administration of glycine. The other patient, who was becoming rapidly worse in spite of the administration of ephedrine, showed a negative nitrogen balance which was somewhat less negative after the administration of glycine. The addition of 30 gm of glycine (5.6 gm nitrogen) to the diet failed, however, to prevent a steady loss of nitrogen. Slightly negative sulphur, phosphorus, and calcium balances were also observed in this case, both before and after the administration of glycine.

SUMMARY

The results of metabolic investigations on patients with myasthenia gravis show that the blood contains normal amounts of calcium, magnesium, sodium, potassium, phosphorus, sugar, urea, creatinine, amino acids, and uric acid.

Contrary to many previous reports, no striking abnormalities were observed in the excretion of preformed creatinine, or usually in the excretion of creatine. A definite creatinuria, exceeding 0.04 gm daily, was observed in only seven out of 30 cases and the greater proportion of the patients who excreted creatine were women.

The administration of glycine was not followed by any definite, constant, type of change in the excretion of creatinine in the majority of cases. If the excretion of creatinine progressively and markedly decreases, the prognosis may be rather unfavorable. The excretion of creatine subsequent to the administration of glycine was in general appreciably increased.

Balance studies which we have carried out, as well as those of previous investigators, indicate that the condition of the patient determines the type of balance obtained, rather than that any particular abnormality in the metabolism is characteristic of myasthenia gravis.

METABOLISM OF CREATINE AND CREATININE IN MUSCLE DISEASE¹

By A T MILHORAT and H G WOLFF, F A C P, *New York, N Y*

1 PATIENTS with diseases which affect the skeletal muscle commonly have a creatinuria even when they are maintained on a creatine-free diet. Accompanying the creatinuria, there is usually a diminution in the excretion of creatinine and in the ability of the body to retain ingested creatine (a low creatine tolerance)

2 In progressive muscular dystrophy, often large amounts of creatine are excreted. The level of the creatinuria and the impairment of the creatine tolerance are usually related to the amount of muscle disability. In advanced stages of the disease the creatine tolerance may be impaired to the extent that all of an ingested dose of creatine is excreted in the urine as creatine. The amounts of creatinine excreted are diminished and appear to be related to the amount of functioning muscle still remaining.

The ingestion of glycine for short periods is followed by an increase in the creatinuria and a further decrease in the creatine tolerance. In fact, under these circumstances, the glycine appears to act as an amplifier of defects in creatine tolerance. Moreover, it is sometimes of use in demonstrating less obvious disturbances in creatine metabolism. Such effects differ markedly and are not to be confused with the results of prolonged ingestion of glycine.

In keeping with the widespread and serious involvement of muscles in the infantile and juvenile forms of progressive muscular dystrophy is the severe disturbance in creatine and creatinine metabolism. Not only is the muscle involvement extensive and the disturbance in metabolism severe, but the march of the defect in muscle function and metabolism is rapid. In contrast, stand those patients in whom the muscle disease appears later in life. The muscular deficiency in these subjects progresses slowly, and the disturbances in the creatine and creatinine metabolism are less. The parallelism between the severity of muscle disease and rapidity of progression of the disturbance in metabolism is probably not coincidental.

3 In most cases of myasthenia gravis, only moderate amounts of creatine are eliminated and the creatine tolerance is only moderately impaired. However, patients in whom the course of the disease progresses rapidly to a fatal termination excrete large amounts of creatine and show a more serious defect in the ability to retain ingested creatine. The diminution in the creatinine output appears to be proportional to the loss in the functional capacity of the muscles. The defect in the creatine tolerance can be exag-

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935.

From the New York Hospital and the Department of Medicine, Cornell University Medical College and the Russell Sage Institute of Pathology, New York, N Y.

gerated by the ingestion of glycine in patients during an exacerbation of symptoms. Glycine usually has no effect on the creatine tolerance during periods of remission.

4 In amyotonia congenita usually considerable amounts of creatine are excreted. Also, the creatine tolerance is low and the creatinine output is much diminished. Glycine increases the creatinuria and further decreases the creatine tolerance.

5 In myotonia congenita no abnormality in the metabolism of creatine or creatinine could be demonstrated by the methods employed. Like normal subjects, patients with this condition eliminate no creatine or only minimal amounts spontaneously, and are able to retain fairly large amounts of ingested creatine. The amounts of creatinine excreted are similar to those observed in normal individuals of the same weight, sex, and muscular development. Glycine, in the amounts used, is without effect on the excretion or the creatine tolerance.

6 In patients with myotonia atrophica, however, the metabolism of creatine and creatinine is abnormal. There is a diminution in the creatinine excretion which appears to be directly proportional to the reduction in muscle mass. There is spontaneous creatinuria, although the amounts of creatine excreted are much lower than in patients with progressive muscular dystrophy showing similar amounts of muscle disability. In fact, extensive wasting of the muscles and considerable disability of important muscle groups can occur with only a slight or moderate creatinuria. The creatine tolerance is only moderately impaired and is unaffected by the ingestion of glycine. Only in patients showing extreme and extensive involvement of the muscles are large amounts of creatine excreted. The creatine tolerance is then seriously impaired, and the ingestion of glycine is followed by an increase in the creatinuria and a further decrease in the ability to retain ingested creatine. In short, in their metabolism of creatine and creatinine, patients with myotonia atrophica resemble only superficially those with progressive muscular dystrophy.

7 In patients with muscle wasting associated with disease of the anterior horn cells or of the peripheral nerves, the diminution in the creatinine output appears to be directly proportional to the reduction in muscle mass. The amounts of creatine eliminated are smaller than are observed in patients with progressive muscular dystrophy with similar amounts of wasting. Furthermore, the impairment in the creatine tolerance is less than in similarly incapacitated patients with progressive muscular dystrophy. Unless the muscle wasting is extensive, glycine is without effect on the creatinuria or the creatine tolerance. However, when the involvement of the muscles is so extensive as to include most of the skeletal muscles, there may occur defects in the metabolism of creatine and creatinine of a magnitude that equals that seen in advanced stages of progressive muscular dystrophy.

8 The effect of glycine on the metabolism of creatine in muscle disease, as shown in the creatinuria and creatine tolerance, is out of all proportion to the effect of comparable amounts of nitrogen from sources other than glycine and creatine. It is postulated that glycine acts as a precursor of creatine.

9 When creatine is ingested, the absolute amount retained is not fixed but is relative and dependent upon the amount, within fairly wide limits, of creatine administered. The percentage retention, however, is constant. Only when very large amounts are ingested is the amount retained no longer proportional to the amount administered. In these instances, the absolute amounts retained are constant and apparently represent the maximum capacity of the body to hold exogenous creatine.

10 In patients with muscle wasting the total creatinine coefficient (milligrams of creatinine plus creatine per kilogram of body weight) is not constant but diminishes as the incapacity of the muscle advances.

Examination of the data makes it seem probable that a defect in the metabolism of creatine and creatinine may be taken as an index of the total amount of improperly functioning muscle rather than of the amount of wasted muscle. In wasting secondary to cord disease, although certain muscle fibers are completely destroyed by disease, others are perfectly adequate and completely functioning. Moreover, in patients severely affected with wasting subsequent to nerve disease there are commonly regions of the body in which muscle structure and function are adequate and even entirely normal. Under such circumstances clearly evident atrophy may be accompanied by only slightly disturbed creatine and creatinine metabolism. In contrast, primary myopathy may be looked upon as the expression of a general disturbance in the muscle metabolism which affects all or most of the muscle tissue of the body. Furthermore, the actual enlargement of the muscles in certain myopathies, notably progressive muscular dystrophy, makes it especially difficult to correlate visible wasting with the known defects in metabolism. Hence, the necessity is apparent of expressing muscle status in terms of functional capacity rather than of size or postulated structural alterations. It is therefore clear why slight or barely visible atrophy may be accompanied by a severe disturbance in the metabolism of creatine and creatinine.

In brief, in patients affected by a generalized defect in the metabolism of muscle, all of the muscle fibers in the body may be affected chemically without striking visible evidence of wasting until the process has persisted for long periods. On the other hand, patients with striking visible evidence of atrophy may have the bulk of the musculature still in a sound state and hence show minimal evidence of disturbance in metabolism.

Thus, disturbance in creatine and creatinine metabolism and muscle defects are related and sometimes parallel each other. The term muscle

defect does not of necessity imply wasting although this may be present (In fact the muscle may seem enlarged) Moreover, in those instances where disease is widespread, notably in primary myopathic diseases, the most serious disturbances in metabolism occur, whereas in the myelopathic diseases in which the muscular involvement is commonly more circumscribed, the metabolic disturbances are less The exceptions to this general correlation are unusual instances of myelopathic diseases which are so widespread as to simulate the myopathic diseases in their effect on the muscles In brief, there is a parallelism between the metabolic disturbances and the total mass of improperly functioning muscle

EXPERIMENTAL THROMBOPENIC PURPURA, CYTOLOGICAL AND PHYSICAL CHANGES IN THE BLOOD *

By LEANDRO M TOCANTINS,† *Philadelphia, Pennsylvania*

WHEN a moderate dose of antiplatelet serum is given to a dog, the animal develops an attack of purpura hemorrhagica, identical in most respects with the human type, and recovers spontaneously. The changes that accompany such a disease in the dog have not as yet been systematically investigated. The observations here presented are the result of a study of some of these changes in a group of 63 dogs in each one of which purpura was produced one or more times.

EXPERIMENTAL METHODS

Cytology Various methods of counting platelets^{1, 2, 3} were tried and the direct method was finally selected. With dogs, when blood was obtained from the ear vein, rapidly handled and with the proper precautions, this method proved to be the most satisfactory. After preliminary shaving and cleaning of the area, the vein was cut with a sharp knife, the tip of the pipette placed against the opening in the vein, and from the freely bleeding wound, blood was aspirated into a 1-200 dilution pipette that had been previously filled with the diluting solution to the 0.5 mark. The diluting fluid was made up of brilliant cresyl blue 0.05 gm, sodium citrate 3 gm, formalin (40 per cent) 0.2 cc, and distilled water 100 cc, and the platelets were counted with a high power dry objective and 10X ocular (400X) in a Neubauer chamber. The average of two determinations was taken, if no agglutination was present and if the difference between them was not greater than 8 per cent (technical error for the method) of that average, otherwise the count was either repeated or reported as lost. Erythrocytes were counted in the same preparations and with equal precautions (technical error 5 per cent). The relative number of macroplatelets was recorded by designating as such any platelet that exceeded in length the diameter of an erythrocyte. Preliminary filtering and chilling of solutions, the use of chilled, certified pipettes, and automatic shaking were precautions taken with each count, care was taken to keep all glassware and solutions free of dirt, dust and bacterial contamination, blank counts being performed at intervals on the solutions. Observations on the morphology of the platelets, as well as differential erythrocyte and leukocyte counts, were done on blood smears stained with Wright's stain and buffer solution. Platelets were measured

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935

† J. Ewing Mears Research Fellow, Department of Medicine, Jefferson Medical College, Philadelphia

along their greatest diameter by means of a micrometer eyepiece, and note was taken of the presence or absence of hyalomere, the type of granules, and quality of the staining reaction. The absolute number of nucleated erythrocytes per cu mm was calculated from their percentage in the differential white cell count since no difference can be made out between white cells and nucleated red blood cells in a counting chamber. The *bleeding time* was measured in at least three separate locations at each occasion: the ear vein, the skin of the abdomen, and that of the anterior surface of the thigh. The vein was not cut across but simply nicked at one side, the incisions in the abdomen and thigh were approximately 5 mm long and 2 mm deep and were performed by the same operator with a sharp knife after pinching the skin up a little. The edge of a piece of absorbent paper was lightly touched to the surface of the wound at intervals of 15 seconds, or at 30 seconds when the blood was flowing at a slower rate. In all but a few instances, the determination was not continued if it exceeded 25 minutes, being recorded as 25'+. The *mean bleeding time* is the average of at least three simultaneous determinations in separate locations on the same animal. Strictly speaking, its technical error cannot be estimated since each determination involves making a cut in a separate part of the skin, and the location and structure of the skin where the cut is made play a part in the duration of the bleeding. Including such differences, the mean per cent variation between simultaneous determinations performed in normal dogs by the same operator was ± 21.2 per cent, which rendered multiple, simultaneous determinations imperative. The *coagulation time of the blood* was determined by aspirating venous blood into clean, dry, previously boiled syringes and placing 1 cc into each of two clean tubes 8 mm in diameter, paraffin coated. Clean sharp needles of wide bore and short bevels, and only trained animals with large veins were used. The blood was incubated at 37° C ($\pm 1^\circ$) and clotting was considered complete when the tubes could be inverted without the contents falling out. If the difference between the time taken by the blood to clot in the two tubes was not greater than 15 per cent of the average of the two, the longer time was considered the clotting time, otherwise the determination was discarded if it could not be repeated. *Retraction of the clot* is expressed in units and was estimated by methods described elsewhere⁴; the blood was placed in an uncoated glass tube 8 mm in diameter, a uniform amount always used (1 cc) and the clot observed and measured $\frac{1}{2}$, 1, 2, 24, and 48 hours after being formed. For the determination of the *petechiae reaction of the skin* an automatic device was employed that produced a graded amount of trauma to the skin surface over an area of uniform size. Depending on the number of petechiae brought out five minutes after the trauma was applied, the result was reported as 0, 1, 2, 3, etc.

Whenever indicated, the usual statistical methods were employed^{5,6} in the grouping and analysis of the results. Correlation coefficients were calculated by Pearson's method⁷. For any coefficient that appeared significant,

the correlation *ratio* was also calculated. If there was a *significant* difference between them, the correlation was regarded as non-linear and the ratio taken as its truer measure. A difference was considered significant when it was greater than four times its probable error, as calculated by Blakeman's method⁸. Correlation coefficients and ratios were considered significant when they exceeded six times their respective probable errors. It should be kept in mind that any correlations found do not apply to the whole universe of facts concerning each pair of variables but simply in normal dogs under the specified environmental conditions and at various stages of experimental thrombopenic purpura. Correlations involving the

Venous clotting time (Minutes)	17.53 ±.364	3.97 ±.25	30 10	22.6%	6	54
Clot retraction (Units)	2.03 ±.02	.29 ±.01	2.5 9	14.4%	6	64

number of platelets, erythrocytes, leukocytes, the mean bleeding time, and the skin petechiae reaction were calculated from a group of 414 pairs of determinations each, those involving the venous clotting time and clot retraction, from 139 pairs. In table 1 are summarized the values for the various determinations in normal, unanesthetized, fasting dogs. The size, breed, and age of the animals, the diet and living conditions have been previously stated⁹. The figures for the platelets and erythrocytes show close agreement with those found by Aynaud¹⁰ on 25 dogs. Only slight differences were found in the platelet content of blood obtained without stasis from vessels

in the different portions of the body (marginal ear veins, right and left jugular, cubital and right femoral veins, right carotid artery)

CYTOLOGICAL CHANGES

Platelets The rapidity of decline in the platelet level after the administration of antiplatelet serum depended on the route employed. Within two to five minutes after an intravenous injection the platelet count was below 50,000 per cu mm, and large masses of clumped lysed platelets appeared in the peripheral blood. After an intraperitoneal injection it took from three to five hours for the platelets to reach a low level (chart 1), subcutaneously,

CHART 1 Mean per cent deviations from normal in dogs that received a single intraperitoneal injection of 0.1 cc of antiplatelet serum per kg body weight (The normal range of values for each animal was ascertained, then the per cent deviation from the upper or the lower limit of this range was calculated for every determination performed at stated intervals after the injection. The curves were constructed from the means of all per cent deviations calculated for each period. Number of animals, seventeen. The curves for the clotting time and clot retraction were derived from seven animals only. Macroplatelets and skin petechiae reaction in absolute thousands and degrees, respectively.)

as long as 12 hours. With a moderate dose the thrombopenia usually lasted 48 to 72 hours, but longer in a few animals. One animal remained thrombopenic for seven days following a moderate dose. The promptness of the recovery was also variable. Most animals regained their previous platelet level three to five days after the last day of thrombopenia and then exceeded it for the next two weeks, the peak being reached from eight to twelve days after the last day of thrombopenia (chart 1). After smaller doses this increase above normal was hardly noticeable. In the few animals

that survived large doses, the thrombopenia lasted many days (18 in one instance) When hemorrhages into the tissues had been numerous and extensive, the platelets reached very high levels Marked variations in the size and appearance of the platelets were evident both in wet and dry stained specimens Macroplatelets appeared as early as three to four hours after the administration of the serum intraperitoneally (chart 2), when the num-

CHART 2 Variations in the size of the platelets of four dogs after the intraperitoneal injection of antiplatelet serum (one count lost on tenth day)

ber of platelets had only been decreased from one-half to two-thirds of their normal level They were not observed in the next 24 hours but reappeared as the platelet level began rising and were greatest in number from 52 to 72 hours after the injection, when the largest forms were usually seen For the next four days they decreased steadily in numbers and eventually were replaced by smaller forms At this stage great irregularity in their size was evident In contrast to normal platelets, they exhibited no hyalomere, were intensely basophilic and filled with dark, coarse granules, a few had a fibrillated cytoplasm The appearance of macroplatelets often coincided with the return of the bleeding time to normal and the beginning of the rise in the platelet level (chart 1) Of 17 dogs on which these observations were

made, 10 showed macroplatelets for the first time (during the course of the purpura) simultaneously with the return of the mean bleeding time to normal, 5, with the last long bleeding time determination, and 2, one and two days, respectively, after the bleeding time had returned to normal. Their appearance coincided with the return of retractility to the clot and a diminution in the skin petechiae reaction (chart 1). They were seldom observed in appreciable numbers after the platelets rose to higher levels.

Erythrocytes After an intraperitoneal injection of a moderate dose, the erythrocytes invariably showed a slight reduction in numbers within 24 hours (chart 1). Decreases were evident during the acute phase of purpura when hemorrhages were prevalent and the bleeding time prolonged. After the hemorrhagic period ceased, they returned slowly to normal. After repeated moderate doses similar observations were made (chart 3). Large

CHART 3 Effect of repeated injections of anti-dog-platelet goat serum followed by repeated injections of anti-dog-platelet rabbit serum in one dog

doses of the serum and the consequent longer phase of purpura depressed the erythrocytes in four animals to a level below one million per cu mm. Normoblasts appeared in the peripheral blood following these phases, after a particularly severe hemorrhage in one dog they made up 36 per cent of the total number of red blood cells. Hemolysis in variable degree was always observed in the blood smears during the acute stage of the attack.

Leukocytes A slight leukopenia often appeared within the first six hours after an intraperitoneal injection. It was generally followed the next day by a leukocytosis which lasted for several days (chart 1). The initial decrease in the leukocyte count took place at the expense of the lymphocytes, monocytes, and eosinophiles, even before the platelets had been reduced to their lowest levels. Twenty-four hours after those cells began a return to their former level, the monocytes usually went beyond it 52 hours after and the lymphocytes four days afterwards. The eosinophiles did not go beyond the level previous to the injection. The rise in the total leukocyte count resulted chiefly from an increase in the polymorphonuclear neutrophils. The peak of this rise coincided with the first evidence of an increase in the platelet level of the peripheral blood. As the platelets rose, the polymorphonuclear neutrophils returned gradually to their previous level, the relative proportions between the other leukocytes not showing any significant changes. An immediate and marked leukopenia, which lasted a few hours, usually followed an intravenous injection of a moderate dose, within the first 5 minutes after such an injection, leukocytes swollen to twice their usual size, enmeshed in clumps of lysed platelets, were often observed in fresh wet preparations of the peripheral blood.

MEAN BLEEDING TIME

With moderate doses intraperitoneally the mean bleeding time first showed a prolongation from three to five hours after the injection (chart 1), sometimes even before the platelets had dropped below 100,000 per cu mm, it remained prolonged for 24 to 48 hours occasionally longer, but rarely more than four days. Cuts made in the oral mucous membrane likewise yielded a prolonged bleeding time during the acute phase. Four minutes after an intravenous injection, a prolongation in the mean bleeding time could be detected. At the height of an acute phase, the ear vein of one of the animals slowly dripped blood continuously for several hours while all about the wound hung thick, stratified blood clots. In animals that survived large doses, a prolongation was maintained for several days 11 days in two instances. Repeated injections of small or moderate doses at short intervals eventually failed to prolong the bleeding time while still having a destructive effect on the platelets (chart 3). Eventually even the effect on the platelets was lost. Animals differed in the number of doses necessary to bring about this refractoriness. One animal became refractory after one moderate dose, another, after seven such doses.

Normally the bleeding time from the ear vein is greater in volume of output of blood per 15 seconds than that of the skin of the abdomen and thigh. During the acute phase of purpura, the bleeding time of many of the animals exhibited wide variations in the output of blood in a given time interval, a fairly small drop would be followed by one from one-half to five times its size, then large drops appeared in quick succession for the next two

or three minutes with a return to the drops of small size and so on, alternately. The volume output of blood in a given time interval varied remarkably in some instances. A better idea was formed of these variations by collecting the blood issuing from the ear vein at 15 second intervals and measuring it. Various rates of flow were obtained representing normal values (chart 4). During the acute stage the volume output of blood was visibly increased and irregular, whereas after recovery the opposite was observed. Toward the end of the phase of hemorrhages, and one day or more before the platelet count had shown an increase, the bleeding time from the ear vein often showed this peculiarity: after a minute or so of a profuse flow of blood there would be a sudden stop with no subsequent bleeding. When the platelet count was above normal levels the bleeding time became unusually short both in duration (chart 1) and volume of output, often a cut into the skin would yield no blood whatever. It was then that the skin was unusually tense and pale, the fine skin and conjunctival vessels being hardly visible.

Changes in the Coagulation of the Blood The destruction of platelets by antiplatelet serum injected intraperitoneally produced at first a diminution in the coagulation time of the blood, followed by a period of instability appearing between 28 and 72 hours afterwards and finally by a return to the normal duration (chart 1). After the intravenous administration of the serum the blood also became hypercoagulable during the initial period of platelet destruction (the first few minutes after the injection). That phase was soon replaced by one of prolonged coagulation with a slow return to normal as the platelets reached their former level. A slight prolongation of the clotting time of the blood in rabbits¹¹ and dogs¹² has been found after intravenous injections of antiplatelet serum, with a slow return to normal accompanying the rise in the platelets. Such was thought to be the usual sequence of events after an injection of that serum. To detect the phase of hypercoagulability, however, it is necessary to collect the blood during the actual period of platelet destruction, or, say, in the first three to four minutes when the serum is given intravenously, and within the first three to five hours when given intraperitoneally. The phase of hypercoagulability is perhaps the result of the great number of destroyed platelets in the circulation, the subsequent period of thrombopenia may partially account for the delayed coagulation.

Clot Retraction The method of judging this property of the clot depends on the setting of an arbitrary standard for irretractility⁴ since platelet-free clots are normally capable of retraction under favorable conditions, as, for example, when forces of adhesion are not dominant. With clots handled under specified conditions, spontaneous syneresis diminished along with the decrease in the number of platelets and was absent when they went below approximately 70,000 (chart 1). It disappeared within the first 10 minutes after an intravenous injection. During the period of purpura, the clots appeared soft, fractured easily, did not hold their shape when removed from

CHART 4 The volume output of blood from the ear vein in a normal dog, and during and after a phase of purpura. Inset: the first five-minute period of the curves in the main graph plotted in terms of the actual amount of blood collected at 15 second intervals

the vessel, and did not dry for 24 hours and longer. Clots became strongly retractile, however, before the platelets had shown a substantial increase from their low level (chart 1).

Correlations All correlations were apparently linear since no significant difference could be found between each coefficient and its corresponding ratio, when Blakeman's⁸ test was applied. The highest correlation was between the number of platelets and the degree of clot retraction ($+0.759 \pm 0.024$). Second to it was that between the bleeding time and the degree of clot retraction (-0.630 ± 0.04). These two correlations are not higher perhaps because of deficiencies in the method of measuring clot retractility. The moderately high correlation found between the bleeding time and the degree of the skin petechiae reaction ($+0.546 \pm 0.022$) may be traced to the influence of parallel changes in the number of platelets. That the correlation is not higher suggests that these changes alone do not account for the phenomena observed and that other factors must be searched for. The moderate degree of correlation between clot retractility and the skin petechiae reaction (-0.554 ± 0.039) may likewise be traced to changes in a common factor, the platelets, thereby influencing both phenomena simultaneously. There was an inverse correlation, moderately high, between the venous clotting time and the units of clot retraction (-0.462 ± 0.044), which may be explained in a similar manner.

The degree of correlation between the platelets and the bleeding time (-0.424 ± 0.026), and the platelets and petechiae reaction (-0.400 ± 0.027), was lower than anticipated. It was lower than the correlation between the bleeding time and petechiae reaction or between either one of these and clot retraction. This points to a closer relationship of the bleeding time and petechiae reaction with the character of the clot than with the platelet level of the blood. The diminution in the retractile power of thrombopenic clots may be related to the diminution or loss of elasticity of the skin observed during the height of an attack of purpura.

The similarity in degree between the coefficients for the platelets and bleeding time, and the platelets and the petechiae reaction suggests that whatever factors, aside from the platelets, influence the bleeding time, perhaps also play a part in the skin petechiae reaction. The relatively lower degree of these two correlation coefficients is another point favoring the existence of these other factors. There was a low correlation, not significant, between the mean bleeding time and the clotting time ($+0.113 \pm 0.056$), this helps to reinforce the impression obtained clinically that changes in the coagulation time of the blood have very little effect on the bleeding time. There was likewise a useless correlation, of no significance, between the number of platelets and the clotting time of the blood (-0.234 ± 0.069). This indicates that, although the platelet undoubtedly plays a part in the coagulation of the blood, this phenomenon is so complex that the rate of coagulation cannot be predicted from the number of circulating blood platelets alone. It also suggests that whatever disturbances in hemostasis were

the result of the destruction of platelets, changes in the coagulation of the blood did not contribute a large share in originating or perpetuating them

DISCUSSION

If macroplatelets may be considered as evidence of increased or abnormal platelet regeneration, it is clear that this may begin within from three to four hours after the platelets have been moderately reduced in numbers by the antiplatelet serum. Their subsequent disappearance and absence during the next 24 hours may be evidence that the young forms are destroyed by the circulating anti-serum or that no new forms can be regenerated because of a disabling effect of the serum on the thrombopoietic tissues. Perhaps the initial effect of the serum on these tissues is a stimulation to greater activity, followed by a depression during which no giant forms are observed. The uniform rhythm of their appearance also argues strongly against the proposed theory that "in vivo" the platelets are not destroyed by the serum¹² and that their disappearance from the peripheral blood is only temporary. If these forms bear a relationship to the mature platelet similar to that of the reticulocyte to the red blood cell, then the response of the marrow to a sudden decrease in the number of circulating platelets is approximately as rapid as the response of reticulocytes after a hemorrhage. Steele¹³ found that the reticulocyte percentage of rabbits bled out of 35 per cent of their blood, increased within a few hours after the bleeding.

The variations in the volume output of the blood from wounds during the various stages of purpura suggest changes in the normal distribution of blood among the vessels or alterations in their caliber, or in the pressure within them. A bleeding time shorter than normal appears to have been previously recorded only by Russell¹⁴ in canaries with chronic malaria.

The correlation between the number of platelets and the bleeding time was not as high as might have been expected. This is perhaps because (a) The number of circulating platelets may not give a true idea of the actual number of available functioning platelets in the blood at a given time. An increased utilization of platelets may take all the platelets being regenerated and leave no balance to swell the numbers in the circulation, this would explain the low platelet count with a normal bleeding time, if the latter were almost exclusively a function of the platelets. (b) Collateral forces of hemostasis of a vascular or extra-vascular nature may take a hand in the control of the bleeding during the thrombopenic interval. The demonstration of the presence and nature of such forces is difficult until more extended studies of the vessels are available. The return of the tonicity of the skin to normal before the platelets have reached a high level may partially account for the diminution in the bleeding time. With two exceptions, no really high correlations were found, which emphasizes the complexity of the mechanism of hemostasis and the multiplicity of factors involved in maintaining its integrity. Among these factors should be considered the permeability of the vessels, the capillary and venous pressure, the colloid osmotic pressure

and viscosity of the blood and the tension or elasticity of the tissues adjacent to the vessels. These forces are known to play a part in the movement of fluid to and from the vessels, it is natural to suspect them of influencing the escape of blood.

SUMMARY

Various cytological and physical changes in the blood of dogs with experimental thrombopenic purpura are described and an analysis made of the extent of the correlation between these changes themselves and the external manifestations of the disease.

Morphological variations in the platelets were regularly observed soon after a diminution in their level in the peripheral blood as well as preceding their return to normal after a period of thrombopenia.

The volume and rate of output of blood per unit time from a skin wound were increased and irregular during the acute phase of purpura and became markedly decreased in the first few days following recovery.

The highest correlations found were between the number of platelets and the degree of clot retraction, and between the latter and the mean bleeding time.

The correlations were of such a degree as to indicate that other factors than those under analysis will be found to play important rôles in the mechanism of normal and impaired hemostasis.

I am indebted to Drs. Thomas McCrae and H. W. Jones for their sympathetic support and to Miss Katherine Pierpoint for efficient technical assistance.

A COMPARISON OF THE RATE OF ABSORPTION FROM NORMAL AND BURNED TISSUES ¹

By EDWARD C MASON, M D , F A C P , PEARL PAXTON, M S , and H A
SHOEMAKER, Ph D , *Oklahoma City, Oklahoma*

IN 1925, Mason, Davidson et al published a series of papers,^{1, 2, 3} recording the observations made on animals which died in 15 to 18 hours as a result of a small piece of liver tissue left free within the abdomen. While doing this work, we conceived the idea that death following burns was probably due to the same factors which caused the death of these animals. Davidson,⁴ at the suggestion of Mason, introduced the tannic acid treatment of burns on the assumption that tannic acid would precipitate the dead and dying tissues and thereby prevent the absorption of toxic materials. The splendid results obtained by Davidson, and subsequent workers, apparently justified our theory.

The theory of toxic absorption accompanying burns has been held by numerous authors, and a variety of substances has been claimed responsible for the cause of death following burns. A very comprehensive list of such substances may be found in the paper of Fender,⁵ on the subject of "Lymphatic Pathology in Relation to 'Toxins' of Burns". More recently, Underhill^{6, 7, 8, 9} expressed the idea that no absorption occurred from burned areas, and in support of this contention he presented data which showed delayed absorption of such substances as strychnine and phenolsulphonephthalein from burned areas. From his observations he concluded that within a period of less than two hours following a burn there is a marked increase in permeability. "The increased permeability of capillaries appears to be in one direction only, namely from the blood to the tissue fluids. From the tissue fluid to the blood there is an apparent decreased permeability." ⁷ As a result of his studies, Underhill stressed the replacement of body fluids, lost from the burned area, as the principal therapeutic measure. He considered that the local treatment of burns was of secondary importance. We have continued the study in order to determine if substances other than strychnine and phenolsulphonephthalein are absorbed from burned areas. We have selected potassium iodide, a readily diffusible substance of relatively low molecular weight, and have studied the rate of excretion following subcutaneous injections in normal and burned animals.

EXPERIMENTAL

Normal rabbits were used to determine the rate of excretion of potassium iodide injected beneath the skin of the abdomen, the amount of potas-

* Presented before the American Physiological Society, Detroit, Michigan, April 13, 1935

sium iodide being 5 c c of a 2.29 per cent (approximately isotonic) solution per kilogram of body weight. The per cent of potassium iodide excreted by such normal rabbits varied greatly, the greatest total excretion for 36 hours being 55.4 per cent of the total potassium iodide injected, while the lowest was 21.7 per cent. Repeating the determinations, we found that animals which excreted a high percentage on the first test also excreted approximately the same amount on the second test and, likewise, those excreting a low percentage on the first test also excreted a low percentage on the second. The urine was collected by catheterization each 12, 24 and 36 hours following the injection. The amount of potassium iodide excreted was determined by a method developed by one of us (H. A. S.¹⁰) which is an adaptation from a variety of existing methods. Briefly, the method includes the destruction of the organic material by oxidation and the conversion of the iodide to iodate by bromine water in a slightly acid solution. Potassium iodide is added, and the liberated iodine is titrated, using sodium thiosulphate with starch as the indicator.

While the animals were completely anesthetized, a burned area was produced on the abdominal surface, and six hours following the burn, potassium iodide was injected subcutaneously in the burned area, the amount of potassium iodide used being the same per kilogram of body weight as was injected into the normal rabbits.

The data obtained from the normal and burned rabbits appear in the following table:

THE RATE OF EXCRETION OF IODIDES ABSORBED FROM NORMAL AND BURNED AREAS

The cross-hatched bar represents iodide excretion by the normal animals
 The solid black bar represents iodide excretion by the burned animals

The values are expressed as the total per cent of potassium iodide recovered at the end of 12, 24 and 36 hours. It will be observed that the excretion is essentially the same in both the normal and burned animals. Three rabbits excreted slightly more in the normal state and three excreted slightly more in the burned state. While one animal's output was practically the same before and following the burn, this rabbit No. 7, developed a respiratory infection during our study and died shortly after the completion of the experiment. No urine was obtained from rabbit No. 6 by catheterization at the end of the first 12 hours, and none was obtained from normal rabbit No. 7 for the 12 and 24 hour periods, however, by washing the cage and collecting the total output, we obtained results quite comparable to the other rabbits.

DISCUSSION

The experience during the late World War demonstrated the fact that the absorption of extracts of freshly crushed tissue and extracts of autolyzed tissue caused toxic symptoms. The generally accepted treatment became that of debridement, and the results verified the contention that a wound freed of dead and dying tissue gave the patient a better chance for recovery. This theory was also strongly supported by the studies of Cannon¹¹ on wound shock.

More recently this old conception has been attacked,^{12, 13} and evidence has been presented to support the theory that with the presence of injured tissue injured either mechanically or by burning, there occurs an outpouring of body fluid into the injured area, and such fluids represent blood serum or blood plasma. It is further claimed that the resulting blood concentration will account for all the symptoms and pathological changes which occur in "secondary shock."

In support of the older idea of "wound shock," Mason and Nau¹⁴ have recently presented evidence that the absorption of products of autolysis of sterile liver does produce definite pathological changes within the host. Also, the marked decrease in mortality,¹⁵ from 28 to 15 per cent, resulting in the use of tannic acid in the treatment of burns suggests that the toxic material is precipitated by the tannic acid and its absorption prevented. Quite recently Blalock has agreed that the absorption of extracts of injured tissue (burned tissue) may be the cause of shock. The following quotation is taken from his discussion¹⁶: "First, I would like to state that I believe some instances of shock are due to the absorption of toxic products. The action of toxic material is probably the main factor in producing death in the patient who has intestinal obstruction with strangulation of the blood supply. I believe that deaths which occur from three to ten days following severe burns are due in large part to the absorption of protein decomposition products."

CONCLUSIONS

1 A readily diffusible substance of low molecular weight, such as potassium iodide, is absorbed from burned areas

2 Death occurring several days following severe burns is due mainly to the absorption of protein decomposition products

STUDIES IN MULTIPLE SCLEROSIS

VIII ETIOLOGIC FACTORS IN MULTIPLE SCLEROSIS*

By TRACY J. PUTNAM, M.D., *Boston, Massachusetts*

THE EXPERIMENTAL PRODUCTION OF LESIONS SIMULATING MULTIPLE SCLEROSIS

IN previous communications, it has been pointed out that lesions closely resembling typical plaques of multiple sclerosis may be produced in animals in either of two ways—by the subcutaneous injection of minute doses of tetanus toxin¹ and by experimental obstruction of cerebral venules². In each case sclerotic lesions could be demonstrated only after an interval of several months from the original injury. The earlier lesions closely resembled those of “post-infectious encephalomyelitis,” a disease occasionally seen following measles³ and vaccinia⁴ and often without obvious antecedent Areas of demyelination, with relative persistence of axis cylinders, accompanied by infiltration in the early stages and gliosis later, have also been described as a result of carbon monoxide poisoning with venous thrombosis,⁵ and chronic cyanide poisoning⁶.

By themselves, these experimental results prove little in regard to the human disease of multiple sclerosis. They do suggest, however, that

1 “Post-infectious encephalomyelitis” and multiple sclerosis may represent the same pathologic process at different stages with variations in intensity

2 Local anoxemia, or more specifically local venous obstruction, should receive consideration as the immediate cause of the primary demyelination

3 The process may be precipitated in some way by an organic toxin, and probably by any one of many

None of these propositions is entirely new, but apparently no attempt has been made to interrelate them. Indeed, they have been considered almost mutually exclusive. Thus multiple sclerosis has been looked upon as a toxic disease, and therefore not circulatory, or as an infectious disease and therefore not toxic. Before attempting to harmonize these points of view, let us see what may be said for each of them separately.

“ENCEPHALOMYELITIS” AND MULTIPLE SCLEROSIS AS MANIFESTATIONS OF THE SAME PATHOLOGIC PROCESS

The essential similarity between “encephalomyelitis” (especially the post-measles and post-vaccinal forms) and multiple sclerosis has frequently

* Received for publication October 3, 1935. (Presented before the Section of Nervous and Mental Diseases of the American Medical Association, Atlantic City, June 12, 1935.)

From the Neurological Unit, Boston City Hospital and the Department of Neurology, Harvard Medical School, Boston, Massachusetts.

The expenses of this investigation were defrayed in part by the Multiple Sclerosis Fund of Harvard University.

been affirmed,⁷ and almost as frequently denied⁸ The points of similarity between the two diseases which are usually pointed out are the patchy distribution of the lesions, which surround venules of the white matter, and the predominant involvement of myelin, axis cylinders often remaining relatively intact On the other side of the question, it has been asserted that the lesions of the acute disease are more diffuse than those of multiple sclerosis, and this is doubtless true in some instances In these cases the picture as a whole is much more similar to that of diffuse sclerosis or Schilder's disease This condition, however, is probably to be considered a variant of multiple sclerosis⁹ Further, it has been objected that there is much more extensive loss of axis cylinders in the lesions of "disseminated encephalomyelitis" than in typical sclerotic plaques This is probably true, but it must be remembered that the patient has died at the height of a severe acute process in most cases of the former disease coming to autopsy, while a milder process, such as multiple sclerosis, might be expected to allow the survival of axis cylinders in greater numbers Even in multiple sclerosis, extensive loss of axis cylinders is common, as all modern investigators have reported In a series of 35 separate plaques from 11 cases of multiple sclerosis studied with this question in mind, almost complete destruction of axis cylinders was found in eighteen¹⁰ A case reported by Walthard¹¹ is often cited as direct evidence that post-measles "encephalitis" is not the equivalent of multiple sclerosis The patient died three months after a typical onset, and at autopsy a considerable loss of axis cylinders was found in most of the lesions Perhaps more relevant, however, may be the cases of Cramer¹² and of Schlesinger,¹³ in both of which the patients survived an unmistakable post-infectious "encephalitis" for many months and in both of which typical sclerotic plaques (figure 1) containing relatively intact axones were found post mortem Walthard's case may then be considered a transitional form of which a number have been reported^{8, 14 15}

Gliosis, which is a striking feature of multiple sclerosis, would scarcely be expected in an acute process It is, however, not as specific for multiple sclerosis as has sometimes been supposed Lesions with loss of myelin but with little or no gliosis occur side by side with typical sclerotic plaques, and on the other hand, areas of secondary degeneration in other pathologic conditions of comparable age and intensity with those of multiple sclerosis develop quite as dense a glial scar (Figures 2 and 3) It is probably a general rule that once myelin has been broken down, it cannot regenerate in the adult central nervous system,¹⁶ and that myelin loss is repaired by a glial fibrosis which grows denser and less cellular with the passage of years An exception to the rule is seen in such conditions as the degeneration accompanying primary anemia, in which gliosis appears to be inhibited by some nutritive lack

Additional points of similarity between "encephalomyelitis" and multiple sclerosis, which have apparently escaped notice, are the vascular ob-

FIG 1 Typical sclerotic plaques in the pons, from the brain of a boy of 7, who died 22 months from the onset of a clinically typical post-measles "encephalomyelitis," after a course marked by remissions and exacerbations (After Schlesinger¹³)

structions and engorgement and the perivascular hemorrhages seen in both, as will be described below

It is assumed by most writers on the subject, often without any display of evidence, that an "encephalomyelitis" in which an infiltration with hematogenous cells occurs must be due to a filterable virus if it occurs in the course of a virus disease. Infiltration with lymphocytes and leukocytes is, however, common in the vicinity of softenings and tumors¹⁷. Further, Rivers¹⁸ has pointed out that all known virus diseases lead primarily to either a necrosis or a proliferation of parenchymal cells, or both, while in "encephalomyelitis" of the type in question the chief damage is to cell appendages, and in particular to the myelin which is probably to be considered as intercellular substance¹⁹.

VASCULAR LESIONS AND DEMYELINATION

In addition to the experimental data already presented, there is evidence from the pathology of other diseases that disturbance of circulation may lead to loss of myelin and to gliosis. Thus the ordinary forms of arterio-

FIG 2

FIGS 2 and 3 Loose filmy gliosis (figure 2) from a plaque from a long-standing case of multiple sclerosis, for comparison with the dense gliosis in a degenerated pyramid (figure 3) secondary to a capsular apoplexy 10 years previous. Note also the absence of axon cylinders in the sclerotic plaque. Masson stain, oil immersion lens.

sclerosis may produce small lesions in the nervous system in which the myelin suffers far more than the axis cylinders. In human as well as in experimental carbon monoxide poisoning, areas of demyelination may be situated in relation to thrombosed veins,⁵ and in one well studied case, exposure to carbon monoxide apparently precipitated a fatal exacerbation of multiple sclerosis.²⁰ In the condition known as chronic subcortical encephalopathy, plaques closely resembling those of multiple sclerosis occur obviously as a result of vascular obstruction.²¹

Alterations in the blood vessels have long been recognized in multiple sclerosis, and formerly a good deal of emphasis was laid upon them as possibly of importance in the etiology of the disease, for example, by Williamson,²² Ribbert,²³ and Borst.²⁴ It was usually assumed that the vascular abnormality permitted the escape of a toxin or "toxic lymph" into the substance of the brain. More recent writers, such as Hassin,²⁵ have dismissed the vascular changes as secondary to the parenchymal degeneration. The perivascular infiltration may well be accepted as the cause of adventitial proliferation, but it seems open to question whether the obstructions, dilations, and perivascular hemorrhages which have been described could be explained on a similar basis.

In "post-infectious encephalomyelitis" vascular engorgement has been reported by most observers, thromboses by several, and perivascular hemorrhages by some. The presence of thrombi in post-measles "encephalitis" has received especial attention from Kreider²⁶ in Ferriaro's laboratory.

It seemed worth while, therefore, to make a special review of the subject. This proved not as easy as had been anticipated. Aside from the difficulties of collecting material,^{*} it was found that the ordinary routine stains and the usual neuropathologic methods were entirely inadequate for a study of thrombi and finer vascular changes. Finally, Masson's stain on paraffin material was tried, and appeared satisfactory. The results of the investigation will be published in detail elsewhere, and are merely summarized here.

In a case of post-vaccinal "encephalitis" and in another histologically similar case, but without known etiology, the vascular changes may be summarized as extreme engorgement, phagocytosis of brown pigment with and without perivascular hemorrhage and intravascular clot formation. In numerous vessels, large and small, there were masses of platelets, a heavy deposit of fibrin adherent to the walls and endothelial proliferation (figure 4).

In every one of 14 cases of multiple sclerosis in which material was available for adequate study, marked vascular changes were observed. The adventitial proliferation, doubtless a result of perivascular infiltration, has already been referred to. In addition, an engorgement, tortuosity and proliferation of veins in the vicinity of plaques were striking (figure 5).

^{*}I am greatly obliged to my friends, Dr. George Hassin of Chicago, Dr. K. Loewenburg of Ann Arbor, Dr. Cyril Courville of Los Angeles, Dr. William Shaper of Pittsburgh, Dr. John Dwyer of Springfield, Mass., and Drs. S. B. Wolbach, T. Leary, F. Parker, C. S. Kubik and I. B. Akerson of this city for their kindness in supplying pathologic material.

FIG 4 Post-vaccinal "encephalitis" Engorged vessel, containing a mass of fibrin adherent to the walls and clumps of leukocytes Cells are growing along a fibrin strand (arrow) Masson stain, oil immersion lens

FIG 5 Multiple sclerosis Congestion and proliferation of vessels in a plaque (on left of photograph) in the cerebral white matter Masson stain, low power

Brown pigment was seen in endothelial and adventitial cells. Clots of fibrin and leukocytes occurred in vessels of various sizes, but they were less numerous and intense than in the cases of "encephalomyelitis". In some of them, invasion by endothelial cells could be demonstrated (figure 6). Complete occlusion of vessels by fibrous tissue was encountered with considerable frequency.

Can these changes be secondary to the parenchymal degeneration? A similar study was made of the vicinity of old softenings, which had produced massive secondary degenerations accompanied by dense gliosis. The vessels

FIG 6 Multiple sclerosis. Platelet clot adherent to wall of vessel, with fibroblast (arrow) growing over the surface. Masson stain, oil immersion lens.

in such areas were approximately normal in size and number, not engorged, their walls contained no pigment, and their lumens contained no clots. There was often a thickening of the adventitia, which occasionally still held a few phagocytic cells.

Since, therefore, the vascular obstructions and dilatations seen in multiple sclerosis and "encephalomyelitis" are not regularly encountered in other types of degeneration, and since demyelination may be produced experimentally by venous obstructions, it seems reasonable to conclude that the

thromboses are primary to the changes in the nervous tissues, and not secondary. The histologic details will be discussed more fully in a paper now in preparation.

THE PART PLAYED BY TOXINS AND OTHER EXOGENOUS FACTORS

It has often been pointed out that the exacerbations of multiple sclerosis are apt to follow infections of various sorts. Pregnancy, trauma, chilling, the injection of foreign protein, and severe emotional strains are also mentioned as precipitating attacks. Von Hoesslin,²⁷ who has recently reviewed the subject, finds that one or the other of the factors mentioned appeared to be associated with the onset or progression of the disease in a large proportion of the cases which he studied. He concludes that there is probably also a predisposition to multiple sclerosis which is perhaps inherited.

If the lesions of multiple sclerosis are the result of thrombosis, it appears natural to seek the predisposing factor in the coagulating mechanism of the blood. Brickner²⁸ has described an abnormal lipolytic activity in the serum of patients suffering from multiple sclerosis, and McKenna²⁹ has pointed out that a leukocytosis is frequently found. It is not obvious, however, just how such abnormalities have a bearing on the presumed occurrence of thromboses.

The matter appears clearer since Solomon and Simon³⁰ demonstrated a functional abnormality in the clotting time in a series of patients with multiple sclerosis. Injection of adrenalin or of typhoid vaccine caused a more marked and more prolonged decrease in clotting time (that is, *increase* in coagulability) than in normal controls or patients with other neurologic diseases.

The mechanism of this increased lability of blood coagulation is still under investigation. It has been found that the blood fibrinogen is high in the majority of cases of multiple sclerosis examined. The blood calcium is within normal limits. No constant abnormality has been demonstrated in the platelet count, but in some instances there appears to be an abnormality in the behavior of the platelets. It is possible that some of the tests may be of diagnostic value.

The results of these investigations may be taken, then, to support the suggestion that some fundamental disorder of the blood leads it to clot in the cerebral venules of the central nervous system as a result of stimuli, infections, pregnancy or emotional upsets which normally would lead only to a mild increase in coagulability.

THERAPEUTIC IMPLICATIONS

No attempt has been made as yet to formulate a definite therapeutic program on the basis of the theory which has been outlined, but it is not difficult to visualize various methods which might be tried. It might be possible, for example, to lower the level of fibrinogen by diet, or to cause

a decrease in the number of platelets, or to administer a suitable anti-coagulant drug. It seems wiser, however, first to define the fundamental abnormality more clearly, if only because of the extraordinary difficulty of reaching a true estimate of the results of treatment simply from symptomatic and neurologic changes.

Obviously, the presumed exciting factors should be avoided if possible. Infections, accidents, and emotional upsets are not easily circumvented, but female patients should be advised not to become pregnant.

Certain negative conclusions are evident. Little is to be hoped for from antiseptic treatment. Heat treatment and cervical sympathectomy can have scarcely more than temporary value, if any. Treatment by injection of foreign protein is certainly to be avoided.

SUMMARY

1 The histologic features of the lesions of multiple sclerosis have been produced experimentally in animals in two ways: by the injection of minute doses of tetanus toxin, and by obstruction of cerebral venules.

2 Thrombi and obstructed vessels have been observed in the lesions of multiple sclerosis, and in those of "post-infectious encephalomyelitis," apparently an acute form of the same pathologic process.

3 It has been recognized, although rather vaguely, that there may be an association between the exacerbations of multiple sclerosis and infections, pregnancy and accidents.

4 Recent clinical investigations have shown that, although the clotting time is usually within normal limits in cases of multiple sclerosis, the coagulability of the blood is greatly increased by the administration of adrenalin or of typhoid vaccine, as compared with controls.

5 Therefore, there is probably a fundamental abnormality in the blood in multiple sclerosis, which interacts with endogenous or exogenous factors to cause thrombi in the cerebral venules.

CORRELATIONS OF THE ENDOCRINE SYSTEM ¹

By DAVID LANDSBOROUGH THOMSON, PH D, *Montreal, Canada*

UNTIL recent years, all discussions of the interrelations of the different endocrine glands were in effect discussions of a single simple diagram which was introduced by Eppinger, Falta and Rudinger ¹ as long ago as 1908, and which is still to be found in certain textbooks of physiology and of medicine at the present day. The diagram took the form of a triangle, whose apices represented the pancreas, the thyroid, and the adrenal medullae, between the two last-mentioned, a mutually synergistic relation was supposed to exist, while the two other sides of the triangle represented reciprocal inhibitory actions. It was not founded upon any very impressive assemblage of experimental data, it obviously left out of count members of the endocrine system whose importance is now more generally recognized, and it gave no explicit suggestion of the nature of the antagonisms and synergisms postulated.

From a purely theoretical standpoint, we may recognize that there are three entirely different mechanisms possible, each of which may lead to one hormone appearing to act as an antagonist to some other hormone. In the first place, the two hormones might react chemically with one another, as an acid reacts with an alkali, to their mutual destruction, so that chemically-equivalent amounts of the two hormones, administered together or secreted simultaneously, would exactly cancel out, with unequal mixtures, the physiological effect would be determined by the difference in the amounts of the two hormones, and could be calculated by subtraction.

In the second place, the two antagonistic hormones may act upon the same responsive tissue, but produce therein opposite or at least incompatible reactions. Arguing by analogy from the few instances that have received satisfactory study, by Clark,² Gaddum,³ and others, we may regard it as probable that in such a case the physiological effect of combined action is to be calculated, not by subtraction, but by division, that is, that it depends, not on the difference, but on the ratio between the two substances.

There is yet a third possibility: one hormone may act upon the endocrine source of some other hormone, so as to inhibit its activity, and decrease the rate of secretion. This may also give rise to an apparent antagonism, which may be physiologically or clinically conspicuous but will tend to disappear in experiments of the pharmacological type in which both the active principles are introduced in known amounts. The action of any one hormone upon some other endocrine gland may be direct or indirect, it may take place by the mediation of the nervous system, or of some third endocrine gland whose participation in the process may easily escape notice.

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

From the Department of Biochemistry, McGill University, Montreal

It is easy to see that these are three fundamentally different types of antagonism, and that there are three analogous and parallel different types of synergistic action, all theoretically possible. Diagrams such as that set up by Eppinger, Falta and Rudinger make no attempt to distinguish between these three possible types of antagonism, or of synergism, but today we are dissatisfied with such vague positions, since in many instances the nature of the observed antagonistic and synergistic effects has been more or less fully elucidated.

No examples of the first type of interaction between hormones have been established, and it does not at present seem probable that direct chemical reaction between different hormones occurs in the body. It was formerly usual to speak of the relation between the characteristic male and female sex hormones in such terms, but it is now clear that such a view is physiologically untenable and, at least for androsterone and the estrin group, chemically impossible.

The second type of interaction is well exemplified by the ovarian hormones estrin, the follicular hormone, on the one hand, and the corpus luteum hormone, progesterin, on the other. Both act upon the same group of responsive tissues, in the uterus, the vagina, and the mammary glands, in some cases, or in some circumstances, their actions are incompatible. The enormous difficulty of obtaining the characteristic vaginal response to estrin in the presence of an active corpus luteum is well known, and the suppression of the usual uterine responses to progesterin (progestational proliferation, sensitization to trauma) by administration of estrin has been described many times. On the mammary gland, however, these two hormones have similar or complementary effects. Even in the case of a single tissue, the endometrium of the rodent uterus, the two hormones may be in some respects antagonistic and in others synergistic. This tissue, when sensitized by a relative excess of progesterin, responds to certain types of trauma by the formation of a large mass of decidual cells, the deciduoma of Loeb⁴, this reaction can be prevented by the administration of estrin. A tumor-like mass of quite different, conspicuously hydropic character may develop, in response to the trauma of slitting in the presence of both estrin and progesterin⁵. In the formation of this type of tumor, which has been called the endometrial mole, progesterin appears to reinforce and enhance the action of estrin, whereas, in the formation of the deciduoma type of tumor, from the same tissue, estrin inhibits the action of progesterin.

Endocrine interrelations of this type may be exceedingly complex. Thus the glycogen-storing cells of the liver are influenced by insulin, adrenalin, the thyroid hormone, probably the hormone of the adrenal cortex, and possibly a hormone of the anterior pituitary, nor are they indifferent to less specific changes in the composition of the blood supplying them, such as changes in hydrogen-ion concentration and sugar concentration. It is obvious that so tangled a skein is not easily unravelled, and that the effect upon the liver glycogen of treatment with an anterior pituitary extract

(which may have a direct action, but is likely also to affect the thyroid and the adrenal cortex and to act upon metabolism in various ways both direct and indirect) is not easily interpreted

Such discussions lead naturally to a survey of the third type of endocrine correlation—the effects, stimulating or inhibitory, that a hormone may have upon some other endocrine gland. The most familiar, and undoubtedly most important instances are the dependence of the thyroid, the gonads, and the adrenals upon the anterior pituitary. It is well known that hypophysectomy leads to an almost complete cessation of activity, and to striking atrophic changes, in these dependent organs, and that these effects of hypophysectomy may be corrected, temporarily at least, by replacement therapy with suitable pituitary extracts. Moreover, the anterior lobe itself is affected by changes in the activity of these dependent organs, the gonads, the thyroid, and (probably) the adrenal cortex. It is certain that these reciprocal relationships between certain glands and the anterior pituitary play a predominant part in the correlation of the endocrine system, and they cannot be passed over thus briefly.

In the meantime, however, it is interesting to note that while the importance of these pituitary correlations is ever more widely appreciated and applied in interpretation, there are relatively few other instances of action of hormones upon endocrine glands. A number of supposed cases of this type of interrelation have been shown, by further study, to be indirect actions, or to be non-specific. Thus the fact that the normal rhythm of estrus is usually interrupted by destruction of the adrenal cortex does not indicate a direct action of the cortical hormone upon the ovaries, since it has been shown⁶ that if the general condition of the adrenalectomized rat can be satisfactorily maintained by supplying large amounts of salt, the estrus cycles continue. The anestrus after adrenalectomy is therefore the reflection of a generalized cachexia and comparable to the anestrus of starvation; it is probable that the anestrus observed in experimental hyperthyroidism is, in part at least, of similar origin and not to be regarded as evidence of a specific action of the thyroid hormone upon the ovaries. There is some reason to believe, however, that the thyroid hormone has a direct influence upon the development of the islets of Langerhans,⁷ and that the ovarian and testicular hormones cause atrophic involution of the thymus.⁸

In the above-mentioned instances the effect appears to be specific, and it is likely, though not certain, that it is direct. There are other cases in which specificity is not in question, but which must be regarded as indirect. The statement that administration of adequate doses of insulin leads to discharge of adrenalin is merely an abbreviated way of saying that the insulin usually produces a fall in blood sugar, which in turn stimulates the nervous centers controlling adrenalin secretion.⁹

Among these indirect correlations of this type, none are more interesting at the present day than those in which the anterior pituitary plays the mediating role. Before these can be discussed, it will be necessary to examine

more closely the direct linkages involving the anterior pituitary. The multiplicity of endocrine activities with which this minute gland has been credited has become almost a byword, and it is too true that some investigators, discovering some minor consequence of injections of pituitary extracts, have been uncritically rash in assuming a direct specific mechanism and postulating a new pituitary hormone. Nevertheless, the fractionation of pituitary extracts into partially-purified products has shown, by the manner in which the manifold activities of the crude original extract have been distributed among the final fractions, that the situation is extremely complex. This chemical dissection of the gland, though far from complete, already permits one to say with some degree of confidence that at least seven distinct and separable hormones are present in the crude extracts. Prolactin, which develops the crop-gland of the pigeon, and brings the developed mammary gland of the mammal into active secretion, possesses distinctive chemical properties which permit its separation from the other active principles¹⁰. Equally distinctive, though very different, are the properties of the adreno-tropic hormone, assayed by its power to restore the atrophic adrenal cortex of the hypophysectomized rat¹¹. It does not seem possible to doubt that there are two active principles affecting the ovary, one primarily follicle-stimulating and one promoting luteinization^{12, 13}. The thyreotropic hormone, which causes hyperplastic changes in the thyroid gland and increased secretory activity in susceptible animals, may be separated from the foregoing¹⁴. The ketogenic principle, which in some unexplained but probably direct manner intervenes in metabolism to cause an accumulation of acetone bodies in the blood, is found to be distributed among various fractions in such a way that it cannot be identified with any of the other accepted hormones¹⁵. The growth hormone may be obtained reasonably free from the others¹⁶. Beyond this it does not, at present, seem profitable to go. It has already been hinted that the principles above mentioned can, in so many different ways, play a part in carbohydrate metabolism, that the existence of a specific hormone acting directly thereon is very hard to establish, if such a substance exists, it is hard to separate from the growth hormone. A dependence of the parathyroids upon the anterior pituitary seems rather clear in some species,^{17, 18} but the evidence for a specific pituitary hormone with a direct action on the parathyroids¹⁹ is relatively scanty. Other postulated pituitary hormones rest upon still more slender bases.

The importance of the anterior pituitary in endocrine correlations is only in part due to the fact that its hormones control other endocrine glands, it is also partly due to the fact that these glands reciprocally influence the anterior lobe. This aspect of the question has been studied in three somewhat different ways. In the first place, histological changes or gross changes in the anterior lobe may be noted after the ablation of some endocrine gland or after the administration of some endocrine principle. The existence of an effect may be demonstrable in this way, but the nature of the effect remains somewhat obscure. When only two pituitary hormones—growth

and gonadotropic—were recognized, it was tempting to connect them with the two chief types of granulated cells in the anterior lobe, and to interpret histological changes accordingly, but if at least seven hormones are postulated, the interpretation can hardly be carried out in detail

Secondly, the effect of various experimental procedures upon the amount of one or other of the hormones actually present in the anterior lobe may be approximately determined. The pituitaries of the experimental animals may be introduced, either as implants or as crude extracts, into suitably reactive test animals and the magnitude of the effects obtained noted. Such procedures are subject to the usual errors of the cruder methods of biological assay, and moreover the interpretation of the findings is fundamentally ambiguous. It is well known that the withdrawal of ovarian hormones by castration leads, in many species, to marked histological change and increase in size of the anterior pituitary, if the pituitaries of such castrates are implanted into immature female rats or mice, they prove to be unusually rich in gonad-stimulating principles, and there is ample additional evidence to show that the anterior lobe not merely contains large amounts of these substances, but that it secretes them in far larger quantities than usual. In this case the amount of hormone present in the anterior lobe is an index of its activity. This correlation is not inevitable. Thus it has been argued²⁰ that the anterior pituitary of the pregnant woman is deficient in gonadotropic hormones, not because it is not producing them, but rather because it is producing them so rapidly that they are not stored in the gland itself. Similarly the hyperactive thyroid gland in exophthalmic goiter contains less than the usual quantity of thyroxin²¹

Thirdly, it is in some cases possible to obtain direct evidence of the degree of the activity of the anterior lobe. The amount of the hormone under consideration present in the circulating blood may be measured, and unless the rate of destruction or of excretion of the hormone varies greatly there will be no likelihood of errors in interpretation. Thus the hyperactivity of the pituitary of the castrated rodent has been established by cross-circulation (parabiosis) experiments²² and by assays of samples of drawn blood²³. Alternatively, structural or functional changes in the animal itself may be indicative of altered pituitary function. For example, the occurrence of thyroid hyperplasia after castration may be taken to mean that the anterior lobe has increased its production, not merely of gonadotropic substances, but also of thyreotropic hormone, an interpretation supported by the finding²⁴ that the thyreotropic-hormone content of the pituitary is increased.

This last example brings the discussion back to the point from which it started—namely, that the influence of one hormone upon some other endocrine gland may take place through the mediation of the anterior pituitary. There is no doubt that this is a common occurrence in experimental studies, and it is probable that it is of great physiological importance in the integration of the endocrine system. Examples are not far to seek when the ad-

ministration of large doses of pregnancy-urine preparations stimulates the ovaries of the rat to unusual endocrine activity, there results an activation of the pituitary which in turn produces enlargement and hyperplasia of the thyroid²⁷, again, enlargement of the adrenals seen after treatment with extremely large doses of the ovarian hormone estrin²⁸ is similarly ascribable to activation of the anterior lobe to produce the adrenotropic hormone. Evidence that the pituitary does participate in these reactions is furnished by the fact that in both instances enlargement of the anterior lobe occurs to a marked degree, and also by the fact that neither effect is obtainable in animals from which the pituitary has been removed.

On the whole, it does not seem that these reactions are highly specific. The structural changes in the anterior lobe produced by thyroidectomy are somewhat similar to, though distinguishable from those produced by ovariectomy, in both cases, the thyreotropic-hormone content of the gland is increased^{24, 27}. One gains the impression that, as a general rule, the anterior lobe reacts with a generalized increase or decrease in activity to alterations in the supply of hormones from the dependent endocrine glands. If the pituitary secretes many hormones, it seems theoretically possible that it might secrete any one of them in excess and the rest in normal amounts, but it is hard to find cases in which this theoretical possibility seems to be realized in practice. Pathological hypersecretion of the growth hormone, producing acromegaly, is very often accompanied by signs of hypersecretion of thyreotropic hormone (causing elevation of the basal metabolic rate by thyroid stimulation), by symptoms of diabetes, and in some instances at least by signs of over-production of gonad-stimulating hormones. Yet this problem has not been thoroughly explored, and experimental means may yet be found whereby one of the manifold endocrine functions of the anterior pituitary may be influenced without disturbing the others.

Perhaps an instance may be found in the study of lactation. Since removal of the pituitary at any time during lactation promptly halts the secretion of milk,²⁸ it is clear that the pituitary hormone prolactin is supplied throughout the whole period, and it has been shown that the mechanical stimulation of the nipples during suckling is responsible for the maintenance of prolactin secretion²⁹. In this case it does not seem that the anterior lobe is activated as a whole, the ovaries, for instance, are quiescent—if they are experimentally roused to activity, pituitary function is affected and milk secretion fails^{30, 31}—and this might indicate that the anterior lobe, though actively producing prolactin, has ceased to secrete gonad-stimulating hormones. However, since it seems that prolactin itself has an inhibiting effect upon the ovaries,³² it is not certain that the interpretation indicated is the correct one.

This example introduces into the question of endocrine correlations the factor, hitherto omitted, of nervous links in the chain of interrelations. It seems difficult to suppose that the influence of suckling upon the pituitary is

transmitted by other than nervous routes, yet since the more obvious possible nervous pathways may be interrupted without effect, it is hard to conceive what these routes may be³⁰ The same difficulty arises in considering the sudden burst of pituitary activity which follows mechanical stimulation of the genital region in the estrous rabbit Yet despite the difficulties, it is hard to escape the view that pituitary function is to some extent under nervous control, and is influenced by stimuli arising peripherally or originating in higher centers It has even been suggested³¹ that the effect of hormones such as estrin upon the pituitary is indirect, and involves the stimulation of a center controlling the anterior lobe by unidentified nerve fibers, but since this view is based chiefly on failure of the usual pituitary response to estrin in transplanted (hence denervated) pituitaries, and since this organ does not lend itself well to transplantation, the question may be regarded as still undecided

This question of the nervous control of the anterior lobe is not more difficult than the problem of nervous regulation of other endocrine organs The adrenal medulla furnishes an unique example of an endocrine gland whose activity is quite certainly dependent primarily upon its innervation The theory that there are true secretory fibers to the cells of the pancreatic islets remains a highly controversial and difficult topic, the same might be said of the thyroid gland On the whole, interest in the question of nervous correlation within the endocrine system has decreased with the increase in knowledge of hormonal correlating mechanisms and especially of the central part played by the anterior pituitary

No discussion of endocrine correlations could now be complete without some mention of the "anti-hormones" These substances, of unknown nature and origin, appear in the circulation of animals subjected to prolonged treatment with certain pituitary extracts, and are detected by their power to inhibit the action of such extracts Our knowledge of them has been summarized elsewhere,³² and is not yet adequate to permit any evaluation of the part they play in the complex system of actions and reactions which ensues the integration and correlation of the endocrine system

ARTERIOSCLEROSIS AND HYPERTENSION IN DIABETES

By HOWARD F. ROOT, M.D., F.A.C.P., and THOMAS P. SHARKEY, M.D.,
Boston, Massachusetts

THAT arteriosclerosis occurs in excessive degree in diabetic patients has found general acceptance among American students. The importance of characteristic metabolic changes of diabetes in its causation was pointed out in the first study of Deaconess Hospital autopsy data by Root and Warren.¹ Further reports by Joslin² emphasized the clinical significance of arteriosclerotic complications of diabetes, and Warren³ summarized the pathologic data bearing upon arteriosclerosis in a large series of diabetics. Other aspects of this problem require investigation, such as (1) when does the excessive arteriosclerosis found in diabetic patients develop? (2) what are the characteristic steps in its progress? (3) are the morphologic changes of arteriosclerosis in diabetes different from those in non-diabetic patients? In this paper briefly are summarized the results of an analysis of the clinical records and the postmortem examinations of 175 diabetic patients at the New England Deaconess Hospital.

Fifty-four per cent of the cases had had hypertension indicated by a systolic pressure exceeding 150 millimeters of mercury. A few patients were included who had only a single blood pressure reading between 150 and 160 millimeters. A considerable number of the hypertensive group could not be said to have a constantly elevated blood pressure. Little attention was paid to the diastolic pressure although it varied from 80 to 130 in the hypertensive group and, though its more fundamental importance is conceded, no great change in the classification of the patients would have occurred by using the diastolic pressure.

The 175 cases included 100 females and 75 males, of whom 93 had a systolic blood pressure at some time between 150 and 230 mm. mercury. Obesity had been present in 87 per cent of the hypertensive and 74 of the non-hypertensive group. The average age at death was 63 years for the hypertensive group and 51.1 for the non-hypertensive group. All the children and cases under 30 years of age fell in the non-hypertensive group.

Age at Onset of Diabetes. The old concept of diabetes as a degenerative disease of old age received its death blow from the publication of data by Pincus, Joslin and White⁴ based on 9853 cases of true diabetes. They showed clearly that the frequency of onset of diabetes declined after the sixth decade. The rate for frequency of onset indicates the susceptibility to the development of diabetes and it is clearly evident from their data that

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935.
From the George F. Baker Clinic, Elliott P. Joslin, Medical Director, New England Deaconess Hospital, Boston, Massachusetts.

diabetes is not a disease produced by senility. Actually the susceptibility to diabetes in the eighth decade of life is less than in the third decade. If vascular disease was a significant factor in producing diabetes, how would we explain the fact that 10 per cent of all diabetes begins in the first 15 years of life, and two-fifths before the fortieth year? In this series, 21 per cent of the cases among males and 17 per cent among females began before the age of 30 years. Furthermore, errors are all in the direction of postponing the age at onset. Eighteen cases died under the age of 40 years, of these, seven had had diabetes over five years, and every one had arteriosclerosis, including two boys 16 years of age, and Case No. 1794 that died at 33 years of age with coronary occlusion. None of these cases under the age of 40 years had hypertension.

Development of Excessive Arteriosclerosis For a demonstration of the difference in the extent and severity of arteriosclerosis in diabetes as compared with non-diabetics, a series of 170 non-diabetic autopsies examined at the New England Deaconess Hospital by the same pathologist was compared with this series of 175 diabetics (see tables 1 and 2). The 170 cases

TABLE I
Coronary Sclerosis in 175 Diabetics at Autopsy

Cases	93 Cases with Hypertension			82 Cases without Hypertension		
	Absent	Slight to Moderate	Advanced	Absent	Slight to Moderate	Advanced
Per cent	75	32	60	44	34	22
Age, yrs	61	61	63	43	57	57
Duration of diabetes, yrs	3	7	11	4	6	8

Note "Advanced" means marked obliteration of lumen and includes cases with old and recent gross infarction.

TABLE II
Coronary Sclerosis in 170 Non-Diabetics

Cases	Absent	Slight to Moderate	Advanced
Per cent	37	50	13
Age, yrs	58	64	66

were unselected except that no cases under 40 years of age were included, whereas in the diabetic group some 18 cases died under the age of 40 years. This difference would have the effect of handicapping the diabetic group since the older non-diabetic group would have more ordinary arteriosclerosis consistent with age. Without quoting in detail any percentages, a striking

excess of advanced arteriosclerotic lesions occurred in the diabetics. Thus, advanced coronary sclerosis with occlusion occurred in 40 per cent of the diabetics and in only 13 per cent of the non-diabetics, in spite of the fact that the diabetics averaged six years younger than the non-diabetics. Our first problem, then, was to determine whether this excessive arteriosclerosis was present when the diabetes began or whether it could be shown to have probably occurred after the onset of diabetes.

For this purpose we selected only those cases of diabetes with duration of one year or less on the assumption that diabetes of such short duration could not have produced much change in the arterial system. There were 23 such cases and in table 3 are shown the average figures. It will be seen

TABLE III
Aortic Atherosclerosis in 23 Diabetics and 170 Non-Diabetics at Autopsy

Grade of Sclerosis	Diabetes Less Than One Year in Duration		Non-Diabetics	
	Number	Per Cent	Number	Per Cent
Slight	14	61	94	55
Moderate and Advanced	9	39	76	45

that in the 23 cases, although their average age was not materially different from that of the non-diabetics, the frequency of severe arteriosclerosis in the aorta was somewhat less than in the non-diabetics. Similar results were obtained when the coronary vessels were compared. If now, cases with diabetes of long duration are examined, the contrast is striking.

Duration of Diabetes In 46 cases the duration of diabetes exceeded 10 years, the youngest case at death being 43 years of age with diabetes of 15 1/2 years' duration. The oldest case was 83 years with diabetes for 33 years. In 32 of the 46 cases hypertension had been present. Twenty-five of these 30 cases died as a result of coronary occlusion. Thus, in this group with diabetes of long duration coronary disease as the cause of death was just four times as frequent in the diabetics as in the non-diabetic control series.

Frequency of Hypertension The excessive frequency of hypertension in diabetic patients has been a matter of frequent comment. Bell and Clawson⁵ from necropsy statistics showed that 42.5 per cent of diabetics had hypertension, and they regarded hypertension as 2.7 times as frequent in diabetics as in non-diabetics. Majoi⁶ also regarded hypertension as more frequent in diabetes. Unfortunately it is difficult to state the relative period of onset of hypertension and diabetes in most series of cases with accuracy. In this series where accurate data were possible, it is true that diabetes preceded hypertension in the majority of cases. Recently in a review of 482 cases under observation for 10 years the blood pressure rose from normal to a level above 150 mm. mercury in 16 per cent of the cases, and in 50 per cent rose over 10 mm. of mercury.

Localization and Type of Vascular Change Aortic atherosclerosis was excessive in the diabetics in this series, in contrast with the 170 controls and in contrast with the aortic lesions in 5060 consecutive post mortems reported by Willius et al.⁷ Absence of atherosclerosis of the aorta occurred in only 7 of the 175 diabetics, and their average age was 26 years and the duration of their diabetes only 0.9 year. The difference in degree of severity is indicated by the frequency of Grade IV lesions. In Willius' series 49 such cases occurred in the 3473 over 40 years of age, or 1.4 per cent. Among our diabetics Grade IV lesions, that is with calcification and ulceration, occurred in 37 cases or 21 per cent, an incidence 15 times as great. Advanced lesions in the diabetics occurred eight times as frequently in the hypertensive as in the non-hypertensive diabetics.

Chemical differences in the aortae of diabetics and non-diabetics studied at the Deaconess Hospital were found by Lehnheir.⁸ The cholesterol content was 8.07 grams per cent in the diabetics as compared with 4.8 grams per cent in the non-diabetics. In the adult diabetic cases the average calcium content was 5.2 grams per cent as compared with 1.57 grams per cent for non-diabetics. There seemed to be a definitely increasing percentage of fatty acids with increasing atherosclerosis, although certain cases presented exceptions. The source of the lipids which appeared in the aortae is not revealed. Whether they come from the blood stream or are formed from chemical disintegration of substances in the wall of the vessels remains unproved.

Heart Disease Coronary sclerosis with the changes secondary to occlusion, either acute or chronic, was the characteristic finding in the diabetics. In the first table these findings are summarized as follows:

Coronary sclerosis was absent only in those cases where the average duration of diabetes was three years. Advanced coronary sclerosis, including only cases with occlusion of the coronary arteries, occurred in 60 per cent of 93 cases with hypertension and 22 per cent of 82 cases without hypertension, in contrast to only 13 per cent of the non-diabetic patients. The effect of duration of diabetes comes out clearly here because advanced coronary disease was twice as frequent in the diabetics as in the non-diabetics. The exceeding frequency of coronary disease in the hypertensive cases is in part related to the greater duration of diabetes and to their greater age. The striking feature of the diabetic heart is the lack of great hypertrophy except in those cases with preexisting hypertension. This failure of hypertrophy may be due to the type of pathologic change found at autopsy, and is in marked contrast to the heart of myocardial insufficiency cases associated with essential hypertension, it suggests further that the hypertension may have followed the arteriosclerotic process, accounting thus for the limitation of any constant or marked hypertrophy.

Retinal Arteriosclerosis During the present year two important reports on the eyes of diabetics have appeared, the one from the Mayo Clinic, Wagener, Dry and Wilder,⁹ and the other reporting the examinations of

2000 diabetic patients at the Deaconess Hospital by Waite and Beetham¹⁰ Both papers come to one conclusion which completely reverses the previous conceptions of retinal arteriosclerosis and its relationship to the retinal disease seen in diabetes Waite and Beetham at the Deaconess Hospital found that retinal arteriosclerosis is no more common among the diabetics than among a control series which they examined with equal care The striking difference is in the frequency of retinal hemorrhages which increase steadily with the duration of diabetes and were unrelated to blood pressure or to retinal arteriosclerosis Interestingly enough the same conclusion was arrived at independently by Wagener and Wilder who reversed their formerly expressed opinion upon this important subject It, therefore, appears clear that these two papers bring out a fundamental point of divergence Retinal hemorrhages are the characteristic feature of diabetes and are due to some specific metabolic effect exerted upon the capillaries As a result extravasations of blood occur These may be absorbed or may be organized The waxy exudates seen may be due to hyaline degeneration of these hemorrhages At any rate there is a great tendency in diabetes for fibrosis to occur with organization of the hemorrhages leading to retinitis proliferans Edema of the discs and the changes characteristic of typical malignant hypertension were not observed in any of the diabetics at the Deaconess Hospital

Peripheral Gangrene Gangrene of an extremity had occurred in 48 of the 175 autopsies In this group 32 patients had had hypertension in contrast to 16 with normal blood pressure The striking feature, however, of the arteries in the leg is the similarity in pathologic findings in both the hypertensive and non-hypertensive cases Diabetic gangrene is characteristically moist where senile gangrene is dry, owing to the fact that the changes produced by diabetes are primarily intimal and progressively occlusive in type So-called Monckeberg's sclerosis is a common type of sclerosis in the muscular arteries of the legs present in a considerable percentage of individuals after 50 years Therefore it is to be expected that the diabetic legs at pathologic examination will show medial sclerosis, but the striking difference between the diabetic and the non-diabetic is not in the media but in the degree of intimal change Here the marked localized proliferation of the intima with deposition of fatty material including cholesterol crystals is striking This process goes on slowly with gradual encroachment upon the lumen, until trauma with infection, producing swelling and closure of the small arterioles or spontaneous thrombosis, leads to gangrene In the small arterioles, obliterative endarteritis with hyaline thickening of the intima and obliteration of the lumen is the rule Hypertension seems to serve as an additional burden accentuating the process The important point is that the muscular type of arteries shows the changes produced by diabetes most characteristically

Nephrosclerosis An attempt was made to classify the degree of arteriosclerosis present in the various types of vessels in the kidneys in relation to

hypertension It appeared that slight degrees of sclerosis were almost constantly found in the larger vessels and arterioles in the non-hypertensive group. The more advanced sclerotic changes in the larger vessels and in the arterioles, however, were more frequent in the hypertensive group. Hyalinization of the glomeruli was found about 1.5 times as frequently in the hypertensive as in the non-hypertensive group. Fibrosis of the glomeruli was reported almost three times as frequently in the hypertensive as in the non-hypertensive group. Intimal changes as noted elsewhere were most frequently found in the larger vessels. Cases classified as moderate to marked renal arteriosclerosis exhibited advanced vascular lesions elsewhere including coronary thrombosis, peripheral gangrene, cerebral thrombosis and hemorrhage, and all but one case showed marked to extreme aortic atherosclerosis with calcification. No case in our series died primarily of uremia, despite occasionally advanced degrees of nephrosclerosis. Renal insufficiency, when it occurred, was secondary to cardiac failure.

Pancreas and Spleen The vessels of the pancreatic-splenic circuit revealed less constant and less easily interpreted findings. The control series studied by Warren³ showed as high an incidence of pancreatic arteriosclerosis as the diabetics. Since then 83 cases have been added to the autopsy series at the Deaconess Hospital and in only 9.5 per cent of these was any serious pancreatic arteriosclerosis recorded. Hyalinization of the islands of Langerhans occurred independently of arteriosclerosis and was associated with the relatively mild type of diabetes. The frequency with which arteriolar sclerosis of the pancreatic vessels is observed in essential or malignant hypertension would lead one to expect a relatively high incidence of diabetes in these cases. This is not substantiated by autopsy reports of hypertensive cases. Bell and Clawson⁴ state that only 5.5 per cent of the hypertensive cases over 50 years of age have diabetes. Murphy¹¹ in his series of autopsies of cases of hypertension found arteriosclerosis in the pancreas to parallel uniformly that in the kidneys. In a personal communication Murphy states that only 14 out of 352 cases had diabetes. This, in view of the age of the patients, he considered a low incidence. No good evidence exists for believing that arteriosclerosis of the pancreas plays any considerable part in the causation of diabetes.

In the spleen arteriosclerosis was present in 32 per cent of the hypertensive cases and in 26 per cent of the non-hypertensive cases. Arteriolo-sclerosis was present in 31 per cent in the hypertensive group and 31 per cent in the non-hypertensive group. The somewhat greater frequency of this condition in the splenic vessels in hypertension was not marked. Conclusions drawn from the occurrence of vascular sclerosis of splenic vessels are of doubtful value.

Discussion Although our chief purpose is to present facts regarding the arteriosclerotic lesions in diabetes, contrasting the hypertensive and non-hypertensive cases, some discussion of their theoretical bearings may be permitted. First is the excess of arteriosclerosis in the coronaries, aorta and

legs in these diabetics as compared with control series of non-diabetics. Second is the fact that among 175 diabetics followed to death hypertension occurred in 54 per cent. Third is the occurrence of all the characteristic vascular lesions of diabetes (retinal hemorrhages, coronary occlusion, gangrene) in diabetics without hypertension as well as in cases with hypertension. The existence of hypertension cannot be considered a *sine qua non* of these complications. Fourth, the incidence of these vascular complications was greater in the hypertensive group, as if hypertension acted as an additional factor increasing greatly the tendency to such lesions. This conclusion must be qualified by consideration of the greater average age of the hypertensive group. The common observation in a diabetic clinic of hypertension developing as time goes by in cases previously non-hypertensive is not to be dismissed too readily as due merely to the natural incidence with increasing age. Fifth, the association of large vessel arteriosclerosis constantly whenever arteriosclerosis was present suggested that changes in the large arteries occurred first.

In considering the etiology of arterial hypertension it has become customary to divide the possible agents under five heads: (1) circulating substances, including hormones, (2) the influence of the nervous system, (3) the structural changes in the vascular system, (4) infections and allergy, (5) constitutional factors. For careful reviews the articles of Meakins, Durig and Weiss may best be consulted. The rôle of the nervous system in the regulation of blood pressure is outstanding. The sympathetic vasomotor system with its constrictive influence is counterbalanced by the activity of the parasympathetic vasomotor nervous system particularly through depressive reflexes. An increase in the pressor mechanism or hypoactivity of the depressor reflexes has been offered as a cause. There is no clear evidence in our cases of unusual psychic or nervous make-up on which to base the theory that hypertension occurred first and vascular disease followed. Similarly the rôles of infections and allergy lack support. It is true that in diabetes, infections of the kidneys are common and that hypertension may follow such infections. Somewhat more reasonable is the theory that the spotty lesions of arteriosclerosis represent the results of low-grade and repeated bacterial invasion or degeneration due to bacterial toxins. However, no one holds the larger arteries responsible for hypertension. One would have to assume that the infections cause a different reaction in the smaller arterioles.

The rôle of inherited constitution has been emphasized in relation to hypertension. Although nervous and psychic factors, vascular changes of senescence, infections and toxins contribute, they seem to be most effective in certain individuals who may have inherited certain anatomical and functional characteristics of the nervous and vascular systems. O'Hare, Walker and Vickers¹² obtained a history of vascular disease in 68 per cent of a group of patients with arterial hypertension. Weitz¹³ concluded that hypertension is inherited as a dominant characteristic. On the negative side Benedict and Root¹⁴ studied a man 92 years of age who showed little evi-

dence of arteriosclerosis and a normal blood pressure. His family history contained no deaths from vascular disease before the age of 75 years. That the predisposition to diabetes is inherited as a Mendelian recessive characteristic has received support from the studies of Pincus and White¹⁵. Possibly a tendency to vascular disease is also inherited in the diabetic, but it is significant that excessive arteriosclerosis only occurred after the onset of diabetes in our series.

The influence of circulating metabolites in the blood and anatomic changes in the vessels themselves can hardly be separated. So far as arterial hypertension is concerned, the rôles of glucose, salt, guanidine, the potassium-calcium ratio and of peptones in the blood are still not clearly defined. The effects of circulating hormones from the pituitary and adrenals, while definite, do not seem to explain more than a small portion of the cases. Other substances, such as cholin and cholin compound, histamine and pancreatic extracts, such as "padutin," have temporary effects upon blood pressure. The one substance found both in the blood and in the blood vessel walls with which, experimentally, typical atherosclerotic lesions can be produced is cholesterol. It is sometimes found in increased amounts in cases of hypertension. Duig points out that it is not the height of the cholesterol in the blood, but the degree of saturation which is important. In hypertension the serum is often over saturated with cholesterol even though concentration in milligrams per 100 c.c. is normal. Thus it is the relation between the cholesterol and the colloids of the serum together with the affinity of the cells of the arterial wall for cholesterol which determines the deposition.

Alvarez and Neuschlosz¹⁶ believe that the arterial wall with marked absorption of cholesterol has a higher contractibility and the muscles of the arterial wall are thus sensitized to adrenalin. However, medial hypertrophy, such as would be expected with continued adrenalin stimulation, was not found in this series. The structural change in the walls of both arteries and arterioles in our diabetics is the outstanding feature. The changes in the younger cases, with relatively shorter duration of diabetes, are found in the aorta and larger arteries. Hypertension develops with increased resistance of the arteriolar bed caused by a narrowed arteriolar system. Arteriolar disease never occurred without advanced changes in the larger vessels as well. That increased arteriolar resistance is due to cellular and structural change rather than to spasm from nervous origin seems most reasonable.

Leary¹⁷ has compared experimental atherosclerosis in rabbits with human coronary atherosclerosis. He points out that atherosclerosis forms 90 per cent of the important arteriosclerosis in human beings and that the coronary arteries, because they are of relatively simple structure, muscular in type and poor in elastica, afford the best field for observation of the process. The coronary arteries possess a buffer layer of muscle and cellular subendothelial fibrous tissue which differ from other muscular arteries. It is without a circulation of its own and depends upon imbibition. These arteries, be-

cause of their anatomical relationship, are subject to great strain, meeting high pressure from the blood-filled aorta and resistance from their compressed intramural branches which are closed during the muscular systole of the heart. Relatively they might be compared with the muscular arteries of the legs of diabetic patients which have been subjected to unusual strain because of the almost universal obesity of most diabetic patients. Leary finds that the characteristic lesion induced with atherosclerosis of coronary vessels is fibrosis associated with the presence of lipid cells. In older age periods there are large accumulations of lipid cells with very little accompanying connective tissue. As a result of poor nutrition massive necrosis occurs causing the so-called "abscesses." In the young adults, therefore, the standard cause of death is thrombosis following subendothelial necrosis. On the other hand, in the older group a rupture of the abscess occurs in the lumen of the artery followed by thrombosis. The process is primary in the intima. Lesions in the elastica and media occur secondarily.

Leary was able to reproduce the lesions accurately by the feeding of cholesterol to rabbits, and he points out that such lesions do not occur spontaneously in rabbits. The lesions produced varied in different animals in their extent and severity. This variation was comparable to the differences exhibited by human beings. In fact, he could produce all the stages of human atherosclerosis in the coronary arteries in the rabbit. He points out that eggs and milk, the most common sources of cholesterol, are really intended as foods for the infant or embryo. Man is the only animal that eats both eggs and milk throughout his lifetime and is the only animal that dies in early life from coronary sclerosis. He emphasizes the analogy with diabetes. Sugar is soluble and combustible, whereas cholesterol is not combustible, is difficult to excrete and tends to be stored. Various idiosyncrasies to cholesterol exist. An inherited poor metabolism of cholesterol is associated with an early death from coronary sclerosis. In diabetes with advancing age there develops an inefficiency of the cholesterol metabolism and more advanced arterial disease.

Our own view is that the premature and excessive development of vascular disease occurs predominantly in muscular arteries under the greatest physical strain, especially in obese patients, and is due to the metabolic changes of diabetes. The coronary and leg arteries are chiefly involved although changes in the arterioles are also found. The necessity of insulin in the glycogen metabolism of muscle and especially for the completion of the lactic acid cycle must be of some significance in this connection although the details are as yet undemonstrated. The importance of the disordered lipid metabolism, more easily demonstrated by present chemical and pathologic methods, is better understood. Hypertension then is an important contributing factor in the clinical course of the disease because it imposes additional strain, even when the patient has lost his obesity, and accentuates greatly the vascular changes in coronary and leg arteries. A further suggestion as to the metabolic factor in the arteriosclerosis of diabetes is the

fact that with modern treatment with insulin and diet more normally balanced, the frequency of arteriosclerosis in the legs of diabetic children is diminishing. The objective in the future should be the earlier possible diagnosis of diabetes and its more aggressive treatment. The final explanation will take full cognizance of the interrelationship of the endocrine glands, of the parts played by preexistent obesity, by infections, especially of the kidneys, and by inheritance.

Physiology of articular structures	

* This report constitutes the second " Rheumatism Review " prepared at the request of the American Committee for the Control of Rheumatism. The editorial comments express the opinion not of the American Committee but of the authors, a subcommittee, of which Dr. Hench is chairman. The first review covered the American and English literature on rheumatic diseases for 1932 and 1933, and appeared in the ANNALS OF INTERNAL MEDICINE last year.

IN THE last century the patient who had articular disease presented no very complicated problem to his physician. The patient's whole body was probably not examined, his joints may or may not have been. But the diagnosis was easy. His story told the tale—he simply had “rheumatism.” The treatment was equally simple—salicylates.¹ The current equivalent of salicylates was likewise probably prescribed to the man of the Old Stone Age whose arthritic fossil is now a museum piece, or to the patient who had arthritis deformans and whose case is described in a medical papyrus written in Thebes about 1550 B C.²

The problem of “rheumatism” began to be complicated only when it became the subject of the intensive researches of the past few decades. The complexity of the situation is, unfortunately, not simplified by the international appearance, at too frequent intervals, of new classifications for rheumatic diseases—classifications too often the “arbeit” of one who feels that only thereby can he attain recognition as a specialist for rheumatism. Through the multiplicity of suggested nomenclatures and the profusion of publications on all phases of the problem, however, definite progress is discernible. By continued international study and cooperation the complicated problem will eventually regain, indeed is now regaining, a certain simplicity of a more enlightened type. As van Breeman, Secretary of the Ligue Internationale Contre le Rhumatisme, expressed it, the problem of rheumatism is a diamond with many facets. He who views it through only one facet will gain a totally different impression of its nature than will he who regards it exclusively from another angle. But he who will view it through many facets, and see it whole, will find the complicated becoming simple again. For after all, in the last analysis the diamond has the simple formula of carbon.

GENERAL INCIDENCE AND OCCUPATIONAL DISTRIBUTION

The incidence of rheumatic diseases is apparently increasing. This is in part attributable to the fact that more individuals are living to the ages when chronic rheumatism is most prevalent. The survey by Bigelow and Lombard revealed that in the State of Massachusetts, of the total population more than 40 years of age one person in every 10 had “rheumatism.” Eighty-three per cent of all patients who had chronic rheumatism, using the term in its broad sense, were between the ages of 40 and 80 years. After the age of 40 years the disease increased with each decade, so that of persons between 70 and 80 years of age, one out of every four was notably afflicted thereby.²

[These statistics pertain to those who actually complain of the disease. The roentgenographic and pathologic studies of others (Garvin, 1927, Keefer and Myers, 1933, Bauer and Bennett, 1933) revealed that actually from 90 to 100 per cent of all persons more than 45 years of age have some type of articular disease, chiefly of the degenerative (senescent, hypertrophic, osteo-arthritic) type which, however, according to Keefer and Myers is symptomatic in only about 7 per cent of cases.—Ed.]

In the State of Connecticut (population 1,655,000) about 50,000 people have chronic rheumatism, of whom about 2,000 are probably completely disabled thereby, confined to bed or chair, needing the constant care of others. So Lombard² has estimated, if the percentage incidence in Connecticut is equal to that in Massachusetts. The disease is 12 times as prevalent as cancer but only one-fortieth as fatal. Were death the end result, everyone would fear it more. Regardless of its relatively low mortality it must be taken seriously. Any disease which carries a 10 per cent morbidity among persons who have passed the age of 40 years warrants the greatest attention.

Invalidism from rheumatic diseases is increasing in Sweden also. Edstrom³ studied its incidence among 3,500 communal workers of Gothenburg between the years of 1928 and 1932. Rheumatism accounted for about 12 per cent of all disability from sickness in this group. Comparing figures for 1932 with those for 1922, it appears that the amount of invalidism has about doubled in 10 years.

Why is it that one person falls a victim to rheumatism while another escapes? To some extent the answer may be found in studies on its incidence in certain occupations. Edstrom found rheumatic disorders much more frequently among outdoor workers (policemen and workers on trains and roads and in harbors and shipyards) than among those working indoors, as in factories.

[These statistics approximate those of Danischevsky, of Kahlmeter, and of Templaar and van Breeman⁴—Ed.]

Of three major factors—infection, constitution, and external conditions—which determine the course in a case of chronic rheumatism, Edstrom expressed the belief that the components of the latter factor (housing and working conditions, climate, environment) are most important. Were an acutely affected person able from the onset of his illness to be placed under good hygienic circumstances, the disease might often be prevented from becoming chronic. Poor housing conditions and exposure to the vicissitudes of weather may be more important etiologic factors than infection, and more worthy of correction.

Rheumatism is more prevalent in rural than in urban communities, according to the Massachusetts survey². Among persons whose economic status was poor the incidence was nearly twice as high as that among the well-to-do. More of those living in damp houses, than others, had the disease. It is probable that the relationship between poverty and rheumatism is attributable to environmental influences. The poor are unable to have as good a diet as the wealthy. They cannot afford good dentistry or early eradication of foci of infection. They are less protected from fatigue and malnutrition, from endocrine deficiency and from faulty digestion and excretion, chief predisposing causes of the disease. In Massachusetts four-fifths of the poor and about half of the well-to-do patients were not under the care of physicians.

The Factor of Predisposition To some, data of the type just noted seem devoid of real value. Thus, Climie⁵ has expressed the opinion that the masses of statistics relating to climate, housing, geographic soil, nourishment of the patient, and so forth, do not lead anywhere. The patient himself is lost sight of, a study of his internal milieu is more important than one of his external environment. What of the patient's own soil? Is there, in truth, a rheumatic diathesis, a fundamental inherent peculiarity of the person who will have rheumatism "which, granted the right coincidence of circumstances, evidences itself by that individual suffering an attack of rheumatism, the degree of illness or extent of body tissue involved depending (only) partly on the activating agent and partly on the state of preparedness of the individual, or in other words, upon his mental and physical condition at the time of the attack?" Adamson⁶ agreed that study of the soil of the person who will have rheumatism or of the victim is an inquiry long overdue. "Much stress has been laid on the nature of the rheumatic attack, perhaps not enough on the resistance of the individual and his tissues. Let us (hereafter) regard the state of the infected tissues even more than the nature of the infective agent."

[Although studies on the patient's soil are being properly demanded with increasing frequency, investigators are slow to accept the challenge. Studies on the physiology of normal joints and on the immunologic and physicochemical status of normal persons, as well as those of rheumatic and "pre-rheumatic" individuals, are meager. To a large extent they await advances in knowledge of general immunity and development of new methods for demonstration of alterations therein. The few current reports on the chemistry and cytology of blood and tissues which are available are reviewed later in this article—Ed.]

CLASSIFICATION OF DISEASES OF JOINTS AND RELATED STRUCTURES

Discussions of the various rheumatic diseases—those of joints and related structures—are arranged as in last year's review.⁴ The scheme of classification is repeated: (1) those attributable to trauma, (2) those attributable to infections of known type, (3) those possibly, or probably, attributable to infection or related toxins, for example, rheumatic fever, atrophic (infectious, proliferative, rheumatoid) arthritis, (4) those of which the chief characteristic is degenerative change in tissue, for example, hypertrophic (senescent, degenerative, osteo-) arthritis, (5) those of which the chief, or only obvious characteristic is some recognizable, or suspected, chemical derangement—a none too well defined group which includes forms of arthritis commonly called "chemical," "metabolic," "allergic," "endocrine," and (6) a miscellaneous group of unclassifiable types. Fuller details and criticism of such a classification will not be repeated. The reader is referred to the first review.⁴

DISEASES OF JOINTS RELATED TO TRAUMA

Etiologic and Clinical Considerations Traumatic arthritis may result from acute (exogenous, extrinsic) trauma, such as that from falls, blows,

accidents, or from chronic trauma incident to the abnormal use of joints in connection with occupation, recreation, obesity or poor posture. In the former variety symptoms arise, as a rule, rather suddenly. In the latter type, in which endogenous or intrinsic trauma is operating, symptoms may develop so slowly that their connection with chronic trauma may be overlooked. O'Connor's⁷ experience is that of others, that in such cases articular lesions may be well advanced without symptoms being noted until some unusual strain is superimposed on changes already present.

An acute injury to any articular component may be followed by minor symptoms and complete healing or by the production of traumatic arthritis with chronic disability. In two cases observed by Key,⁸ contusions of articular cartilage led first to acute, then to chronic, monarticular, progressive arthritis unrelieved by conservative treatment. Because of continued pain and stiffness Key explored the knees. In each case a single, small, irregularly rounded mass of fibrillating, degenerating, necrotic cartilage was found. Synovial proliferation and villus formation were present, also several small, compact collections of round cells.

[These collections, seen in Key's photographs, seem to resemble those which Allison and Ghormley, 1931, considered specific for atrophic arthritis. Recently Fisher (1935) expressed the opinion that the lymphocytic collections of Allison and Ghormley were similar to those found by him (1929) in a minority of cases of atrophic arthritis. It should be noted that Fisher now speaks of those he described as perivascular. Those noted by Allison and Ghormley were not perivascular. Recent unpublished studies of Ghormley and Deacon strengthen their opinion of the specificity of non-perivascular round-cell collections for atrophic arthritis.—Ed.]

There are, according to Jepson,⁹ four classes of traumatic backache: (1) when trauma affects a patient who already has arthritis of spine or pelvis, (2) when trauma affects only soft parts of the back, such as muscles, tendons, and ligaments, (3) when patients, because of faulty posture, have a predisposition to injury, and (4) when patients are affected by occupational strain. In Jepson's 50 cases of traumatic backache, injuries to the lumbar portion of the spinal column were most common, to the cervical portion, less frequent, and to the thoracic portion, which is the least flexible and least liable to injury, infrequent. Jepson reviewed the technic and significance of various tests used to localize injury or disease of the spinal column or pelvis and to distinguish between real and fictitious pain. Smith-Petersen's and Gaenslen's procedures, the Laquer sign, Yergason's chair test, and forcible compression of the sacro-iliac joints.

Laboratory Data. Roentgenograms in traumatic arthritis may be negative or may reveal a variety of alterations: capsular distention from synovial exudate in early cases, destructive and proliferative changes in cases wherein acute trauma is followed by chronic progressive arthritis.^{9,10}

The cell count of normal synovial fluid is as follows: total number of cells per cubic millimeter, ± 50 , polymorphonuclears ± 5 per cent, mesothelial cells ± 3 per cent, monocytes ± 58 per cent, clasmotocytes ± 30

per cent Forkner (1930) was not sure whether lymphocytes are present or not In two cases of traumatic arthritis the cytology of synovial fluid was found by Keefer, Myers and Holmes¹¹ to be as follows total cell count per cubic millimeter, 4,800 and 3,550, polymorphonuclears 94 per cent and 10 per cent, lymphocytes 3 per cent and 2 per cent, monocytes 0 and 42 per cent, clasmotocytes 3 per cent and 46 per cent

[Counts on these two cases are noted because so few have been made in cases of traumatic arthritis—Ed]

Treatment Conservative treatment consists of rest, supports or bandages, physiotherapy and graded exercises A high percentage of Jepson's⁹ patients who had traumatic backache recovered under his program which is outlined in detail When conservative treatment fails, as occasionally it does, a fusion operation may be indicated

Slight posttraumatic effusion in knee joints may be disregarded When significant, the effusion may be reduced by application of compression bandages in conjunction with physiotherapy When distention from fluid occurs recurrently, as a late sequel to injury of a knee, Glissan¹² reported that adhesions or weakened control by quadriceps muscles generally were found

When arthritis follows contusion of articular cartilage, Key expressed himself in favor of excision of the degenerating cartilage At first he hesitated to do this because his experimental resection of rabbits' cartilage generally had resulted in progressive arthritis However, similar experiments by him on dogs and cats, and by Bauer and Bennett (1933) on rabbits, were not attended by arthritis unless postoperative patellar displacement occurred Therefore, in his two cases, Key excised the injured cartilage and part of the affected synovia The knees became asymptomatic⁸

GONORRHEAL ARTHRITIS

In some cases articular complications of gonorrhea subside rapidly and completely in the course of treatment for the local infection, with or without special therapy for the joints In many others the articular disease becomes progressive, producing marked destruction and limited motion The varieties of articular involvement are of the acute type, (1) arthralgia, (2) acute synovitis, (3) acute non-purulent arthritis (serofibrinous exudate) and (4) acute purulent arthritis, of the chronic type, (1) synovitis (2) arthritis Additional forms of "gonorrheal rheumatism" are tendinitis, myositis, and keratoderma blenorrhagica (with arthritis) The patient's resistance, the virulence of the particular bacterial strain infecting him and the type of treatment used, determine the type of articular disease and the prognosis of the latter Several interesting studies on various phases of gonorrheal arthritis are current

Clinical Data Of 69 cases of gonorrheal arthritis studied by Keefer

and Myers¹³ 58 of the patients were males and 11, females. Their ages varied from 18 to 70 years. The time between the onset of the primary gonorrheal infection and the arthritis could not always be determined because of the presence, in some cases, of old infections of the genito-urinary tract of indeterminate duration, reinfections, or the appearance of exacerbations in the genital tract. Joints became involved generally within 10 to 21 days after the initial infection, in three cases, within two to six months thereafter, and in one, simultaneously with the initial infection. In three cases evidence of local gonorrhea had disappeared. It is again pointed out that polyarticular invasion (present in 60 cases, or 87 per cent) is more common than monarticular involvement (present in nine cases, or 13 per cent). Any or many joints may be attacked, but knees, ankles, and wrists were most frequently involved, hands, shoulders, and feet, less often. Heels were affected in only seven cases, a sternoclavicular or a costosternal joint, in two cases.

[A chill is often an early symptom. An acute migratory polyarthritis or polyarthralgia which recedes in favor of an acute and more stubborn monoarthritis is a feature of many cases, and one of considerable diagnostic significance.—Ed.]

Tenosynovitis often accompanied involvement of ankles or wrists. In 33 cases it was the feature which dominated the clinical picture. Tendon sheaths most frequently affected were those about the internal and external malleoli, and those over the dorsum of hands and feet, less frequently those about knees, palms, or heels were affected.

When periarticular redness, pain and thickness were marked, extensive effusions appeared and aspirations of joints yielded 40 to 165 c c of fluid. Periarticular muscular atrophy, sometimes marked, was present in all cases. Genital infections present were prostatitis in 54 cases, urethritis in 43, cervicitis in 10, epididymitis in five, and seminal vesiculitis in one. Abscess of Cowper's glands, of Bartholin's glands, and of Skene's glands each occurred once.

Temperatures of 99 to 103° F were generally present. Salicylates gave insignificant relief, a point of value in distinguishing this disease from acute rheumatic fever. The leukocyte count varied between 9,000 and 23,000 per cubic millimeter of blood, the percentage of polymorphonuclears, between 70 and 88. Sedimentation of erythrocytes was rapid in all cases, varying from 0.4 to 1.7 mm per minute (method of Erstene and O'Rourke).

Complications. In Keefer and Myers' ¹³ series, in 16 cases (23 per cent) catarrhal conjunctivitis developed, generally before, occasionally with, the arthritis. Three patients had iridocyclitis and conjunctivitis, one had endocarditis, and two had perichondritis of the cricoid cartilage, causing painful swallowing. The association with acute polyarthritis of some of these complications, especially the combination of tenosynovitis and perichondritis, may be helpful in suggesting the gonococcal nature of a case of arthritis.

Arterial thrombosis in association with gonorrhea is rare (Welch 1909) Mead and Stewart¹⁴ reported the case of a patient with acute gonorrheal polyarthrititis and salpingitis. After she was given 8 c.c. of milk intramuscularly, a general reaction culminated in peripheral arterial thrombosis necessitating amputation of three gangrenous toes. Mead and Stewart found no previous record of arterial thrombosis after injections of milk and concluded that the gonorrheal arthritic infection may have induced the thrombus.

[Five cases of acute thrombosis, involving the iliac, popliteal, or femoral arteries, after typhoid vaccine had been given intravenously are noted by Hensch (1932) in his list of unusual reactions to such treatment. In two cases amputation was necessary. Several untoward reactions to milk were also listed, not thrombosis, however. It seems likely that the thrombosis in the case of Mead and Stewart may have been an unusual reaction to the foreign protein of milk and may have had nothing to do with gonorrhea.—Ed.]

Pathology The classification of articular complications, as noted heretofore, indicates the variety of pathologic reactions which may occur. From the observations of Keefer, Parker and Myers¹⁵ on the different pathologic reactions, it would appear that the prognosis in a given case of gonorrheal arthritis depends on how severely the surface cells of the synovia are involved. The pathologic reactions in knee joints were studied in two cases that came to necropsy. In one case the synovial membrane was essentially normal, but the subsynovial connective tissue was markedly congested, edematous, and infiltrated with a marked cellular reaction. Thus the patient presented a subsynovitis with involvement of subsynovial tissues, rather than a synovitis involving superficial synovial cell layers. Gonococci were not recovered from synovial fluid. In the second case the subsynovial connective tissues were not extensively involved, but the more superficial layer of synovia was markedly affected and largely destroyed. Numerous gonococci were found in synovial membrane and fluid.

From these comparative studies Keefer, Parker and Myers concluded that the less the superficial synovial cells are involved and the more the inflammatory reaction is confined to subsynovial or the more frankly extra-articular (periarticular) tissues, the better is the prognosis as far as preservation or restitution of function of a joint is concerned, and the less the chance of isolating gonococci from synovial fluid or tissues. When "infected exudates" are present the more serious types of gonorrheal articular disease are probably present.

Significance of Laboratory Data Although certain features of the clinical picture, in conjunction with an honest history, are sufficient for a presumptive diagnosis of gonorrheal arthritis, conclusive evidence should always be sought by laboratory investigations. Conclusions on the value of such data, particularly smears from the genito-urinary tract, have been summarized in the first report of the Neisserian Medical Society of Massachusetts.¹⁶

The Society's report included a discussion on organisms resembling gonococci, criteria necessary for a diagnosis of presumptive, as well as of proved, gonorrhea in males, females and infants, the significance of extracellular, as compared to intracellular, gram-negative organisms, and the likelihood of obtaining "negative smears" in certain cases of gonorrhea. The report is recommended to those of limited experience in this field, particularly to those faced with a doubtful case of gonorrhea or gonorrheal arthritis.

Cultures of gonococci. It was the opinion of members of the society (February, 1934¹⁶) that, to date, culture of gonococci, as a routine laboratory procedure, is impracticable, and that there is no practical method for sending material to a central laboratory for culture.

[A new culture method for the identification of *Neisseria gonorrhoeae* has been recently elaborated by McLeod and his colleagues¹⁷. Its value has been confirmed by Leahy and Carpenter¹⁸ and the method has been simplified by Thompson¹⁹. Cultures are apparently simple to make and the results reliable, indeed some workers are finding them more reliable than the isolation and identification of gonococci in smears—Ed.]

Cultures of synovial fluid from 40 patients who had gonorrheal arthritis, and who were seen by Myers, Keefer and Holmes,²⁰ were positive for gonococci in only 25 per cent of the cases. Judging from pathologic studies noted in the foregoing,¹⁵ these workers believed that negative cultures or smears from synovial fluid in cases of gonorrheal arthritis result not from faulty technic but because infection is localized beneath and not on the synovial surface. As has been mentioned, when the inflammation is essentially subsynovial, and when the superficial cells of synovia are not much affected, the cell-membrane on the surface is intact, organisms do not get into the synovial fluid, and if an exudate is present it is a non-infected one. Gonococci can be isolated with ease in smears or cultures of synovial fluid only when the synovial surface membrane is the site of an intense inflammatory reaction, in such cases organisms have advanced from peri-articular tissues into the cells of the synovial surface and thence into the synovial fluid, hence exudates are infected.

Complement fixation test. The complement fixation (Schwartz-McNeil) test for gonorrhea is in principle similar to the Wassermann test for syphilis. Members of the Neisserian Society expressed the belief that it is of limited value. It is usually negative in cases of acute gonorrhea, for sufficient changes have not had time to occur in the blood.

[It is rarely positive during the first 10 days of infection—Ed.]

It frequently remains positive for months or years after the disease is "cured" by clinical or other laboratory standards, and false positives and false negatives may occur. A positive test, however, may serve as evidence confirmatory of other data.

According to Keefer, Myers and Holmes^{11 20} however, the test is of distinct value. The test was positive on the blood serum in 80 per cent

(45 of 55 patients¹³) to 86 per cent (37 of 43 patients²¹) of their cases of gonorrheal arthritis "at some time during the course of the disease" In about 90 per cent of these cases the test was positive on the first examination It was negative in some cases in which genital infection had been present for no longer than two weeks The test was positive on synovial fluid in from 71 per cent (17 of 24 cases²¹) to 76 per cent¹¹ In the majority of cases tests on blood and synovial fluid were in agreement Occasionally the reaction was positive on blood serum, though not yet positive on synovial fluid When differences were noted, the blood serum, except in one case, gave a positive reaction before synovial fluid gave such a reaction Therefore, there is no advantage in testing synovial fluid rather than blood In three cases very early in the disease, gonococci were found in synovial fluid, but complement fixation tests on blood and synovial fluid were negative In three other cases it was possible to watch the tests change from negative to positive In cases in which both syphilis and gonorrhea were present a positive Wassermann reaction did not disturb complement fixation of gonococcal antigens

Tests were done on 71 controls 24 patients who had rheumatic fever, 30 who had atrophic arthritis, and 17 who had other articular diseases (tuberculous, hypertrophic or hemolytic streptococcic arthritis or Charcot's joints) A positive test was obtained from only two a 14 year old boy who had rheumatic fever, and a girl who had rheumatoid arthritis and psoriasis A doubtful test was obtained in a case of rheumatic fever accompanied by old, proved gonorrheal prostatitis

The investigators concluded that the routine use of the test on patients who have arthritis seems indicated and that a positive test is highly suggestive of the gonorrheal nature of an arthritis Tests should be repeated in all cases, especially when their results seem at variance with other data However, when the history and clinical findings suggest gonorrheal arthritis, but organisms cannot be isolated from synovial fluid or the genital tract, a positive test on blood or synovial fluid affords data of diagnostic worth

[These interesting studies need confirmation Such a test, if reliable, would be of much value The authors omitted certain desirable details They stated that a certain number of tests were positive "at some time in the course of the disease" More data should be given regarding the initial positivity of the test in relation to exposure to infection, and to the appearance of genital and articular disease Controls should include normal persons as well as patients who have various articular diseases—Ed]

Other tests on synovial fluid Cell count The total cell count on infected fluids varied between 7,350 and 158,000 per cubic millimeter, and on non-infected fluids from 1,800 to 78,250²⁰ Polymorphonuclear leukocytes formed 46 to 100 per cent of the cells Clasmatocytes and monocytes were commonly present, in a ratio of 1 to 16 per cent and 1 to 33 per cent respectively Lymphocytes varied from 1 to 33 per cent, rarely was the percent-

age more than 10 In infected fluids the percentage of polymorphonuclear cells was always more than 76 Non-infected fluids generally contained more monocytes and clasmotocytes than infected fluids ²⁰

Chemical determinations The concentrations of total protein, non-protein nitrogen, and sugar in blood and synovial fluid were determined,²⁰ but the data were not of diagnostic value Estimations of total protein were of significance only as they, with the cell counts, indicated the presence of an exudate, not of a transudate According to Forkner (1930), since bacteria utilize sugar in their metabolism, a low concentration of sugar in synovial fluid in a case of arthritis suggests bacterial arthritis, and the lower the concentration of sugar the greater the likelihood of positive cultures being obtained from joint-fluid Myers and his colleagues ²⁰ found that the concentration of sugar in synovial fluid depended on three factors—the concentration of sugar in the blood, the synovial leukocyte count, and the presence of microorganisms in the fluid—but that of the three factors the first two were more important than the third Inasmuch as a low concentration of sugar was found in non-infected synovial fluids, a reduced concentration of sugar did not always indicate the presence of organisms Thus, Forkner's generalization was upheld, but only in part

Treatment Fever therapy Accumulating evidence indicates that fever therapy is the treatment par excellence for gonorrheal arthritis and that in the majority of cases not only are articular lesions markedly and promptly benefited thereby but also gonorrheal lesions elsewhere in the body In 12 cases of acute gonorrheal arthritis treated by Simpson ²² with radiotherapy or with heated, air-conditioned cabinets, results were uniformly successful and all patients became free of symptoms Jones ²³ expressed the opinion that fever therapy is practically specific in such cases All of his 10 patients who had acute gonorrheal arthritis, of three to 12 weeks' duration, were "cured" Joints became symptom-free and urethral discharges generally ceased after two to five treatments Hedrick ²⁴ also noted marked improvement in one acute case "Striking results" were obtained by Kovacs ^{25, 26} even in cases of stubborn chronic gonorrheal arthritis Doses of fever generally preferred are five hours at 105 to 106.5° F Two to six sessions of fever are generally given, one about every four days ^{22, 27}

Fever therapy is a highly specialized form of treatment The Council on Physical Therapy of the American Medical Association ²⁸ has recommended that the technic of its administration be given as much study as a surgeon gives his specialty It should be administered only by a trained personnel under the supervision of a physician familiar with the reactions Under such circumstances fever therapy is an essentially safe procedure However, The Council's report lists 29 deaths among 4809 patients who had various diseases which were treated by hyperpyrexia (a mortality of 0.6 per cent)

[Many of the deaths undoubtedly were of patients who had neurosyphilis, and some deaths should be ascribed to the disease, not to the treatment—Ed]

Other measures Where fever therapy is not available, older methods must be invoked The usual forms of therapy for gonorrheal arthritis were listed by Hedrick,²⁴ and include administration of stock and autogenous vaccines, intramuscular injection of autogenous synovial fluid, foreign protein therapy, administration of convalescent serum, injection of the prostate gland and seminal vesicles with various chemical substances, intravenous injection of meicrochrome, deep roentgen therapy, aspiration, and irrigation or open drainage of joints In addition to certain of these measures, Hedrick expressed himself in favor of intravenous injections of ammonium iodoxy benzoate, twice a week, four to 10 injections in all, aspiration or irrigation of joints and insufflation with air, and in refractory cases, fever therapy

[The wave of enthusiasm for ammonium iodoxy benzoate and allied substances in cases of atrophic arthritis has about run out—Ed]

Aspiration of large effusions generally gives considerable relief of pain¹⁸ Particularly in cases of gonorrheal pyo-arthritis are aspiration and irrigation indicated²⁴ Irrigation with 1 to 5000 solution of mercuric chloride is a method for which Oxford²⁹ expressed favor Insufflation of air, as proposed by Porter and Rucker (1929) has the approval of some After aspiration, 75 to 100 c c of air³⁰ are injected, or enough to create a pressure of 40 mm of mercury²⁴ The air is absorbed in three to four days and insufflation can be repeated Presumably the air helps to prevent adhesions by keeping synovial folds apart It is suggested, also, that nitrogen mixed with the injected air may inhibit growth of gonococci Taylor³¹ approved injection through the rectal mucosa, into the prostate gland, of Pieg's iodine solution Excellent results not only for the genital infections but also for the arthritis have been claimed by him and by others

Prognosis and Results of Treatment In a given case, prognosis is difficult Some patients recover rapidly without permanent disability In many cases the disease results in progressive, chronic arthritis with restriction of motion or ankylosis Reinfection occasionally retards healing The poorest results seen by Myers, Keefer and Holmes²⁰ were in cases in which the cell count of the synovial fluid was more than 40,000 per cubic millimeter and the fluids were infected In such cases residual chronic arthritis often eventuated Those patients who recovered completely were as a rule those who had non-infected fluids, in which the leukocyte count was low, or infected fluids in which the leukocyte count was low Even so, the outlook for complete articular recovery was not good Only 37 per cent of the 69 patients recovered without signs of disease of joints

[These statements presumably refer to cases in which treatment was other than by fever therapy As we have noted, results therewith are very much better than with other forms of treatment, especially when the arthritis can be treated by fever therapy within the first two to four weeks of its onset—Ed]

TUBERCULOUS ARTHRITIS

The incidence of tuberculous arthritis is on the decline, partly because of certification of herds and pasteurization of milk. Tuberculous arthritis is always secondary to a tuberculous lesion elsewhere in the body. The infection is blood-borne to joints. Henderson^{32, 33} found that various joints were affected by tuberculous arthritis in the following order of frequency: spine, knee, hip, elbow, ankle, shoulder, wrist. Symptoms are stiffness, pain, local increase in temperature, swelling, deformity and, if the lower extremities are involved, limp. Children give "night cries," adults experience "night jerks," the latter are attributable to muscular relaxation, followed by sudden contraction in sleep. Tuberculous arthritis is persistently chronic although incomplete remissions occur. When it afflicts adults it is generally monarticular, although it may be polyarticular, it is more often polyarticular when it affects children than when it affects adults.

Of 274 proved cases of tuberculous arthritis of a knee seen by Henderson, in two-thirds the patients were males. Trauma was an inciting or precipitating factor in 13 per cent. Only 8 per cent of patients gave family histories of tuberculosis. In 44 per cent of cases tuberculosis was found elsewhere in the body. In 91 per cent articular bone was involved, in 9 per cent only synovia was affected. In 50 per cent bone abscesses were present, in 11 per cent, sequestra occurred.

Roentgenograms Henderson expressed agreement with his colleagues, Ghormley, Kirklin, and Brav,³⁴ that roentgenograms, although often characteristic, do not give incontrovertible evidence. Comparing the alterations in 65 cases in which the presence of tuberculous knee joints was proved, to those in 11 cases of non-tuberculous arthritis (gross and microscopic sections also being studied) Ghormley, Kirklin and Brav found them to be essentially similar. In very early tuberculosis, roentgenographic signs were absent. For a time, in the non-tuberculous case more change will be seen than in the tuberculous case. Marginal erosions, and long preservation of articular spaces were seen in both but were more suggestive of tuberculous involvement. Marginal lipping, seen in both, was more often present in non-tuberculous cases. In tuberculous arthritis, areas of greatest destruction of cartilage or bone were either central or marginal, in non-tuberculous arthritis destruction was practically always central. Bone abscesses and sequestra indicate tuberculous arthritis, but in a large percentage of cases sequestra, when present, were not visible in roentgenograms. In one case of proved tuberculous arthritis of a knee associated with tuberculous spondylitis, seen by Bennet and Hinricson,³⁵ the roentgenographic appearance resembled that of a Charcot joint, and the latter diagnosis was entertained for a time particularly as the knee was painless.

Pathology Herniation of joint cartilage into subchondral tissue and plication (folds or pleats) were frequently noted by Freund³⁶ in tuberculous joints, in which undermining of joint cartilage is extensive. It does not

lead to marked deformity of the surface of the joint because the entire cartilage usually becomes resorbed or sequestered

Synovial Fluid The total cell counts of synovial fluid in five cases were found, by Keefer, Myers and Holmes,¹¹ to vary between 6,500 and 110,000 per cubic millimeter. The differential count was as follows: polymorphonuclears 45 to 93 per cent, lymphocytes 3 to 30 per cent, monocytes 1 to 31 per cent, clasmatocytes 1 to 7 per cent, eosinophiles 0 to 3 per cent. The differential formula thus disclosed no absolutely characteristic features, but there were generally more lymphocytes and monocytes than in other types of arthritis. Chemical examinations revealed no characteristic alteration: total protein per 100 c c of synovial fluid varied between 4.3 and 5.5 grams, the non-protein nitrogen of fluid equalled that of blood, the sugar of the fluid (91 to 160 mg) was always a few milligrams higher than that of the blood (79 to 116 mg).

[The sugar determinations on synovial fluid did not always represent fasting values—Ed.]

Treatment Henderson expressed the opinion that non-operative therapy is erroneously called conservative treatment. In fact surgical treatment, arthrodesis (at least if patients are more than nine years of age), may be more conservative, and more saving of time and money, even though it is granted that a few patients can be cured by long rest and articular fixation under supervision in hospitals. The knees, hips, shoulders, and spine are best suited for arthrodesis, the elbows, wrists, and ankles are next in choice. Of 274 cases of tuberculous arthritis of the knees, in which Henderson^{32, 33} performed arthrodesis between 1913 and 1934, fusion resulted in about 90 per cent. Nine per cent of the patients were found to have died of their non-articular tuberculosis. Synovectomy was performed on four patients whose articular tuberculosis was confined to synovia. Of these four patients two were well and comfortable several years later.

“TUBERCULOUS RHEUMATISM”

An extensive résumé of literature on this subject has been made by Brav and Hench.³⁷ As described by its proponents, this condition is a form of polyarthritis, simulating in some cases acute rheumatic fever, in other cases, chronic atrophic arthritis, but bearing some etiologic relationship to tuberculosis. It is thought to be attributable to a tuberculous toxin from some distant focus, a filtrable virus, an attenuated form of the bacilli of tuberculosis, or an allergic reaction. True tubercles are not the expected finding, and when present, they indicate superimposed tuberculous arthritis rather than tuberculous rheumatism. Evidence for the diagnosis of tuberculous rheumatism includes familial tuberculosis, associated visceral tuberculosis, demonstration of Koch's bacilli in synovial fluid and the blood stream, positive results of inoculation of guinea pigs with joint-fluid, and in some cases the presence of a typical tuberculous joint before, coincident

with, or subsequent to, the development of polyarthritis. Reported pathologic findings have included focal collections of round cells, of plasma cells and of histiocytes, isolated instances of necrosis, internal thickening and vacuolization of the vessels, and the presence of giant cells and endothelial cells. These alterations are considered either a transition stage between simple inflammatory tissue and tuberculosis, or an allelic manifestation of the latter.

Against acceptance of the syndrome of tuberculous rheumatism have been arrayed a large number of competent investigators who argue that there is no adequate clinical method of identifying it, no consistently characteristic roentgenographic evidence, no experimental or laboratory evidence in its favor that is not highly controversial, and no consistent demonstration of its supposedly characteristic microscopic pathology.

A statistical study by Brav and Hench of a series of 150 cases of acute rheumatic fever and 250 cases of chronic atrophic polyarthritis revealed no significantly higher incidence of familial tuberculosis or associated visceral tuberculosis than that found among 250 control cases. The controls were consecutive non-arthritic cases, studied in the same period as the arthritic series. The control patients registered a multiplicity of complaints in no way related to joints. Of a series of 75 cases in which a diagnosis of chronic atrophic polyarthritis had been made, and in which the pathologic characteristics of a single joint were determined by microscopic examination of tissues or by inoculation of guinea pigs, the joints of eight patients were found to be definitely tuberculous. In each of the eight cases, the tuberculous nature of the arthritis was suspected prior to examination of tissue or inoculation of animals, but the presence of polyarthritis was confusing. Brav and Hench concluded that further investigation will be required to determine the acceptance or rejection of the syndrome of tuberculous rheumatism. At present, they concluded that no incontrovertible proof of such an entity exists.

LeSage,³⁸ however, accepting the entity without question, was surprised how seldom the condition was diagnosed and how often it was confused with gonorrheal or gouty arthritis. He admitted that generally no direct proof of its tuberculous nature can be found either on pathologic or bacteriologic examinations. "We have only clinical signs to guide us," he wrote. In a few cases, although cultures and examination of the joints may be negative, the subcutaneous or intraperitoneal inoculation of bacteriologically-negative synovial fluid into guinea pigs will produce tuberculosis. LeSage expressed the belief that a tuberculous virus may manifest its presence in serous membranes only by ordinary, simple, inflammatory lesions in the "pre-bacillary stage." In the later "bacillary stage" the primary inflammatory lesions undergo evolution to the state wherein their tuberculous nature may be revealed.

In evidence, LeSage included the following cases. A man, aged 26 years, in 1923 had vague pains and stiffness in the neck and spine, inflammation and ankylosis of the right ankle. The case progressed as follows: in 1924, involvement of the left ankle, in 1925, of the temporomandibular joint, with orbital neuritis, in 1926, progressing "rhizomorphous spondylitis", in 1930, swelling of the left knee, in 1931, left orbital neuritis, corneal ulcerations and amaurosis, in 1932, involvement of the right knee, and in 1933, involvement of both shoulders. Roentgenograms disclosed the following: those of the thorax "ganglionic spots with dense peribronchial and pulmonary fibrosis", those of the joints, destructive arthritis, exostosis and rarefaction. Fluid removed from the right knee in 1932, when injected into guinea pigs, produced extensive tuberculosis, and bacilli were recovered.

A woman, aged 61 years, had arthralgia of the feet and effusion of the left knee. She presented no evidence of tuberculosis. The cutaneous reaction was positive for tuberculosis. Fluid from the knee joint was negative, as was the guinea pig test, but culture of the patient's blood (Lowenstein's technic) gave colonies of virulent Koch's bacilli after three weeks.

From such evidence, LeSage concluded that lesions of inflammatory tuberculosis (ante-bacillary period) are attributable to a filtrable virus, whereas specific lesions are produced by Koch's bacillus.

[In three other cases the diagnosis seems to have been made chiefly from clinical data, data which may have been clinically unmistakable to LeSage, but perhaps inadequate for others—Ed.]

To Buckley³⁹ much of the evidence for the entity was unconvincing. Positive cutaneous reactions may easily be attributable to latent tuberculous foci in lymph nodes or elsewhere, and isolation of bacilli of tuberculosis from the blood in cases of acute polyarthritis, by the method of Reitter and Lowenstein (1932), generally has been unsuccessful in other hands. In two cases of chronic polyarthritis, Buckley found bacilli of tuberculosis in effusions from knee-joints. Admitting the possibility that a chronic tuberculous focus in lymph nodes, or elsewhere, may sensitize tissues to, and thus favor infection by, streptococci, it seemed more probable to Buckley that sensitization is first produced by streptococci and that infection by bacilli of tuberculosis occasionally follows.

PNEUMOCOCCAL ARTHRITIS

This rare disease occurs only once in every 800 to 1000 cases of pneumonia. When pneumococci gain access to a joint they produce acute, generally purulent, arthritis. Fagge⁴⁰ reviewed the literature, and the experience of the physicians of Guy's Hospital between 1918 and 1932, during which years only seven cases, including at least two that were doubtful, were seen. Three-fourths of cases of pneumococcal arthritis occur in conjunction with pulmonary infection, generally after the stage of resolution, occasionally in the stage of red hepatization. A fourth of the cases occurs in association with pneumococcal septicemia but without pneumonia. Larger joints are generally involved, the knees most commonly, next in frequency of involvement are the shoulders, wrists and elbows. In three-fourths of

cases the involvement is monarticular. When pneumonia is present the appearance of acute arthritis raises the suspicion of its pneumococcic origin. Otherwise the diagnosis is made on bacteriologic examination of aspirated joint-fluid. In spite of purulent exudates and gross involvement, complete articular restitution often occurs and ankylosis is rare. Of patients so affected, 24 per cent die from non-articular pneumococcic infection.

Of Fagge's patients, one had pneumococcic meningitis, and a shoulder was affected, one had pneumonia and a knee was involved, one acquired influenza shortly after spraining an ankle, and pneumococcic abscesses developed about the affected ankle. In the cases at Guy's Hospital, pneumococcus type I was found once, type III, twice.

Farah⁴¹ described a different course of presumed pneumococcic arthritis in one case.

A man, aged 31 years, acquired a sore throat and bronchitis in 1924. Fifty days later subacute, febrile monoarthritis of the right knee developed and was evident for a few days. Complete restitution occurred. In July 1924, without any associated sore throat, the left knee became similarly involved and remained involved for 20 days but recovery was complete. In December 1925, three days after onset of a sore throat, the right knee and left wrist were briefly affected, in February 1927 the patient again had a sore throat and an involved right knee. In the next six years he had repeated mild attacks in one to three joints, occasionally after onset of a sore throat or cold. These and all previous attacks apparently responded notably to salicylates. In February 1933, generalized febrile polyarthritis developed. Roentgenograms of joints were normal in spite of repeated involvement through 10 years. The heart was normal. From the blood pneumococci were obtained in pure culture. From the red throat, pneumococci, type III were obtained and agglutinins thereof were present in the serum in a titer of 1 to 2000. Skin tests to several bacteria were negative but to the pneumococci obtained from the patient were strongly positive. Articular cultures were not permitted.

Farah assumed the case to be one of an unusual form of pneumococcic arthritis from focal infection (pneumococcic sore throat), of special interest because of the absence of purulent effusion or articular residues, and because of the later resemblance to acute rheumatic fever, including response to salicylates. He suggested that other cases of acute rheumatism may be so caused.

[It is to be noted that the early attacks were monarticular, not typical of rheumatic fever. Somewhat similar cases of recurrent monoarthritis and polyarthritis of short duration, leaving no residue in joints or heart, have been reported as instances of allergic arthritis. This report should stimulate appropriate investigations in unclassifiable cases. One of us saw a case in which a parotitis was the only infected focus. Pneumococci could always be isolated from saliva but not from joints.—Ed.]

Pathology. Details of pathologic reactions in a case of pneumococcic arthritis of an elbow joint were described by Keefer, Parker and Myers.¹⁵ An intense inflammatory reaction of synovia—thickening of subsynovial fibrous tissue and destruction of synovial surface cells—and extensive destruction of cartilage and subchondral bone were noted.

Treatment Immobilization, prompt articular aspiration and irrigation with physiologic saline solution, repeated as necessary, are advocated^{15, 39}

SCARLATINAL ARTHRITIS, POSTSCARLATINAL RHEUMATISM

In the course of, or following, scarlet fever the joints or heart may be affected in about 6 to 10 per cent of cases by (1) toxic lesions appearing early in the disease, (2) septicopyemic lesions appearing early or late, and (3) so-called allergic lesions which generally appear late. Both the suppurative and the non-suppurative varieties of scarlatinal arthritis, or post-scarlatinal rheumatism, have been considered by some to be more or less specific manifestations or complications of scarlet fever. Others believe that the non-suppurative forms, with or without carditis and with or without a previous history of rheumatic fever, should be regarded as forms of true rheumatic fever, activated by the hemolytic streptococcal infections of scarlet fever in the same way that other streptococcal infections are prone to activate latent rheumatic fever. Comparing epidemiologic studies in cases of postscarlatinal rheumatism with those in cases of rheumatic fever, Paul, Salinger and Zuger⁴² expressed agreement with the latter viewpoint. A high incidence of rheumatic fever was found in families of patients who had had postscarlatinal non-suppurative arthritis or carditis. The clinical course of these two complications is essentially similar to that of rheumatic fever. Although every case of non-suppurative arthritis or carditis following scarlet fever is not necessarily a manifestation of rheumatic fever, the majority probably are, and are not specific complications of scarlet fever.

The case of a boy 14 years of age who suffered from fever and a red, swollen hip a few days after inoculation against scarlet-fever was reported by Stewart⁴³. In the next five months, while the patient remained in bed destructive arthritis and marked stiffness of the hip appeared. Since, in roentgenograms, the epiphyseal line seemed open and motion of 10° was present, motion was encouraged. Finally flexion of 40°, hyperextension of 10°, and rotation of 30° were accomplished by the patient. At last he could sit in a chair and walk a mile and a half without pain. Fluoroscopy gave evidence of pseudo-arthritis, motion originating wholly in the epiphyseal line.

[Bacteriologic studies relative to the hip apparently were not made, and the data furnished do not permit a positive diagnosis.—Ed.]

SYPHILIS AFFECTING JOINTS

Clutton's Joints, Symmetrical Serous Synovitis The most common articular affection of congenital syphilis among children is Clutton's joint, a relatively painless, simple, serous or gummatous synovitis which is generally bilateral, lasts for months or years, and is not accompanied by bony changes. It generally affects one or both knees, one being affected some

time before the other. Elbows, wrists or fingers are less frequently affected. It is uncommon among adults who have acquired syphilis. When present it usually precedes or accompanies the secondary eruption. Of 363 cases of congenital syphilis encountered by Klauder and Robertson,⁴⁴ in 63 Clutton's joints were present, one or both knees were involved in all, and in two an elbow also was affected. Little or no pain, tenderness, heat, redness, limitation of motion, or muscular atrophy were present. The patients were generally from eight to 15 years of age. Pathologic reactions include formation of villous processes and synovial fringes and simple or gummatous synovitis. Untreated, the process becomes chronic but generally terminates spontaneously. Antisyphilitic therapy may affect it markedly or not at all. Splints, rest and surgical operation seem useless. In all of Klauder and Robertson's cases effusions eventually disappeared without ankylosis. If ankylosis is present the condition is not Clutton's joint but may be syphilitic arthritis. Patients who have Clutton's joints are more likely than others to suffer from interstitial keratitis.

Eleven cases of chronic synovitis of the knees, with persistent or recurrent effusions, were seen among children by Gill and Orr⁴⁵ and were considered very similar to cases of Clutton's joint although Wassermann reactions on blood and spinal fluid were negative in all but two. In one of the latter a positive reaction was obtained only after administration of provocative doses of neoarsphenamine. Tissue obtained in one case revealed a red, thick synovial membrane, synovial fringes and early formation of pannus, with some erosion of underlying cartilage.

[Gummatous infiltrations were not mentioned—Ed.]

Although the etiology was undetermined, all the cases were thought possibly to be syphilitic. In similar cases Klauder and Robertson recommended provocative tests. Only one case was cured by therapy. Buck's extension, casts, splints, braces, physiotherapy, heliotherapy, compression bandages, repeated aspirations.

[Antisyphilitic therapy apparently was not administered. It seems to us that one has no right to make or suggest a diagnosis of Clutton's joint in a patient with negative Wassermann reactions on blood and spinal fluid unless the parents reveal evidences of syphilis, or the patient shows stigmata of congenital syphilis. Some believe that conservative treatment of Clutton's joints is generally followed by recovery whether or not specific antisyphilitic treatment is administered—Ed.]

Syphilitic Arthritis The Wassermann reaction was performed by Keefer, Myers and Holmes¹¹ on four specimens of synovial fluid from two patients who had syphilitic arthritis. The blood serum and synovial fluid were positive on three occasions, once the reaction of blood serum was positive when that of synovial fluid was doubtful. In two cases the cytology of the synovial fluid was as follows: total cells per cubic millimeter 3,200 to 4,500, polymorphonuclears 17 to 52 per cent, lymphocytes 35 to 51 per cent, monocytes 7 to 32 per cent, clasmotocytes 3 to 16 per cent. In one

case the total concentration of protein in the synovial fluid was 3.8 gm per 100 c c , of sugar, 78 mg , of non-protein nitrogen, 24 mg

UNDULANT FEVER

The symptomatology of this disease was reviewed by Miller⁴⁶ An almost constant symptom is aithralgia, sometimes severe enough to suggest acute arthritis In some cases articular pain and tenderness are present, but no swelling Some cases resemble instances of acute rheumatic fever If the patient has an afebrile period, the joint disturbance may largely subside In one of Miller's seven cases, the spindle-shaped swellings of the fingers resembled those seen in atrophic aithritis, and in this case the diagnosis of atrophic aithritis had been made An intermission in the fever was followed by disappearance of the swellings Suppurative arthritis of costosternal or costochondral junctions, and suppurative spondylitis, have been reported by others Blood cultures, when positive, as they are in only 25 per cent of cases, establish the diagnosis Agglutination tests are useful but variably positive, in many active cases they are negative unless repeated frequently

A case of undulant fever, resembling a case of acute rheumatic fever, was seen by Twedell and Schlotzhauer⁴⁷ A young man had sore throat, malaise, pains in the chest and right knee, and later had headache, cough and fever In a few days the pain in the knee disappeared but migratory pains affected the opposite leg, shoulders, and elbows A diagnosis of rheumatic fever was made but the effect of salicylates was poor A month later an enlarged spleen was noted Several blood cultures revealed *Brucella abortus* and agglutinins were present in a titer of 1 to 1,600

Treatment According to Miller, treatment with specific vaccines and chemotherapy is not of proved value Occasional results from typhoid vaccine or arsphenamine are reported In a case of three months' duration, seen by Jones,²⁸ one session of fever therapy (two and a half hours at 105.5° F) was followed in a few days by complete cessation of malaise, weakness and fever

[Arthritis was not mentioned as being present in this case—Ed]

Experimental Undulant Fever Feldman and Olson⁴⁸ were unable to produce demonstrable lesions in swine by injection, by various routes, of strains of *Brucella abortus* of porcine origin, consistently pathogenic to guinea pigs Agglutinins were produced in the blood serum of all animals that received injections Although the strains had been isolated from lesions of spontaneous spondylitis of hogs, no similar lesions could be reproduced experimentally It is concluded that the apparent predilection of such organisms for vertebral bodies does not represent an inherent tendency of the organism for elective localization, but that the predilection is accidental or casual

HAVERHILL FEVER, ERYTHEMA ARTHRITICUM EPIDEMICUM

Full details of this disease, one of recent identification (Levaditi, Nicolau, Poincloux, Place, Sutton, Willner, 1926) were given in three reports. Haverhill fever has four main characteristics: (1) an abrupt onset with chills, fever, malaise, vomiting and headache, (2) an early eruption, rubelliform or morbilliform, occasionally first, and often only, on the extremities, especially about the ankles and wrists, with a tendency to become hemorrhagic, (3) multiple arthritis of varying, but often of severe, degree and (4) a peculiar remittent (saddleback) fever curve, of abrupt rise, with remission in from two to five days, and after a few days of relative freedom from symptoms a febrile recurrence with which the arthritic manifestations appear.⁴⁹

Symptoms referable to joints are outstanding and distressing. Generally they appear with the secondary rise of fever, on the third to the fifth day of the disease, very occasionally later. Several joints may be attacked, the wrists, elbows, knees, shoulders, fingers and ankles most commonly. Joints may be markedly painful, redness and swelling are variably present. Roentgenograms of joints are negative. Muscles are "lame" but not tender. Hydrops is often present in a knee, and in two cases pure cultures of the causal organism, *Haverhillia multiformis*, have been isolated therefrom.^{49, 50} The arthritic symptoms may last from a few days to several months, but generally they last about four weeks. They may persist longer than the fever. In general, articular restitution is complete or almost so.

The condition must be distinguished from rheumatic fever, which has no such peculiar fever curve, from dengue, from infectious erythema with arthralgia, from erythema multiforme, from Malta fever, and from rat-bite fever. In Haverhill fever the heart is negative, and although sore throat is a common symptom it is a diffuse catarrhal type of injection without exudate or tendency to involve lymphoid tissue, such as is seen in rheumatic fever. The diagnosis is confirmed by isolation of the specific organisms from the blood or from joint fluid. Specific agglutinins are present. Unpasteurized milk is believed to be the usual source of infection, but Scharles and Seastone⁵¹ have shown that the condition may follow a rat bite. A medical student who was bitten by a laboratory rat acquired the disease, and it was identified by agglutination tests and by recovery, by Bauer, in fluid from an ankle, of the specific organism of Haverhill fever. All attempts to find spirilla of rat-bite fever failed. It is suggested that certain cases of supposed rat-bite fever may in fact be cases of Haverhill fever.

SEPTIC (PURULENT) ARTHRITIS

The common forms of septic arthritis, aside from the gonococcal form, are attributable to *Staphylococcus aureus* or to *Streptococcus hemolyticus*. A hip, a knee, or a shoulder is most commonly affected, and roentgenograms often disclose no abnormality for the first 10 days.⁵² Early diagnostic

aspiration is recommended. Particularly if leukocytes number more than 15,000 per cubic millimeter of blood, and if thick pus is present, Oxford has expressed himself as in favor of arthrotomy with open drainage. Such treatment was necessary in 15 (60 per cent) of his 26 cases, in the remainder conservative therapy was permitted such as drainage by aspiration and then traction or fixation. Ankylosis, however, frequently results, particularly if the arthritis arose from infection (osteomyelitis) of juxta-articular bone. The most marked alterations in synovial cytology, noted by Keefer, Myers and Holmes,¹¹ were seen in three cases of arthritis caused by hemolytic streptococci. The total number of cells per cubic millimeter varied from 109,500 to 350,000, and polymorphonuclear cells constituted 94 to 100 per cent thereof.

The articular pathology in two cases was described by Keefer, Parker and Myers¹⁵ and included synovial thickening and cellular infiltration, with regions of complete destruction, cartilaginous thinning and erosion, infiltration of leukocytes, abscesses in bone marrow, and masses of visible bacteria.

In four cases in which treatment was administered by Taylor,⁵³ transfusions were employed and bacteriophage seemed of value.

ARTHRITIS OF SUBACUTE BACTERIAL ENDOCARDITIS

Pains of the joints commonly occur with infective endocarditis. The joints do not suppurate. Their pathology has not been described heretofore. In a case of subacute bacterial endocarditis affecting a young man, and attributable to an unidentified form of gram-negative coccus, Keefer, Parker and Myers¹⁵ found the essential articular lesion in the synovial connective tissue with perivascular lymphocytic infiltration. The synovial surface cells were generally intact.

MENINGOCOCCIC ARTHRITIS

Brief clinical details of two cases, with pathologic reactions found at necropsy, were reported by Keefer, Parker and Myers¹⁵. Arthritis occurs in from 4 to 7 per cent of cases of meningococcic meningitis (Herrick and Parkhurst, 1919) and may assume three forms. 1 One form comprises brief, early polyarthritis characterized by pain and tenderness but without swelling or hydrops, and generally accompanied by a hemorrhagic rash. The joint pains may be attributable to hemorrhages in articular and peri-articular tissues. 2 Metastatic pyoarthrosis with meningococci in the effusions is characteristic of the second form. Recovery occurs in one to four weeks, with or without ankylosis. 3 Arthralgia from meningococcus serum constitutes the third form. From their studies, the writers¹⁵ concluded that in meningococcic arthritis the metastatic lesion involves deeper synovial tissues first, later, the superficial cells, with effusion of fluid into the joint cavity and varying degrees of destruction of cartilage.

In a case in which chills, fever, jaundice, meningitis and meningococcic arthritis developed, and which was seen by Jaffe,⁵¹ the use of meningococcus serum was followed by relief of all symptoms and signs, but the patient later died of pneumonia

RHEUMATIC FEVER

Incidence Some studies indicate that the incidence of rheumatic fever depends largely on various factors of climate and environment the patient's geographic habitat, his social condition, exposure to damp, cold and respiratory infections, and to seasonal change Glover and others⁵⁵ have reminded us that the Medical Research Council's investigation, which included familial incidence and heredity, familial evidence of sore throats, maternal care, exposure, sleeping conditions, clothing, birthplace, occupation, income of parents, types and sites of houses, and so forth, concluded with the statement that the findings were largely negative It is nevertheless felt by many that some of these factors are important, and Glover and Miller and others^{55, 56} have voiced the general belief that the incidence of rheumatic fever and rheumatic heart disease is low in the tropics, higher in the temperate zone and among persons living near sea level or in basements, and also that it is higher in cold, damp months

Geography Reviewing the distribution of rheumatic heart disease, which is the best proof of the existence of rheumatic fever, in various parts of the world, Nichol⁵⁷ reported that it is prevalent and severe between latitudes 50° and 40° North, diminishes in warmer climates, is almost unknown between the Tropics of Cancer and Capricorn, increases again as cooler climates are reached and is common between latitudes 30° and 40° South Thus it is practically unknown in the subarctics, in southern India, Puerto Rico, southern China, the Malay States and Panama It is common among school children in England (1.5 to 2.0 per cent), northern Europe, northern United States of America (0.89 to 0.66 per cent), South Africa and Australia Its incidence varies widely in the United States, from 0.86 in Boston to 0.45 per cent in Miami Admissions to hospitals are more impressive, for a variation of 0.2 to 5.8 per cent exists, the latter in cold wet climates, and the former in warmer regions Rheumatic fever and chorea are rare in Florida, according to Nichol (16 cases in 16,200 medical admissions to hospitals) Rheumatic heart disease is particularly rare among children born in Miami and is seen three times as often among children now living in Miami but born in the North Of 103 patients who had rheumatic heart disease, seen in a given period, in only seven cases did it originate in southern Florida Simmons⁵⁸ found the incidence of rheumatic heart disease in Kentucky to be the same as that in Texas and Louisiana, half that of Virginia and Maryland, and a fourth that of New England According to Chase⁵⁹ it is rare in Oklahoma, a warm, dry state, it is becoming less frequent in Omaha, Nebraska,⁶⁰ and although it is increasing in the United States as a whole it is not increasing in New York City⁶¹

Compared to its incidence in Great Britain, rheumatic heart disease is relatively infrequent in Australia Cleland⁶² found 116 cases (3.9 per cent) in 3000 postmortem examinations

[Figures are not given to support some of these later statements—Ed.]

Social Conditions It is believed that the disease is more common in crowded cities than in the country, and that poor hygiene and environment favor its development In Australia it is more common in the city and suburbs (194 of 218 cases came from the city and suburbs) than in the country, but it is common in the hill districts and low-lying valleys⁶³ Although poverty is a factor, children of the poorest parents are less affected than those of less poor parents (Miller) Glover expressed the opinion that the true incidence of the disease is directly proportional to the degree of poverty, and that it is seen 20 to 30 times more frequently among children of the poor than among those of the well-to-do The incidence of rheumatic heart disease was 48 per 1000 children in a public school in the poorest city district, 31 per 1000 children in public school in a better residential area Thus, the former was one and five-tenths times higher than the latter, but it was moreover found to be eight times higher than the incidence among children of a wealthier class from urban private schools From these figures, Paul, Harrison, and DeForest⁶⁴ concluded, again, that rheumatic heart disease is in part a manifestation of poverty

Effect of Seasons In England, rheumatic fever is more prevalent in the cold, damp months of fall and winter,⁶⁵ but in Rochester, New York, it is more common in late winter and spring⁶⁶

Heredity A high family incidence is frequently reported, Swift⁶⁶ recently indicated that he still believed this phenomenon means an inherited state Thus a hereditary tendency is present in a third of the cases, according to Benjamin,⁶⁷ who found that of 280 rheumatic children, 38 per cent had rheumatic parents and 17 per cent had rheumatic brothers or sisters

Physical Type Although the rheumatic child may differ from the normal one in other constitutional traits, he does not differ in physical type, as indicated by bodily dimensions, sexual differences, color of hair and eyes, type of contour (slender or thick) or posture, according to the exhaustive report of Young⁶⁸ who studied 1,212 children, 459 of whom were rheumatic, 368 asthmatic, and 385 normal

Sex and Age Juvenile rheumatism is more frequent among females^{65, 67} Of Kaiser's 1200 rheumatic children, 54 per cent were girls, 46 per cent, boys Kaiser noted the disease infrequently among patients who were less than the age of three years, he found an increasing frequency among patients from three to 10 years of age, and a declining frequency among those from 10 to 15 years of age, thereafter the condition was as infrequent as it was before the age of three years Only six cases of rheumatic heart disease of children less than two years of age have been reported White (1926) saw a patient who was sixteen and a half months old, and

Schroeder (1922), one 20 months old As Swift⁶⁶ noted, the cases of rheumatic fever in very young infants have almost all occurred in instances wherein the mother had the disease while the child was in utero, this suggests that both the susceptibility, and the infectious agent were transferred to the infant during pregnancy because, in general, other infants of rheumatic families do not give clinical evidence of the disease until after the fourth or fifth year of life It is likely that during a considerable portion of this pre-rheumatic period the infant's tissues become so conditioned that they finally develop the capacity for showing true rheumatic lesions

The youngest patient on record has been reported by Fischer⁶⁹, the child was twelve and a half months old and died of rheumatic heart disease The mother had active rheumatic fever from the third to the seventh month of pregnancy The child developed fever, convulsions, otitis media, pneumonia and the typical picture of rheumatic valvulitis Aschoff bodies were found at the necropsy Fischer expressed the belief that the process was acute and probably did not date from birth although the child might have been stigmatized during fetal life

Symptoms The progress of the disease, as shown in new studies, conforms to the accepted pattern, major manifestations are sore throat, tonsillitis or infection of the upper part of the respiratory tract, fever, abdominal pains, arthritis, myositis, nodules, cutaneous eruptions, purpura, and carditis Of 206 patients who had rheumatic heart disease, seen by Simmons,⁶⁸ 68 per cent gave definite histories of rheumatic fever, 19 per cent had had only recurrent tonsillitis, 4 per cent gave histories of chorea and 8 per cent had none of these The first rheumatic attack occurred before the age of 20 years in 70 per cent of cases, before 30 years in 94 per cent In nine cases symptoms did not develop until after the age of 50 years As is well-known, and as has been emphasized again by Black,⁷⁰ the symptoms of the disease differ somewhat as they are seen in children and in adults The latter generally present an acute onset, high fever, polyarthritis and drenching sweats In children the symptoms are less definite slow onset, frequently infection of the upper part of the respiratory tract, malaise, growing pains, fatigue, intermittent fever, rapid pulse without fever, night sweats, pallor, anemia, epistaxis, chorea, occasional nodules and frequently slight cardiac murmur Growing pains or chorea may be the only symptom⁶⁷ Nodules, generally over knuckles, occur in 15 to 20 per cent of cases^{67, 70} According to Benjamin⁶⁷ rheumatic growing pains are characteristic vague, dragging, fleeting pains in muscles, occasionally in joints, frequently accompanied by easy fatigability, loss of weight and anorexia

[According to Shapiro (1935) rheumatic growing pains are more often in joints, nonrheumatic growing pains of children are more often in muscles—Ed]

Some of the 1200 children seen by Kaiser⁶⁵ had six or more symptoms, others, only a few Pancarditis and nodules usually denote a serious form, tonsillitis, pallor and anorexia may indicate less serious rheumatism Major

manifestations were present as follows: pericarditis in 64 per cent of cases, rheumatic fever with severe arthritis in 39 per cent, mild arthritis in 32 per cent, chorea in 29 per cent, muscular rheumatism (growing pains) in 18 per cent, pneumonitis in 3 per cent, erythema nodosum in 2 per cent, nodules in 1 per cent, pleurisy in 1 per cent and purpura in 0.4 per cent. Minor manifestations were present as follows: tonsillitis or sore throat in 43 per cent, fatigue in 36 per cent, anorexia in 34 per cent, pallor in 30 per cent, epistaxis in 15 per cent, cephalalgia in 6 per cent, abdominal pain in 5 per cent, cardiodynia in 4 per cent and nausea in 3 per cent. Chorea was not as frequently associated with carditis as was arthritis. Those patients who had mild arthritis or myositis had less carditis than those who had acute fever or severe arthritis. Tonsillitis or pharyngitis immediately preceded arthritis, chorea or endocarditis in 43 per cent of cases.

According to some⁶⁸ the disease, in general, behaves similarly in all latitudes, producing the same cardiovascular and other lesions. According to Schlesinger⁷¹ the geographic variations are enormous, there is less carditis in the Netherlands than in England, more nodules in England than in America.

[In our last year's review, differences of opinion were noted as to whether the manifestations of the disease, when it occurs in the southern American states, are the same as those when it occurs in the north. The weight of evidence is in favor of geographic differences in symptoms: in the south the disease is milder, there is less arthritis for which reason the disease often goes undiagnosed.—Ed.]

Special Symptoms, Lesions, and Complications, with Pathologic Studies of Heart. Recent data confirm accepted ideas. Of Simmons'⁵⁸ 206 cases the mitral valve was involved alone in 83 per cent, the mitral with the aortic valve in 11 per cent, the aortic valve alone in 6 per cent. According to Cleland's⁶² report on rheumatic carditis in 88 cases, it was found that mitral stenosis was more common in females than in males, aortic valvulitis more common in men. Evidence of unsuspected rheumatic carditis is often found at death in the bodies of persons who presumably were clinically unaffected by the disease. Of all patients dying at the Presbyterian Hospital, New York City, aside from those known to have had rheumatic fever, 1.2 per cent were found, by Hawking,⁷² to have latent or active rheumatic carditis. The specificity of Aschoff bodies is doubted by some. Gross and Ehrlich⁷³ have made a contribution to the descriptive classification, life cycle, sites of predilection, and relation of the Aschoff body to the clinical course of the disease. They concluded that the myocardial Aschoff body is of a type specific for the myocardium and to be considered apart from other rheumatic lesions. Aschoff bodies pass through three stages. The earliest stage occurs up to the fourth week of the disease and presents small-cell coronal, and reticular, Aschoff bodies. The second phase occurs from the fourth to the thirteenth week and presents large-cell coronal, syncytial coronal, mosaic, and large irregular-cell polarized bodies. Polarized bodies occur

from the ninth to the sixteenth week, fibrillar bodies, after the thirteenth week Aschoff bodies are found in 90 per cent of hearts of patients who die with evidence of active disease, in 59 per cent of those who die with evidence of old or recent activity

It is generally believed that heart failure depends on myocardial rather than on endocardial damage, since degrees of the latter are not related to the occurrence or extent of cardiac failure A study by Rothschild, Kugel and Gross⁷⁴ indicates that the severity of endocarditis bears no relation to the degree or age at onset of myocarditis and that rheumatic heart failure is related less to valvulitis, more to continued or recurrent myocarditis

Blood vessels Lesions in coronary arteries in rheumatic fever were described as being found in 56 cases by Karsner and Bayless,⁷⁵ and in four cases by Fraser⁷⁶ In both articles specific lesions were described in detail, Karsner and Bayless also described vascular lesions not specific for the disease There is a significant association between rheumatic heart disease and periarteritis nodosa (necrotizing arteritis) according to Friedberg and Gross⁷⁷ who reported four cases An unusual case of portal obstruction, retroperitoneal varix and fatal hemoperitoneum, in the presence of rheumatic carditis and adherent pericardium, was seen by Feldman and Gross⁷⁸ Easby⁷⁹ reported the appearance of spontaneous subarachnoid hemorrhage, possibly from a mycotic aneurysm, in a rheumatic child

[The patient recovered, no pathologic data were given—Ed]

Renal lesions Opinions differ as to the incidence of renal lesions in association with rheumatic fever According to Blaisdell⁸⁰ a high percentage of rheumatic patients suffer from renal damage early in life Of 2400 consecutive cases which came to necropsy, in 128 active or healed cardiac lesions were found Of the latter group 38 subjects exhibited interstitial nephritis, half had been less than 40 years of age at death, a third, less than 30 years The reported pathologic details in 16 such cases were related to small vascular structures, cortical arterioles and intralobular and arcuate arteries

Pulmonary lesions The pulmonary complications of rheumatic fever, according to Klein⁸¹ include fibrinous pleurisy, pleurisy with effusion, atelectasis secondary to enlarged heart with pericardial effusion, vascular lesions of the pulmonary artery and its branches, and rheumatic pneumonitis Symptoms of the latter may be evanescent, its course very variable, its characteristics hemorrhage and fibrinous exudate

Cutaneous lesions, nodules and purpura Nodules may be subcutaneous or cutaneous Rosenberg⁸² has reviewed their clinical differences and the histology of the latter, they vary from the size of a pinhead to that of a hazelnut, last for variable periods, and appear most commonly on the fingers, palms, and neck, also on the forehead, chest, and cheeks In an epidemic in a hospital, observed by Chester and Schwartz⁸³ the predominant sign was crops of bluish, not tender, maculopapular, purpuric spots, chiefly on

the legs and arms, lasting one to six months and disappearing without scarring or desquamation Holtz and Friedman⁸⁴ described an "unreported lesion" a hemorrhagic eruption confined to the mucosa of mouth and throat, seen rarely in examination of normal or nonrheumatic persons (occasionally in association with malnutrition, diabetes mellitus, vascular nephritis, and mumps), but especially in examination of patients in "the rheumatic state" It consists of one, two or a shower of circular, elevated, deep red spots, varying in size from that of a pinpoint to 2 mm in diameter, looks like a fresh hemorrhage and fades in 24 hours, perhaps to reappear in different oral situations for as long as two weeks The authors⁸⁴ expressed the belief that it is unrelated to purpura, and that it may be a non-embolic hemorrhagic enanthem It does not exhibit the specific rheumatic lesions

Abdominal symptoms and lesions It is not generally realized that abdominal symptoms are not infrequent in cases of rheumatic fever and that on occasion they are marked, simulating appendicitis, too often leading to negative exploratory operations Guptill⁸⁵ has given these symptoms consideration, describing details of eight cases (from a series of 160 cases of acute rheumatic fever) which simulated cases of acute appendicitis but in which inflammation of the appendix was not proved Four patients were operated on, the appendices were normal In Guptill's cases and in seven similar cases seen by Jones⁸³ the onset of the disease was manifested by fever, pain, nausea, and occasionally by vomiting The pain was in the middle or lower part of the abdomen and was often lancinating It subsided in two or three days in favor of characteristic polyarthritis To distinguish it from appendicitis may be difficult In rheumatic pseudo-appendicitis there is much less vomiting than in appendicitis, abdominal tenderness is present but muscular spasm is absent, and the leukocytes of the blood are increased in number without an increase in juvenile granular cells, the Schilling differential count is normal In appendicitis, vomiting is almost universal among persons less than 20 years of age, and the Schilling differential count is abnormal, for there is an increase in juvenile cells Careful inquiry concerning recent pharyngitis, arthralgia, carditis or previous rheumatism may prevent needless laparotomy When in doubt it is safer to risk negative exploration of a rheumatic patient than to overlook possible appendicitis Some writers believe such pseudo-appendiceal pain is referred from the pleura

In two additional cases of Guptill, true suppurative appendicitis was proved at operation in the course of rheumatic fever A few cases of true peritonitis attributable to this disease have been reported and probably are more common than is supposed In one such case Rhea⁸⁶ noted plaque-like areas on the lateral and posterior peritoneal surfaces, the lesions were similar to Aschoff bodies The intestines and mesentery were congested and edematous

With periarteritis nodosa, abdominal symptoms may be notable Ulceration of the intestine from arterial necrosis and occlusion often has pro-

duced diarrhea simulating that of ulcerative colitis. In two cases of periarteritis nodosa with rheumatic heart disease seen by Friedberg and Gross⁷⁷ abdominal symptoms dominated the clinical picture and led to exploration. These authors expressed the belief that such a complication may be the organic basis for some cases of "abdominal rheumatism."

[The diffuse hemorrhagic changes which, as noted in our last year's review, Collis believed were responsible for acute abdominal symptoms in three cases in which exploration was made are not mentioned in these various reports—Ed.]

Laboratory Data Sedimentation Rates, Blood Counts, Electrocardiograms Blood counts of course should be made in cases of rheumatic fever. Lymphatic leukemia may occasionally simulate rheumatic fever.

[See later, herein, the note of a case described by Sutton and Bosworth, also, see notes on cases of aleukemic leukemia and leukopenic myeloid leukemia simulating rheumatic fever, in last year's review—Ed.]

Previous opinions on the sedimentation rate have been confirmed^{55, 87, 88, 89}

The rate is elevated in rheumatic fever and rheumatic carditis, it varies with the activity of the disease and affords one of the most delicate gauges of activity. It is normal in cases of uncomplicated chorea. However, it is elevated in cases of chorea with carditis, changes occurring even before the carditis is distinguishable. Because uncomplicated chorea is associated with a normal rate, Elghammer⁸⁸ suggested that it may not be a true rheumatic lesion, and Warner suggested that chorea is not an infective process although associated carditis is. According to Struthers and Bacal,⁸⁷ and to Perry,⁸⁹ the rate returns to normal or goes to less than normal with the onset of congestive cardiac failure with edema, a sign of bad import. Elghammer stated that when the rate increases after removal of foci of infection he suspects reactivation of infection.

Alterations in the rate in rheumatism result from a fall in the concentration of albumin in the blood, a rise in globulin, and alterations in the albumin-globulin ratio.⁸⁷

Rheumatic children give no significant statistical variation from normal children, with regard to acidity and total chloride of gastric content, although the former exhibit greater variations on either side of mean values, according to Ogilvie.⁹⁰ The pH of the urine of rheumatic children is similar to that of normal or asthmatic children, even though the former show a higher excretion of various urinary acids.⁹¹

[This work does not seem to us to have been well controlled—Ed.]

Values for blood lipids of children who have acute and chronic rheumatism were found by Kaiser and Gray⁹² to be essentially the same as those of normal persons or of patients convalescing from scarlet fever, but the standard deviations were much greater for those who had the two diseases than for normal persons.

Electrocardiograms Prolongation of the A-V conduction time and

alteration of rhythm are the best known electrocardiographic changes of acute rheumatic fever. Changes in the S-T segment and the T-wave are probably as characteristic and frequent, although they are not pathognomonic. Alterations reported by Easby and Roesler⁹³ and by Kohn⁹⁴ indicate that during the active stage the T-wave may be rounded and small, sometimes iso-electric, diphasic or inverted, and that during recovery it may become upright, tall and sharply peaked before returning to normal. In both reports it is noted that changes similar to those of coronary disease occur and it is suggested that they may result from alterations in coronary circulation, with consequent interference with myocardial blood supply.

Course of the Disease, Evidences of Activity or Reactivity The average duration of the disease, according to Olesen,⁶¹ is 17 years. Kaiser⁶⁵ studied the course of 564 children for three years. Within that time, 49 per cent had recrudescences, particularly those who had chorea. Within the first three years, 5 per cent died. Between the third and fifth years of the disease, 40 per cent had recurrences but only 1 per cent died. Within the first 10 years, 6 per cent died, 25 per cent had recurrences. After the first five years, the prognosis for ultimate recovery and freedom from recurrence is definitely improved. Of Simmons' 206 patients who had carditis, 17 per cent died, their average age was 33 years at death.⁵⁸

Estimation of activity of the disease must always be made in absence of effects derived from salicylates or other antipyretic drugs. Evidences of continued or renewed activity include loss of weight, pallor, fever of low grade, abnormal pulse rate, fleeting muscular and joint pains, tonsillitis, epistaxis, abdominal symptoms, cutaneous lesions, increased cardiac force, transient pericardial friction, electrocardiographic alterations, leukocytosis and increased rates of sedimentation^{66, 65}. Evidences of quiescence include steady gain in weight, slowing of pulse rate to normal, lack of extension of cardiac signs, absence of nodules or of chorea and fall in rate of sedimentation.⁷¹

Comparison of Rheumatic Fever with Tuberculosis and Atrophic Arthritis Cecil again has reminded us of certain relationships between rheumatic fever and atrophic arthritis. Both are prevalent in cold, damp climates and rare in the tropics, both progress with exacerbations and remissions, both attack joints and resemble chronic infections, both are associated with foci of infection, iritis, and nodules, both present proliferative and exudative granulomatous lesions—one involving chiefly the vascular system, the other, the joints, and, according to Cecil, both seem related to streptococci.

Similarities between rheumatic fever and tuberculosis have been pointed out for years. Recently (1932) Reitter and Lowenstein reported 70 per cent positive cultures for bacilli of tuberculosis in the blood of patients who had rheumatic fever. If the condition is related to tuberculosis, tuberculin reactions of rheumatic patients should be significant. Pascher⁹⁶ found no differences in the reactions of 245 rheumatic patients and 273 control subjects. Positive reactions were present in about 25 per cent of each group.

Etiology and Pathogenesis Since conceptions of the etiology of rheumatic fever have not changed in any important particular from those outlined in detail in last year's review, we shall note current studies but briefly. The three chief theories continue to be (1) the microbic, (2) the metabolic and (3) the endocrine.

Microbic theory The great majority of writers favor one of the variants of the bacterial theory (1) the theory of bacteremia, (2) the theory of bacterial toxemia, (3) the theory of bacterial allergy. For each group, some hold responsible one bacterium, or its toxin or its antigen, others consider that any one of a number of bacteria, or their toxins or their antigens, may be causal. Highlights in pathogenesis are thought to be preceding tonsillitis or pharyngitis (generally with attendant hemolytic streptococci), a latent period of one to three weeks and then the attacks (fever, polyarthritis, and so forth).⁹⁷ The facts that sore throat so often precedes the initial or recurrent rheumatic attack, and that the disease, always one of low infectivity, occasionally assumes epidemic proportions, strengthen the bacterial theory.

Five varieties of microorganisms have been isolated from the blood of rheumatic patients (1) a "sporulent" bacillus, anaerobic but facultatively aerobic, (2) a diplococcus, aerobic but facultatively anaerobic, (3) a streptococcus, generally hemolytic, (4) diphtheroid organisms (aerobic coccobacilli), (5) enterococci. Such is Bertrand's⁹⁸ grouping. Farah⁹⁹ listed about 25 organisms held responsible at one time or other. Hemolytic streptococci are currently the prevailing culprits, but the majority of writers have hesitated to ascribe more than contributory potentialities thereto, and believe infections therewith precipitate attacks in sensitized persons.^{66, 100}

The bacteremic theory has been supported by Bertrand⁹⁸ who has isolated, from joints and in blood cultures, organisms which, in vitro, change from bacilliform types to diplococci, the cycle—bacillus, diplococcus, coccobacillus, streptococcus—could be developed in either direction. In monkeys inoculated intravenously with these organisms typical acute articular rheumatism developed in 81 per cent of those inoculated with the bacillary form of the organism and in 52 per cent of those inoculated with the diplococcic form. It was concluded that in its virulent state the organism produces acute disease, in its attenuated form, it produces chronic disease. This organism, formerly called "Achalme's bacillus," is now called the "*diplostreptobacillus of rheumatism*." According to Bertrand it is similar to the *Bacillus welchii*.

Howell and Burton¹⁰¹ were unable to "dissociate" streptococci obtained from blood cultures of four patients who had rheumatic fever. The idea of dissociation, or mutation-forms, implies that each bacterium contains a virulent and an avirulent factor. It is believed that the virulent element, or form, of streptococci produces the smooth (S), and the avirulent, the

rough (R) colony It might be of great clinical value to change the smooth, virulent strain into the rough, avirulent type Two strains of nonhemolytic streptococci (*Streptococcus salivarius*), one of hemolytic streptococci (*Streptococcus pyogenes*) and one of *Streptococcus viridans* (*Streptococcus mitis*) were recovered in blood cultures In spite of chemical and physical means, and passage through animals, the strains remained virulent, smooth, and stable for eight months Howell and Burton concluded that there is little possibility of producing dissociation, a permanent change that occurs in a bacterium and then is transmitted to subsequent generations

Farah⁹⁹ expressed the belief that the disease is attributable to pneumococci which inhabit the throat and are generally mistaken for streptococci Intensive studies in a case of pneumococcus arthritis were used in evidence of this idea We have already mentioned the idea of Reitter and Lowenstein (1932), that the bacillus of tuberculosis is the cause

[Some of us have been unable to confirm the finding of tubercle bacillemia according to their method—Ed]

The chief proponents of the toxemic theory have been Birkhaug (1927) and Small¹⁰² Both have lately approved the allergic theory, as have many others^{90, 103}

[*Conclusions on Etiology* It is obvious that the cause of the disease has not been established The fact that so many different organisms have been isolated and are considered the cause of rheumatic fever suggests that probably no one of those so far isolated is responsible Rheumatic fever is a fairly distinct disease entity It would indeed be surprising were it found to be caused by many different organisms—Ed]

Special laboratory studies No new studies on blood cultures and agglutination tests are reported Eighty per cent of a series of 51 rheumatic children were skin-sensitive to hemolytic or nonhemolytic streptococci⁹⁰ Numerous investigations on throat cultures and on the relationship to rheumatic attacks of infections of the upper part of the respiratory tract have been summarized by Pilot and Davis,¹⁰⁴ by Weinstein and Styron,¹⁰⁵ and by Bradley⁹⁷ Not all epidemics of sore throat produce initial or subsequent attacks of rheumatic fever Only a small percentage of patients who have pharyngitis acquire the disease, but those who do acquire it or who already have it seem peculiarly sensitive to nasopharyngeal organisms, chiefly of the hemolytic streptococcal variety The *Streptococcus epidemicus* (a hemolytic streptococcus) seemed the major invader to Pilot and Davis¹⁰⁴ Weinstein and Styron¹⁰⁵ made 727 throat cultures of 261 patients (101 patients had rheumatic disease, 160 were controls) Green-producing streptococci were present in all throats, and indifferent streptococci in most Hemolytic streptococci were found in examination of 43 per cent of the patients who had rheumatic disease and in examination of 31 per cent of the control subjects, and were equally abundant in both Although the pharyngeal flora of the rheumatic patients was essentially the

same as that of the control subjects, exacerbations of the disease bore a definite relationship to the presence of hemolytic streptococci

Todd (1932) found in blood serum a substance (antistreptolysin, antihemolysin) capable of neutralizing the hemolytic substance formed in vitro by hemolytic streptococci. After any infection with hemolytic streptococci, the antihemolysin titer of serum rises materially. Increases were almost always found by him after an attack of acute rheumatic fever, a point in favor of a connection between the disease and hemolytic streptococci. The normal limit was thought to be 50 units. Coburn and Pauli (1932) agreed with these conclusions. Griffiths¹⁰⁶ found high titers (more than 50 units) in work with the serum of the majority of patients, who had subacute rheumatism, infective arthritis, spondylitis, or fibrositis, but generally the titer was normal in cases of spondylitis osteo-arthritis or in cases of osteo-arthritis. This suggests "an association between rheumatic disease and hemolytic streptococci that cannot be ignored." Much higher titers (more than 200 or 300 units) were found in working with the serum of normal persons by Myers and Keefer,¹⁰⁷ and by Wilson, Wheeler and Leask¹⁰⁸. The former agreed that in the majority of cases of rheumatic fever high titers are found, but states that in 21 per cent of them titers were no higher than those seen among normal persons. Furthermore, according to Myers and Keefer,¹⁰⁷ titers of the serum of patients who have atrophic and other forms of arthritis are normal. Wilson, Wheeler and Leask¹⁰⁸ found about the same very wide range of variation in both rheumatic and nonrheumatic patients, and concluded that the results are of no etiologic significance. Titers bore no relationship to the presence of agglutinins and were not related to results of cutaneous sensitization tests.¹⁰⁷

Fibrin of man is normally completely liquefied by filtrates of hemolytic streptococci (Tillett and Garner, 1933). The fibrin of patients recently recovered from hemolytic streptococcal infections is resistant to such lysis. Resistance to fibrinolysis is apparently attributable to production of anti-fibrinolysin and bears a close analogy to the production of antihemolytic antibody. Hadfield, Magee and Perry¹⁰⁹ have noted that patients who have a rheumatic relapse frequently demonstrate total resistance to lysis.

Other theories of etiology. The year's literature affords little support for other than the theory of infection. The metabolic theory was favored by Wainer⁵⁵. At least, Warner expressed the belief that many of the manifestations of the disease (not carditis) are due to causes other than infection, presumably an "altered underlying biochemical state" resulting from dietetic deficiency or imbalance. Rheumatic patients tend to eat too much carbohydrate, too little fat. Dietary correction lowers the tendency to the disease. Llewellyn's⁵⁵ discussion of his ideas along these lines is interesting but highly theoretical.

That rheumatic fever may result from the combined influence of vitamin deficiency plus infection, and from neither factor alone, was the thesis of Rinehart, Connor, and Mettier.¹¹⁰ Guinea pigs subjected to experimental

scurvy (deficiency of vitamin C), and then to superimposed infection, acquired cardiac, articular and other lesions markedly resembling those of rheumatic fever. Minor changes only were induced by either the diet or infection alone. Perhaps latent scurvy of man provides the rheumatic diathesis, conditioning patients to later precipitating infections.

[In a recent discussion on this work it was agreed that changes could be induced but some workers felt that the changes were probably scorbutic, not rheumatic—Ed.]

The combination of experimental deficiency of vitamin A and infection did not produce significant lesions at the hands of Stimson, Hedley and Rose,¹¹¹ but with other dietary deficiencies certain valvular lesions were produced in a few animals. Lesions similar to Rinehart's experimental myocardial lesions in scorbutic guinea pigs were produced by injections of streptococcal exotoxin, without introducing live microorganisms.

Treatment The value of established methods has been reaffirmed, no new treatments were proposed.

Drugs We are again reminded that salicylates are helpful in reducing fever and pain but that they do not prevent or alter cardiac complications.^{95, 112} Fantus¹¹³ advocated amidopyrine when salicylates fail or are not tolerated. Jenkins¹⁰³ expressed the belief that the use of atropine hypodermically is more efficient than salicylates in reducing fever and joint-distress but that it is equally as useless as salicylates for a real cure. The dangers of cinchophen have been overstressed, according to Lawler¹¹⁴ who expressed himself as in favor of the use of mono-iodocinchophen. No relief was received by six patients whom Slot and Deville¹¹⁵ treated with gold (solganol). Untoward reactions may occur therefrom: nephritis and jaundice. Injections of histamine were given by Shanson and Eastwood¹¹⁶ to patients who had subacute rheumatism, moderate relief was noted.

Tonsillectomy The controversy regarding the value of tonsillectomy has continued. The majority of observers favored it. Thus Miller¹¹⁷ expressed the belief that it gives the best chance of safeguarding rheumatic children from the more serious forms of the disease. According to Swift, among nonrheumatic persons, five to 30 years old, who have tonsillitis or pharyngitis, only about 10 per cent may be expected to suffer from definite rheumatic fever, but among those of that age who have previously had rheumatic fever, at least 50 to 60 per cent who acquire infections of the throat will have a new attack of rheumatic fever. Thus the importance of tonsillectomy in safeguarding such patients is obvious. The opinions of Kaiser⁶⁵ are well known: subsequent attacks of rheumatic fever occur slightly more often among children whose tonsils have not been removed at the initial attack. The mortality rate is nearly 50 per cent less among those whose tonsils have been removed before the initial attack. Tonsillitis or sore throat preceded rheumatic fever in 59 per cent of children studied. Although tonsillectomy lessens the mortality and the incidence of the more serious rheumatic manifestations, it does not prevent recurrences. The

views expressed by Coates and Gordon¹¹⁸ were similar. Stahl¹¹⁹ noted no ill effects, but often much benefit, from early tonsillectomy.

Wholesale tonsillectomy is useless, according to Schlesinger⁷¹ and to Poynton,¹²⁰ for pharyngitis affecting a tonsillectomized child can cause rheumatic fever. The tonsils should be removed, however, if they are septic or markedly enlarged, or if the child has repeated attacks of sore throat.

Diet. Poynton¹²⁰ has not noted the reputed dislike of rheumatic children for fat. A diet such as is given in the presence of any febrile disease seemed indicated to Douthwaite¹²¹ but in spite of cellular destruction and loss of nitrogen from fever, he advised not to increase the intake of proteins lest indigestion ensue. For the sickly child an increase in calories may be most helpful.⁷⁰

Rest. The value of prolonged rest was stressed by all writers.

Vaccines, antigens, serums. Contrary to the opinion of many, Wolffe⁹⁵ and Cecil⁵⁶ expressed the belief that streptococcal vaccines are of value in treatment and prophylaxis. Injections of bacterial antigen of *Streptococcus cardio-arthritidis*, in smaller doses than any yet used in biologic therapy, are definitely helpful, according to Small¹⁰². The antigen is diluted to an extent which at first appears to be an absurdity, but control studies convinced Small of their potency and usefulness. Overdosage is followed by prompt exacerbations of rheumatic fever. A discussion of the various reactions to treatment and a detailed plan of dosage are given in the article. In general, the use of foreign proteins is unsatisfactory but occasionally, in obstinate cases, it gives startling results, and stops the acute attack speedily.^{70, 113}

[Some may have a remission shortly thereafter, however—Ed.]

In 12 cases results with streptococcus (scarlatina) antitoxin were encouraging.¹¹²

Climate and institutional care. Convalescent homes constitute one of the greatest advances in the therapy of this disease.^{61, 71} A prolonged sojourn in a subtropical climate may be a "specific." Eleven of 14 patients who had active carditis and who were sent by Nichol⁵⁷ to Miami improved markedly or went into a remission. Roche and Jones¹²² sent to Florida 14 children who had been affected with severe carditis for an average of four years, 12 of them were conspicuously improved. Even after they had returned to New England improvement continued.

Effect of pregnancy. From a study of 40 males (as controls), 28 nulliparous women and 41 parous women who had carditis, Gilchrist and Murray-Lyon¹²³ were unable to show that two pregnancies shortened the life of the rheumatic patient. One or two children may generally be borne without detriment. Similar conclusions were reached by Scott and Henderson¹²⁴, the physical strain of pregnancy can be minimized or counteracted by sufficient rest. If the patient has the means to obtain rest, one or two pregnancies may be permitted. However, repeated pregnancies are not well borne and may provoke fatal cardiac decompensation.

Prophylaxis Prevention of relapses is more likely under the following regimen^{71, 113} a nutritious diet high in vitamins, cod liver oil, tonsillectomy, outdoor life with graded exercises, avoidance of chilling and, above all, of respiratory infections. If the latter are epidemic, avoidance of chilling and of crowds, spacing of beds, isolation from patients who have colds, sterilization of the patient's plates, cutlery, and pencils, concentrated treatment with acetylsalicylic acid for three weeks after an infection of the throat, and a stay in a warm room during such an infection, are indicated. Institutional care or life in a subtropical climate is most helpful in certain cases.

SYDENHAM'S CHOREA

It was accepted by Mutch¹²⁵ and by Copeman¹²⁶ that Sydenham's chorea is related to rheumatic infection, as is indicated by the occurrence of cardiac sequelae in 30 to 40 per cent of cases of chorea. Nervous strain and deficiency of calcium may also be factors¹²⁵. However, since the sedimentation rates are generally normal in cases of chorea not accompanied by carditis, some investigators⁵⁵ have expressed the belief that the condition may not be infective, although complicating carditis probably is. The average duration of the disease is about 27 days in mild cases, 44 days in moderately severe cases and 62 days in severe cases^{125, 127}. Copeman expressed the belief that it lasts more nearly three months than six to ten weeks as generally is stated.

Treatment The therapy of the past was outlined by Mutch¹²⁵. Three newer contributions to the therapy of chorea are the use of the sodium salt of phenyl-ethyl-hydantoin (nirvanol), of ketogenic diets, and of typhoid-paratyphoid vaccine. Mutch and others got little result with diet. It has been noted repeatedly that patients who have chorea have been benefited by intercurrent fever (Turnovszky, 1930) and that measures which help most in chorea are accompanied by fever. Various methods of fever therapy have accordingly been advocated: the use of nirvanol (Roeder, 1919), auto-serum (Brown, Smith, Phillips, 1919), chemical protein (Horton, 1922), fever reactions with milk (von Kern, 1923, Hymanson, 1926), *Typhoid-paratyphoid vaccine* (Sutton, 1931, Trawley, Pepper and Wathe, 1932, Bateman, 1933).

[More recently, fever machines and colloidal sulphur have been employed. Reports on these belong in our next review.—Ed.]

Nirvanol The usual nirvanol reaction includes drowsiness, headache, fever, rash, eosinophilia and leukopenia, the fever presumably is the useful component. Untoward reactions may occur: purpura, jaundice, diarrhea, nephritis, incontinence of urine, enlargement of the spleen and liver, prolonged high fever, coma and occasionally death^{125, 128}. Of 28 cases in which Silber and Epstein¹²⁹ administered treatment, in 10 improvement was prompt, choreiform movements stopping completely. In 18 there was no improvement, in nine of these cases the reaction failed to develop. Asso-

ciated carditis is not affected by the treatment Marick¹³⁰ noted improvement in the majority of 55 cases in which treatment was given. However, two to three years later some of the patients had recurrences, others, dyspnea, many were still nervous. Recurrences therefore apparently are not prevented by nirvanol. Its value was accepted by Call¹³¹ with reservations. Of 26 patients, 18 were markedly improved in 10 days, five became free of symptoms in 20 days. In one case, adenitis, ulcerative stomatitis and gingivitis, and ulcerative conjunctivitis developed but the patient recovered. In spite of these and other favorable reports (Pilcher and Gerstenberger, 1930), the Council on Pharmacy and Chemistry of the American Medical Association has not seen fit to accept the drug (1932). Mutch¹²⁵ expressed the belief that the use of nirvanol is dangerous, Copeman¹²⁶ found it of little value. Don¹²⁸ stated his belief that generally it can be given with confidence, however, he noted prolonged, persistent fever in one case.

Typhoid-paratyphoid vaccine. The advantages of febrile reactions produced by vaccine were first reported by Sutton (1931). A second report¹²⁷ concerned 150 patients so treated and 150 patients treated otherwise. By inducing fever with the vaccine, the duration of mild cases was shortened (as compared with those treated otherwise) from 27 to six days, moderate cases, from 44 to nine days, severe cases, from 62 to 16 days. The average number of treatments required was six (from three to 18), they were usually given daily. In only 10 per cent of cases was the result disappointing. No untoward reactions were encountered. Active carditis was not a contraindication, indeed, it seemed to be benefited. Capper and Bauer¹³² induced 297 reactions in 23 cases (generally in series of one each day for one week). The disease in these cases had lasted from four months to four and a half years. Marked improvement in some, and in several prompt cures were obtained and were maintained many months. Equally impressive results were obtained by Fish¹³³ and by Redfearn¹³⁴ in one case each, and by Hoverson¹³⁵ in two cases. Hoverson also treated four patients who had Huntington's chorea, two completely recovered, two were unrelieved.

Comparing the results from the use of typhoid vaccine (23 cases) with those obtained with nirvanol (24 cases) Montfort¹³⁶ strongly favored the former on the grounds that it shortens the course of the disease, is harmless, is followed by a significant lack of recurrences and sequelae, and is easy to administer. With nirvanol, which was definitely helpful, the disease lasted an average of 24 days, with vaccine, 16 days. Marick on the other hand felt that each was helpful but that nirvanol was safer.

Other medicines. Believing that a disturbance of calcium metabolism occurs with chorea, Mutch¹²⁵ prescribed calcium-acetylsalicylic acid, 60 grains (4 gm.) daily. The nervous manifestations were controlled after an average of 17 days (7 to 46 days).

CHRONIC ARTHRITIS

Introduction and Terminology Because of its frequency and the chronic disability which it produces, chronic arthritis in conjunction with fibrositis has an enormous morbidity rate. The economic importance of this disease is greater than that of tuberculosis, heart disease and cancer combined.^{2,4} When the term "chronic arthritis" is used, it generally refers to "atrophic arthritis" or "hypertrophic arthritis" or to both forms undifferentiated, all other forms of chronic arthritis such as tuberculous, gonorrheal, traumatic, or gouty arthritis are, or should be, tacitly excluded. In this review, regardless of the terms used by authors quoted, we shall use the nomenclature adopted by the American Committee,¹³⁷ according to which "atrophic arthritis" is employed as synonymous with "chronic infectious," "proliferative," "type one," "synovial" and "rheumatoid arthritis", and "hypertrophic arthritis" as synonymous with "chronic senescent," "degenerative," "type two," "chondro-osseous arthritis" or "osteo-arthritis". Terms approved by the committee as a group are not necessarily those individually preferred by members of the committee or by the editors of this review. It is assumed that the reader is familiar with the basis of these terms and with the various criticisms thereof.^{4, 137, 138, 139} Each term has its merits and its demerits. Under certain circumstances a pathologic term may be preferable, under other conditions a clinical term seems best, it is important for the reader to recognize their synonymy.

Etiology, General Remarks Current reports continue the arguments as to the relationship between the two great types. The majority of authors feel that the two are so different in clinical, chemical, roentgenologic, and pathologic manifestations, as well as in prognosis, that they must be considered separately and must represent two distinct diseases. Others believe that the two are merely different manifestations of the same fundamental disturbance and that their obvious differences arise merely from the factors of the patient's age at the time of onset of the disease, of his physique (asthenic or hypersthenic constitution) or because of differences in the reactions of various individuals to the same insult. Still others believe that the so-called differences are more imaginary than real, and that there is but one type which may, however, arise from one or several causes. Regardless of whether the two types have a common etiology, the great majority of writers insist that clinically they are sharply distinct.

Strictly speaking nobody, of course, confines himself to a belief in one solitary cause. All recognize the interdependence of seed and soil, but opinions differ as to whether abnormality of the seed or of the soil is the more important, and as to what is the essential cause without which, regardless of the presence or absence of contributory or precipitating factors, the disease could not eventuate. At times the contention simulates the one on the priority of the hen or the egg. Those who favor the theory of infection ascribe primacy to the seed and believe that a microorganism is the essential cause,

although admitting the need for a proper soil. Those who favor the "metabolic theory" generally admit the secondary importance of focal or other infection but lay stress on physiologic alterations which prepare the soil for various bacteria to produce arthritis. The two viewpoints are by no means as antagonistic as some would believe. The adherents of each are probably but facing each other, perhaps at times a bit angrily through the same window.

Those who favor the idea of separate types and of the probability of a separate cause for each type are too numerous to mention but include, in this country, Bauer, Boots, Dawson, Cecil, Ghrist, Hall, Hench, Holbrook, Key, Miller and many others.

Those who favor the clinical separation of the two types but believe that both may have the same cause, or very closely allied causes include, in this country, Fletcher, Osgood, Pemberton, White and many others. Adamson⁶ expressed his viewpoint thus: "As champagne or port wine will do nothing to one person, give another gout and give a third a headache so streptococci on a soil previously prepared by intestinal toxemia may produce rheumatoid (atrophic) arthritis in one, (hypertrophic) osteo-arthritis in another, fibrositis in a third, one of the differences being not in the bacterial invasion but in the physico-chemical or 'electro-chemical' state of the tissues."

[The analogy is interesting but is worthy of criticism. Nobody believes that champagne and wine are causes of gout. They merely act as one of many widely different predisposing or precipitating factors. Much confusion is fostered by such statements in which writers do not assiduously differentiate in their papers, or even in their own minds, between what are merely inciting or predisposing factors and what should be considered the actual etiologic factor, the *sine qua non*. Were the numerous secondary factors in the production of the chronic arthritides not so often thoughtlessly or carelessly raised to the status of prime cause, there would not be so many theories and variants thereof to pester us.—Ed.]

R and J Kovacs¹⁴⁰ argued that a streptococcal infection of low grade is present in both types of arthritis, the type resulting depends on the patient's constitutional configuration—atrophic arthritis in the asthenic, hypertrophic in the sthenic type. Sherwood's¹⁴¹ therapy is based on the idea that both, and also the menopausal type, are of infectious origin.

[No proof is offered regarding etiology. "Menopausal arthritis" is not a clearly defined entity.—Ed.]

Brooks¹⁴² expressed the belief that both are infectious but that atrophic arthritis is probably streptococcal, hypertrophic arthritis staphylococcal, in origin.

[This is the exact opposite of Crowe's ideas, 1930.—Ed.]

According to Haden¹⁴³ the fundamental factor in both types is probably a disturbance in capillary circulation. Elsewhere, however, Haden^{144, 145}

has seemed to favor the theory that any one of a number of different causes may produce either type of arthritis

Those who would reunite the two types under one heading, and who favor a unity of causation, include Archer, Burbank, Clawson and Wetherby, Knaggs, Willcox, and Wright. According to Archer¹⁴⁶ the (unstated) cause of both may be the same, since, in a somewhat analogous manner, syphilis can cause either a proliferative (syphilitic) arthritis or a degenerative arthritis of the Charcot type. Wetherby¹⁴⁷ was unable definitely to segregate atrophic or hypertrophic arthritis or even rheumatic fever one from another because of the clinical, humoral, radiologic, and pathologic similarities which he found they exhibited. He expressed the belief that all are probably streptococcal. In his opinion chronic arthritis may often result from an acute attack indistinguishable from rheumatic fever.

[Shapiro,¹⁴⁸ in the same city, studying "several hundred cases" of rheumatic fever from childhood to adulthood, found no instance wherein chronic arthritis directly followed rheumatic fever—Ed.]

Burbank¹⁴⁹ expressed the view that chronic arthritis is caused by an infection, the chief offenders are streptococci, not of a specific strain, together with a variable, "X." The latter factor may be dietary defect, endocrine abnormality, sensitization, depletion from some intercurrent cause, mental and physical trauma, faulty posture, or some other abnormality. While infection may play a rôle in each type of chronic arthritis, a nutritional change, probably a vitamin deficiency, is the fundamental cause of both, according to Wright¹⁵⁰, the difference mainly arises from the variable reactions of different people.

[Again no proof whatever is offered—Ed.]

The idea of one clinical type produced by various causes is again advocated by Nissen,¹⁵¹ Nissen and Spencer,¹⁵² and Ober.¹⁵³ Accepting the concept that chronic arthritis is one disease, Nissen expresses the belief that variations are a matter of individual reaction and that the very multiplicity of functional disturbances points definitely to the conclusion that there may be no one etiologic agent. With this Ober agrees, although elsewhere he and Burnett¹⁵⁴ have suggested that "non-specific arthritis" is a deficiency disease.

[Data given do not permit this conclusion. True arthritic changes, as contrasted to scorbutic changes, have never been clearly demonstrated in animals on diets variously deficient—Ed.]

Arthritis is not a disease, per se, according to Wolf,¹⁵⁵ but a symptom—an expression of an inflammatory reaction to an infinite number of factors.

[The editors cannot but feel that, regardless of etiology, the two diseases are separate and not merely different manifestations of the same process among persons of different age groups. Classical atrophic arthritis frequently is seen just appearing when patients have passed the age of 50, 60 or 70 years. Atrophic arthritis at this

stage is essentially the same as it is at the age of 20 years. Conversely, not infrequently one sees cases of premature senescent arthritis—typical hypertrophic arthritis with Heberden's nodes—affecting a woman 30 to 35 years of age. Thus, too, rheumatic fever occasionally may first appear in a person past 50 years of age. Although minor variations appear in adult rheumatism as compared to juvenile rheumatism, the two chief characteristics of the disease, carditis (not endocarditis) and articular resolution without chronic arthritis, are manifest in both groups, regardless of age. It is admitted that the patient's tissue-age and chronologic age are not necessarily identical but it seems apparent that, regardless of age at onset, the two diseases tenaciously retain their distinct identity too often for us to accept the idea that the varying clinical expression of arthritis is conditioned by age only, either tissue-age or chronologic age. It is understood, of course, that the editors recognize the differences between clinical hypertrophic arthritis, one disease, and radiologic hypertrophic arthritis, several diseases—Ed.]

The terminology favored by individual writers depends of course on their ideas on etiology. If they are sufficiently convinced of the bacterial causation, they call the condition "infectious arthritis", otherwise they rely on less committal terms based on pathologic, radiologic or clinical differences. Brooks¹⁴² subdivided streptococcal rheumatic disease on anatomic grounds into types affecting various tissues such as mucous, dermal, connective, fatty, muscular, cardiac, nervous, glandular, ocular, otic, and articular tissues. Others also (Fisher, 1929) have subdivided "chronic arthritis" into synovial (atrophic) arthritis, or chondro-osseous (hypertrophic) arthritis. Another writer¹⁵⁶ has proposed a numerical and alphabetical system as a simplified means of recording the various etiologic factors: allergy, bacteria, climate, diet, endocrine abnormalities, fatigue, gastrointestinal disturbances, trauma, nervousness. The unknown factor, "X," is the soil. If "B" signifies bacteria, "E" endocrinopathy, "N" nervous disturbance, and "T" trauma, and the patient has such abnormalities, his formula reads Patient = X (B + E + N + T).

[Such a "simplified" concept seems more ingenious than practical—Ed.]

DISTINCTIONS BETWEEN THE TWO TYPES CLINICAL, PATHOLOGIC, AND RADIOLOGIC

The accepted distinctions between the two types were outlined fully in the first review⁴ and in the Primer¹³⁷ and will not be repeated here. Gelber and Goldberg¹⁰ reviewed the usual roentgenologic differences, using Goldthwait's¹⁵⁷ classification, in which rheumatoid arthritis is subdivided into "infectious arthritis" and "atrophic arthritis."

[Here as elsewhere the roentgenologic subdivision seems not clear, and unnecessary—Ed.]

Various roentgenographic alterations are common to all types of arthritis, according to Taylor, Ferguson and Kasabach,¹⁵⁸ and there is no one diagnostic feature in any. However, each type has a characteristic combination of alterations that makes a roentgenogram valuable in diagnosis.

To venture a clinical or etiologic diagnosis, the roentgenologist should at least be told the duration of the disease. The roentgenogram in a case of fairly early gonorrheal destructive arthritis may simulate that of late tuberculous destructive arthritis. In roentgenograms, atrophic and hypertrophic arthritis appear to be distinct entities. Both may affect the same joint, even so, the characteristics of each type are generally demonstrable. The constancy of the findings in cases of atrophic arthritis does not favor further subdivision of this group.

ATROPHIC (INFECTIOUS, PROLIFERATIVE, RHEUMATOID) ARTHRITIS

Symptoms and Course In some cases the onset is abrupt, with an acute, febrile reaction, considerable articular heat, redness, swelling and other constitutional signs of infection, this subtype is often distinguished from the more chronic variety and has been called "subtype a" by Holbrook,¹⁵⁹ "group one" by Cox and Hill,¹⁶⁰ "secondary rheumatoid arthritis" by Buckley¹⁶¹ and "infectious arthritis" by Senturia.¹⁶² This variety of the disease is generally attributed to infection. Foci of infection are usually to be found and their removal may cause prompt and notable improvement, with early cessation, instead of an indefinite, smouldering progression of the disease.

In the majority of cases, however, the onset is insidious and relatively afebrile, joints are affected somewhat symmetrically, foci of infection either are not found or their removal gives little relief. This major variety has been called by various authors "subtype b,"¹⁵⁹ "group two,"¹⁶⁰ "primary rheumatoid arthritis,"¹⁶¹ and "atrophic arthritis."¹⁶²

Usual symptoms of the disease need not be listed again here.⁴ Wethely again has reported his analysis of 350 cases (1932 and 1934¹⁴⁷) of chronic arthritis but since cases of both types were indiscriminately included, the analysis does not lend itself to comparison with others.

[Even though an author believes in unity of cause, for the sake of comparative statistics he should include a clinical differentiation, otherwise his data are practically useless—Ed.]

Acute rheumatoid (atrophic) arthritis and Still's disease are one and the same, according to Moltke¹⁶³ who reported four cases of the former (adult Still's disease) in males, aged 15 to 28 years. Common characteristics were subacute, sometimes remitting, fever, peri-arthritis with fusiform swelling, poly-adenitis (in 37 per cent of a larger group of cases of atrophic arthritis), anemia, muscular atrophy, sweats, increased rate of sedimentation, and chronicity. Splenomegaly is not a requisite for Still's disease, it was absent in three of Still's 10 cases. Serositis of the pericardium, pleura, and peritoneum are variably present in Still's disease, they are rarely found in atrophic arthritis. Splenomegaly in cases of juvenile Still's disease represents a physiologic response more common in children than in adults.

Of four cases of *scleromalacia perforans* (various-sized holes in sclera without dominant signs of inflammation) reported by van der Hoeve,¹⁶⁴ in three the patients were women who had advanced atrophic arthritis. Perhaps both affections have a common cause.

Nissen¹⁵¹ and Nissen and Spence¹⁵² expressed the belief that "individual reactions" rather than factors of heredity, environment, focal infection, worry, age of onset, severity or duration of arthritis, or treatment determine the prognosis. Following the course of 95 patients with different types of arthritis to their deaths, these authors found that four life courses were graphed regardless of the type of arthritis present. Course A is that of the patient who, with the onset of arthritis, drops to some lower level of activity. He remains there for a time, and then, because of better tissue inheritance, determination, successful therapy, or natural individualistic reaction, he climbs back to the former level of activity and remains there for the rest of his life. The average duration of life after the onset of the disease was 27 years. In course B the patient, after his initial attack, experiences remissions and relapses, the latter increasing in duration and frequency, the mean course is a slow, steady decline. The average duration of life after the onset was 17.3 years. In course C the patient progresses until he receives a severe systemic upset, perhaps an infection, then rapidly polyarticular destruction develops, at which level of crippledness he may remain, with little variation in his arthritis, he may survive long at a minimal level of function. The average duration of life after onset was 19 years. In course D the disease develops acutely or insidiously, it progresses with variable rapidity, the life course dropping steadily to death, in such cases surgical measures may be dangerous. The average duration of life after onset was seven years.

[Such figures as the authors gave, mixing various types of arthritis—atrophic, hypertrophic, mixed types, gonorrheal, tuberculous and rheumatic fever—all together are unfortunately of little value. It might be said that a patient who has almost any chronic disease, regardless of all other factors, will (a) soon get well, (b) slowly get worse but not die, (c) rapidly get worse but not die, or (d) die fairly soon. After all, there are no other possibilities. However, such few statistics as the authors gave on the course of the separate types represent valuable information. The authors must have some very useful information were it restated.—Ed.]

Of 27 patients who had atrophic arthritis (type I) 4 per cent (one case) followed life-course A, 36 per cent (10 cases) course B, 30 per cent (eight cases) course C and 30 per cent (eight cases) course D. In comparison, 3 per cent (one case) of 30 patients who had hypertrophic arthritis (type II) followed course A, 70 per cent (23 cases) course B, none course C, and 20 per cent (six cases) course D.

[This statement is not clear. It implies that in certain cases hypertrophic arthritis leads to fairly rapid death, an untenable idea.—Ed.]

Of 26 cases of mixed (atrophic and hypertrophic) arthritis, 12 per cent (three cases) followed course A, 46 per cent (12 cases) course B, 15 per cent (four cases) course C, and 27 per cent (seven cases) course D. Of eight cases of Strumpell-Marie's disease (atrophic spondylitis) 80 per cent (five cases) followed course B and 20 per cent (three cases) course D.

The effect of intercurrent disease (tuberculosis, syphilis, pernicious anemia, gout, psoriasis, diabetes, and hyperthyroidism) on the course of atrophic arthritis was discussed by Cecil¹⁶⁵ who expressed the belief that atrophic arthritis rarely but occasionally occurs in association with tuberculosis, he gave examples of the coincidence of arthritis with the diseases mentioned.

Pathology The pathologic distinction between atrophic and hypertrophic arthritis has been fully given^{4, 187, 188, 139} and has been reviewed by Pemberton and Bach¹⁶⁶. No new work was presented.

Routine Laboratory Data In atrophic arthritis (18 cases) according to Steinberg¹⁶⁷ the average leukocyte count is higher than it is in hypertrophic arthritis (26 cases), in the former there is a definite tendency for the Schilling differential count to shift to the left. This fact may be helpful in differentiation. Persistent eosinophilia of 5 to 8 per cent may occur in severe cases. As does the sedimentation rate, so does the nuclear count in atrophic arthritis reflect the severity of the disease to a great extent and together with the rate of sedimentation, the nuclear count can be used as an index of activity, according to Rawls, Gruskin, Ressa and Jordon¹⁶⁸ who studied 263 determinations of the rate of sedimentation and 258 nuclear counts in 50 cases. The value of the rate of sedimentation has been similarly confirmed by Stainsby and Nicholls¹⁶⁹ who, using the corrected sedimentation index of Rourke and Ernstene, noted that the average rate increases with the patient's age and tends to be lower in summer than in winter. Changes in the agglutinin titer for hemolytic streptococci appear and develop slowly, they are not related to the activity of the disease and no correlation between them and the sedimentation rate exists. A method of determining the sedimentation rate with blood obtained from a pricked finger, without venipuncture, was described by McSweeney¹⁷⁰.

Degenerative diseases are more likely to be associated with hypercholesteremia than are inflammatory diseases, which are often associated with hypocholesteremia. Some significance may be attached, therefore, to the finding by Bruger and Poindexter¹⁷¹ that in seven cases of hypertrophic arthritis the concentration of plasma cholesterol was higher (178 to 441 mg per 100 c c) than it was in three cases of atrophic arthritis (168 to 229 mg per 100 c c). These findings were confirmed in the larger series of Hartung, Greene and Bruger¹⁷² (33 cases of atrophic, 59, of hypertrophic arthritis). The concentration of serum calcium in atrophic arthritis is essentially normal, in hypertrophic arthritis it is slightly but significantly increased, an increase not attributable to age¹⁷².

Etiology and Pathogenesis In general the year's literature presents no

significant modifications of the outline and schemes given in last year's review. Current theories remain (1) that of infection with the three variants, (*a*) bacteremia, (*b*) bacterial toxemia, and (*c*) bacterial allergy, (2) that of metabolic abnormality with its numerous variants such as the ideas of (*a*) deranged metabolism of carbohydrates, (*b*) deranged metabolism of protein, (*c*) deranged metabolism of sulphur, (*d*) food allergy, and (*e*) vitamin deficiency, (3) the theory that circulatory imbalance or deficiency leads to articular "blood hunger" and consequent arthritis, and (4) the theory of endocrine abnormality. Writing on the etiology and pathogenesis of arthritis, investigators in the past have, of course, recognized the interrelationship of three factors (1) the predisposing factor, soil, (2) the true or fundamental etiologic factor, generally thought to be a micro-organism, and (3) the precipitating factor, such as shock, grief, nervous fatigue, endocrine crisis and so forth. Thus, there has been formed the useful equation of the causal factor as the numerator, and the person's resistance (soil) as the denominator. When the value of the denominator is equal to, or greater than, that of the numerator, arthritis does not occur, regardless of foci of infection and so forth. When the balance is upset by an increase in the numerator (added infection) or by a decrease in the denominator (a change in the patient's resistance making the soil proper for the development of the disease, the soil perhaps altered as a result of some precipitating factor) then arthritis may occur. Tacitly admitting the importance of all these factors of the equation, writers, nevertheless, have been inclined to stress sharply the overwhelming importance of the seed—the fundamental factor without which arthritis cannot develop regardless of soil, precipitating factors or other factors. In articles of the past, the tendency was for the author to state rather boldly what he believed the main cause of the disease to be, whether infection, metabolic abnormality, endocrine disturbance, or neurogenic disorders, and for the author to give but little recognition to the arguments of others.

In current literature a subtle change is evident. It is rare now to read the blunt statement "a germ is responsible" or "circulatory derangements are the cause." Now, while still defending the claims of their favorite causal factor, writers are admitting the significance of other factors. Speaking with less assurance on their favorite theme, they are careful to erect a small monument to the unknown god of others. They resemble the roulette player, who, after carefully placing his chips, tosses a precautionary one on the 0 or double 0 just before the "rien ne va plus." Thus splitting their ticket, they are taking the best from each theory to support the eclectic theory that there is probably no one cause for the disease and that any one of a number of causes may be responsible.^{143, 173}

This indicates a growing tolerance, perhaps a broadening of vision, but it has not yet led to increased clarity of ideas, rather the opposite. For during this stage of transition the literature has become less clear, ideas are less concise and it becomes increasingly difficult to catalogue a writer. One phy-

sician wrote "There is no one cause for chronic non-specific arthritis of either type. Perhaps most cases result from the interaction of several factors. It is quite probable that a disturbed circulation is often the primary disturbance."¹⁴⁴ But elsewhere¹⁴³ he wrote, "There is not one cause for chronic rheumatism. Perhaps most cases result from the interplay of several factors. Infection is the most important factor in the atrophic type." And again,¹⁴⁵ "Possibly the disease (atrophic arthritis) cannot develop in the absence of bacteria but the presence of bacteria alone is insufficient in most cases to produce the disease, so other factors are of equal or greater importance." Thus it is difficult to know just what the writer believes on causation, but it is evident that he, long a thoughtful student of the subject and once a firm believer in the theory of infection, is becoming less certain of the rôle of bacteria in arthritis. This state of affairs, confusing and fruitless at the moment, presages advance, because it indicates dissatisfaction with current ideas.

[The eclectic theory does not satisfy the editors of this review. A disease as consistent in its manifestations and course as is atrophic arthritis is assuredly not caused one day by this, the next day by that, factor. Granting the soil and other predisposing, precipitating and aggravating factors all the importance they deserve, there surely must be one prime cause, "X," without which the disease cannot begin or continue. Current confusions, including ideas on polymicrobial origin, are entirely analogous to those held in regard to tuberculosis before the "X" of that disease, the bacillus of tuberculosis, was finally isolated.—Ed.]

Factor of heredity Buckley¹⁶¹ stated that heredity is a factor in about 50 per cent of cases and that, probably because of endocrine influences, sympathetic instability, and defective assimilation of calcium, the bodily characteristics of the candidate for arthritis are a slight, spare physique resembling that of persons who are prone to acquire tuberculosis. Walker¹⁷⁴ also stressed the congenital nature of the disease and gave family charts of 13 patients, five of whom had arthritis. He suggested that arthritis is a congenital abiotrophy, resulting from the union of unsuitable types: the union of short and tall persons, of persons with different blood groups, and of persons with straight and with wavy hair.

[Blood groups in 1000 cases studied by Race¹⁸⁹ were what might be expected from a sampling of the general population.—Ed.]

Walker wrote "These people inherit the diaphyses of all or part of their bones from one racial element and the epiphyses from another. Sometimes this inheritance is one-sided. The receptivity of these tissue-masses cannot be expected to be the same to a given hormone." By some process of reasoning Walker deduced that therefore the pancreas has to work overtime and becomes exhausted. Hence improvement may follow the use of pancreatin and a starch-free diet. In one of Cecil's families the disease was traced through four generations.¹⁶⁵

[We believe that statements like the above will lead the reader to agree with Cecil that remarks on the hereditary nature of arthritis are usually very loosely presented and unsupported by accurate data. Of course almost every family presents arthritis and many are riddled with senescent arthritis if with no other form. Statistics on heredity and arthritis are erroneous because generally data on the type of arthritis present are not given.—Ed.]

Factor of infection That some infection, probably streptococcal, is the major factor is still the belief of the majority, and the familiar arguments are presented by many. Buckley,^{30 161} Cecil,¹⁷⁵ Sprunt¹⁷⁶ and Burbank¹⁴⁹ Cecil, Griffiths,¹⁹⁶ and Dawson, Olmstead and Jost¹⁷⁷ are among those who incriminate hemolytic streptococci. The bacteremic variant of the infectious theory is held by Cecil and by Burbank. The latter has expressed the belief that although the streptococcus is the chief offender, it is not a specific strain but one which has developed the power to ferment mannite and to live in the presence of a comparative deficiency of oxygen. Such organisms possess definite powers of adaptation and mutation, and may reduce their chains to appear as diplococci, or may dissociate into diphtheroid forms, or even may appear as staphylococci similar to Crowe's *Micrococcus deformans*. According to Burbank, the power of adaptation is shown by the fact that the apparent focus of infection rarely contains a streptococcus similar in type or in power to ferment sugar to that isolated from the joints at biopsy. The organism changes its nature from one with invasive properties to one more parasitic in nature, thus avoiding the strong immunologic reactions of the host, which would kill it.

The idea of specific bacterial toxemia apparently has been abandoned in favor of that of bacterial allergy from one or from multiple strains of streptococci or other bacteria. The basis for this idea has been reviewed by Hitchcock¹⁷⁸ indirect evidence based on cutaneous reactions, variability in cultural results, supposed desensitization by the use of bacterial antigens, and so forth. On the basis of skin tests, Wainwright¹⁷⁹ has tentatively accepted the idea of bacterial allergy. From 94 blood cultures made in 91 cases of atrophic arthritis he recovered streptococci (viridans) in only one case, diphtheroid organisms in four cases and contaminants in seven cases (staphylococci four times, gram-positive bacilli three times). In 14 cases cultures of joint tissues were made in 12, these cultures were negative, in two, molds were found. The serums in 46 (90 per cent) of 51 cases were found to possess agglutinins for hemolytic streptococci in dilutions varying between 1 to 20 and 1 to 1280. Thus the extent of the dilution was somewhat lower than that reported by others. The presence of such agglutinins in serum of patients who have this disease seems well established, but this does not of necessity indicate a causal relationship. As has been suggested by others, agglutination may be attributable to the presence of natural, not acquired, or specific agglutinins, but the frequency with which it occurs is to Wainwright the best evidence thus far produced that the streptococcus is the cause of the disease.

All of Wainwright's 55 patients who were tested gave positive cutaneous reactions to one or more strains of hemolytic or green-producing streptococci. Whole organisms were used. In 24 cases the reactions were positive to hemolytic streptococci only, in three, to *Streptococcus viridans* only, and in 28 to both types. In 90 per cent maximal reactions were to the hemolytic type, in 10 per cent to viridans, but no single strain predominated in causing maximal reactions. When cutaneous sensitivity exists it does not necessarily also indicate articular or general sensitivity. Objections raised to the interpretation of cutaneous reactions to autogenous vaccines, that they may indicate varying irritability of the patients' skins, natural toxicity of the bacterial species, or perhaps sensitization to certain bacterial groups, must be considered.

Further indirect evidence of a relationship between hemolytic streptococci and atrophic arthritis is, according to Dawson, Olmstead and Jost,¹⁷⁷ provided by a comparative study of precipitins and agglutinins. It was found that there was close approximation, but not absolute agreement, in the capacity of the serums of 71 patients who had atrophic arthritis to agglutinate strains of hemolytic streptococci and to precipitate various group-specific fractions of this organism. These findings suggest that agglutination tests represent a true immunologic reaction, but both agglutinin and precipitin reactions are group-specific and not specific for any particular strain. Whether hemolytic streptococci play a primary or secondary etiologic rôle cannot be concluded.

Discussing the reliability of such indirect evidence, Dawson¹⁸⁰ admitted that cutaneous reactions in his cases have been variable and difficult to interpret. No correlation was found by him between the degree of cutaneous reactivity and the clinical condition of the patient. Cox and Hill¹⁸⁰ found no apparent relationship between variations in the patient's clinical course and his agglutination titers, or between the latter and cutaneous reactions. Cecil's hemolytic streptococcus AB13, however, had greater serologic selectivity for atrophic arthritis than for any other disease-group studied, and the high percentage of serums which contained agglutinins to this strain could not be accounted for on the basis of previous artificial immunization or on that of previous or concomitant streptococcic infections. Cox and Hill concluded that agglutination to this strain has a definite but limited use as a diagnostic aid. Difficulties in interpretation of cutaneous tests were further stressed by Jones and Mote,¹⁸¹ who noted certain reactions attributable not to the streptococci but to animal proteins injected therewith.

More direct evidence of infection has been sought by others. Blair and Hallman¹⁸² made 57 cultures of synovial fluid and of tissue derived from patients who had atrophic arthritis and 175 cultures from patients who had other types of arthritis. Of the former 75 per cent, of the latter 81 per cent, remained sterile. A variety of organisms was found in the remaining cultures, to none of which etiologic significance was attached. Shapiro¹⁴⁸

found no organisms in blood cultures of 20 patients who had atrophic arthritis or in blood cultures of 30 patients who had rheumatic fever

The antihemolysin titer was found by Griffiths¹⁰⁶ to be definitely high in the majority of cases of infective arthritis and spondylitis ankylopoietica (atrophic spondylitis). According to Boys, Gunn and Lang¹⁸³ the blood of patients who had active atrophic arthritis (also that of patients who had mixed arthritis, streptococcal septicemia or certain non-streptococcal infections) contained more bacteriolysins to Clawson's strain of *Streptococcus viridans*, than that of normal controls. The blood of patients who were recovering from atrophic arthritis, or who had hypertrophic arthritis, was no more bactericidal than was that of controls.

The conclusion of most of those who uphold the theory of infection is that atrophic arthritis is most likely an infectious disease although final proof thereof is lacking. Thus they can sympathize with Key in the recital of his "personal futile attempts to prove the infectious origin of chronic arthritis"¹⁸⁴. From a multitude of cultural studies on blood synovial membrane and fluid, and on experimental arthritis he concluded that chronic arthritis of human beings is probably not caused by streptococci, staphylococci or diphtheroid organisms. Nevertheless atrophic arthritis presents many characteristics which are most satisfactorily explained on the basis of infection of low grade. Unable to discover more direct evidence in support of this theory, workers are now vigorously seeking indirect evidence in the form of skin tests and various immunologic reactions. The value of such evidence is at present impossible to measure, and the current favorite idea that the hemolytic streptococcus is the cause of the disease is built almost entirely on such indirect evidence. The idea of bacterial allergy is attractive because it seems to explain certain cultural and biologic diversities otherwise impossible to harmonize but it should by no means be accepted as an established fact. Vigorous objections to it are being registered and the value of such evidence as cutaneous sensitivity is sharply contradicted by several investigators. Thus from their skin tests on 34 patients who had arthritis, using a large number of autogenous strains and controls, Short, Dienes and Bauer¹⁸⁵ found no allergy of the arthritic patient comparable to that in cases of tuberculosis or in certain other chronic infectious diseases. Skin tests, without using several subjects as controls, are without significance. Even so variations in cutaneous reactions may be explained by differing irritability of the patients' skins, natural toxicity of the bacterial species, or possibly by sensitization to certain bacterial groups.

Wolf¹⁸⁶ listed several objections to the theory of bacterial allergy and concluded "It seems as though the whole theory of allergy has been introduced as the result of a desire to explain something which it would be far more satisfactory to describe. The conception of allergy does not explain rheumatic arthritic manifestations in general. It does not help us in therapeutics. It really only complicates the problem. The whole theory itself is vague and not clear enough to be used to clear up other problems."

[Bray¹⁸⁷ has tried to describe the so-called allergic joint and has given Pavist's (1933) classification of allergic arthropathy as follows (1) that of serum origin, (2) that of non-serum origin (a) acute forms simulating acute articular rheumatism, (b) allergic hydrarthrosis, either intermittent or chronic, (c) chronic rheumatism of allergic origin. Bray added that there is an entire lack of any convincing evidence that the so-called allergic muscular pains in the limbs of children are rheumatic in origin, for among 2000 children attending his asthma clinic, and a similar number attending the rheumatic clinic, there were only two children who gave distinct evidence of both diatheses. With the ideas quoted above from Wolf, Freeman¹⁸⁸ apparently was in complete agreement. All who would connect the terms "allergy" and "hypersensitiveness" with chronic rheumatism and arthritis should read his recent discussion thereon. According to him, the use of dermal reactions in rheumatism affords little or no assistance in settling the question of allergy. In the first place, the reactions are practically never similar to those seen in true allergic diseases. He concluded that a "fog of research" blankets the whole subject of allergy in rheumatism. "We are working in a fog and have as yet no clear vision. The word allergy is, to my mind, not a gleam of sunshine breaking through, but an extra wisp of fog"—Ed.]

Factor of circulatory disturbance. In many cases there are obvious alterations in the general blood flow—low blood pressure, cold, clammy extremities, and lowered cutaneous temperature. Some investigators, chiefly Pemberton, have laid considerable stress on such alterations as probably being of major etiologic importance. The exact nature and reason for them has not been fully determined. Kovacs^{189, 190}, Wright¹⁹¹ and Hench¹⁹² have agreed that they do not represent derangements of large vessels. Many workers consider them attributable to capillary vasoconstriction. Thus, Kovacs found small, constricted capillaries in 53 per cent of cases, a slow blood flow in 65 per cent, and a decreased number of capillaries in nail beds peripheral to swollen joints in cases of atrophic arthritis. Hench was unable to find consistent alterations—some patients exhibit vasomotor alterations long before, others not until long after, the onset of arthritis, and still others not at all. Capillaries are more often dilated with a sluggish flow than constricted. After sympathectomy, with improved arterial and arteriolar circulation, capillaries of arthritic patients are not more, but less, dilated, however, the flow within them is faster. Since such circulatory alterations are so inconsistently present they must represent, according to Hench, not the cause of the disease, not even an essential part of the disease, but "a complication appearing at varying times and in varying degrees as the sympathetic nervous system is perhaps variously affected by the toxins of the disease." Wright, Kovacs and Hench agreed that capillary alterations are probably not an etiologic, but may be a definite aggravating factor, worthy of correction.

Arteriosclerotic changes were roentgenographically evident in the examination of 38 per cent of 90 patients studied by Nissen and Spencer¹⁹³. Many were less than 40 years of age and of these, 27 per cent were so affected. No definite relationship was found between the sclerosis on the one hand and the hypertension or the cardiorenal abnormalities on the other.

Of 72 cases of hypertrophic arthritis, in 78 per cent arteriosclerosis was present 7 per cent of the patients were below the age of 40 years The writers could not conclude whether these findings were coincidental, or of etiologic significance

[No figures are given on the incidence of sclerosis in non-articular disease affecting patients of similar age groups, and no correlation is established between the anatomic situation of the sclerosis and that of the arthritis—Ed]

Factor of altered metabolism Different things are meant by different people when they use the term "altered metabolism" Varied is the evidence pointed out as indicating the presence of altered metabolism, and the representations made in favor of the theory of disturbed metabolism are no more, indeed less, definite than those in behalf of the theory of infection Fletcher is of the belief that the value of Pemberton's low-calorie, low-carbohydrate diet lies not so much in the curtailment of the latter as in the fact that such a diet is high in vitamins, especially vitamin B, and that vitamins act more effectively when ingested with a ration low in carbohydrate With this idea Pemberton, Peirce and Bach¹⁹⁴ expressed disagreement Patients who received a low-carbohydrate, very low-vitamin diet improved as well as those who received a low-carbohydrate, high-vitamin diet

Patients who have atrophic or hypertrophic arthritis do not tend to follow a diet essentially different from the normal in total calories or in relative amounts of proteins, fats and carbohydrates, according to Sladen, Ensign and McColl¹⁹⁵ However, on close analysis many reveal a hidden dietary error—a tendency to choose carbohydrate foods of small bulk and containing small amounts of minerals and vitamins Correction in the kind, not in the amount, of carbohydrates is in order

The well known ideas of Pemberton and his colleagues on the metabolic and nutritional aspects of the disease have been carefully reviewed again^{166, 166} Apparent alterations in sugar tolerance and in metabolic rates do not necessarily indicate pancreatic or thyroid deficiency but are probably dependent on the curtailment of blood flow to various tissues, especially to muscles The sugar tolerance was found by Nissen and Spencer¹⁹⁷ to be normal in 43 per cent and abnormal in 57 per cent of a group of 222 cases of arthritis, represented by patients, 82 of whom had atrophic arthritis 62 hypertrophic arthritis, and the remainder, arthritis of other types Correlation was not found between the sugar tolerance on the one hand and on the other the age or sex of the patient, the duration or activity of the arthritis, or the presence of foci of infection, of hypertension or of arteriosclerosis An abnormal tolerance did not necessarily become normal when the disease became inactive Nissen and Spencer queried whether the etiology of arthritis might lie in disturbed function of the pancreas, liver, suprarenal gland or pituitary body, such that the autonomic control of the body is affected without a diabetic syndrome being present

An undefined type of food deficiency was suspected as the cause of the disease by Wright,¹⁵⁰ who particularly prescribed whole wheat flour instead of white flour, and by Burnett and Ober¹⁵⁴ According to the latter, the deficiency does not occur from lack of a complete diet but from incomplete digestion and absorption of food, leading to failure of nutrient substances to construct or preserve normal bone and cartilage Contrary to the belief of most investigators, that arthritic patients tend to exhibit definite delays in passage of a meal, Burnett and Ober expressed the belief that such a patient tends to hurry along a meal, an index of incomplete digestion and absorption The majority of patients eat too much fat or fruit and not enough vegetables Rather than favoring more roughage or a more rapid emptying time of the bowel the authors named favored slowing down the passage of intestinal content to a normal rate to permit anabolic nutrition

[This entire discussion is highly theoretical No proof is offered for statements made—Ed]

Snyder, Traeger, Fineman and Zoll¹⁹⁸ adopted the opposite and more common view that intestinal, particularly colonic, stasis is present, and that this is exhibited by roentgenograms of redundant, atonic, dilated colons and by certain symptoms of dyspepsia With this view Hartsock¹⁹⁹ expressed agreement

[Objections to this viewpoint are contained in last year's review—Ed]

The idea of the overproduction by the arthritic patient of an acid-ash from foods rich in proteins and carbohydrates has been advanced again,²⁰⁰ but Boyd²⁰¹ investigating the chemistry of urine and sweat of rheumatic patients could not conclude that the beneficial effects of heat were attributable to the elimination of acid constituents The induced sweat of arthritic patients was chemically the same as that of normal persons

A revival of sulphur therapy is being attempted as the result of Cawadias' theory (1927) that the cells of an arthritic patient have lost the ability to retain sulphur Sullivan and Hess,²⁰² and Sullivan²⁰³ expressed the belief that the cystine content of the finger nails of arthritic patients of the "infective" or "mixed types" is definitely low, an indication of disturbed metabolism of sulphur The cystine content of the nails of 103 arthritic patients averaged 9.8 per cent (7.2 to 13.1 per cent) as compared to an average of 11.7 per cent (10.2 to 13 per cent) in the nails of 30 normal persons According to Sullivan and Hess, the body uses compounds of sulphur, cystine, cysteine and glutathione to render injurious material innocuous, a detoxication process The low cystine content of nails may imply a factor of abnormal intoxication depleting their content of sulphur Among 25 patients who had atrophic arthritis, Woldenberg²⁰⁴ found even lower values for cystine in nails (6.5 to 9.8 per cent, normal values presumably 12 to 12.5 per cent) However, by Senturia²⁰⁵ no variations from the normal glutathione content of blood (30 to 40 mg per 100 c c) were

found in the blood of 18 patients who had atrophic arthritis, nor in the blood of 27 patients who had hypertrophic arthritis, nor in that of eight who had peri-arthritis

Factor of endocrine relationships A commonly seen but infrequently discussed phenomenon of the arthritic patient was considered by Rugh²⁰⁶ the exacerbation of arthritis in the course of menstruation. Recalling the work of Macht, Rugh suggested that the menotoxin may be responsible. Aside from the conjectures of Nissen and Spencer,¹⁹⁷ and of Walker,¹⁷⁴ noted in the foregoing, and the statements by Pemberton and Bach¹⁶⁶ and by Ober¹⁵³ that lowered metabolic rates are frequently seen, no other data on endocrine abnormalities were forthcoming.

Conclusions on etiology and pathogenesis From this mass of confusing, sometimes conflicting, data one cannot as yet form any conclusive ideas on the etiology and pathogenesis of the disease. It is obvious that no evidence has been brought forth to change the statement of the American Committee for the Control of Rheumatism, that to date no one etiologic factor, no single infection, dietary abnormality or metabolic derangement has been conclusively shown to be the prime cause of the disease.

Treatment *General remarks* The need for a broad approach to the problem of treatment is obvious from the foregoing and was stressed by Irons,^{207, 208} Cecil,^{165, 175, 209} Pemberton and Bach,¹⁶⁶ Haden,¹⁴⁵ Archer,¹⁴⁶ Holbrook and Hill²¹⁰ and Holbrook.¹⁵⁹ One must initiate a therapeutic program with an open mind, without prejudice against the theories of others, because any program of treatment based on one theory or on one causative factor will fail in clinical use. A physician must not concentrate on only one form of treatment or he will become a faddist. In selecting his physician a patient probably will do best by choosing a well-rounded internist. There is no one specific, no one standard form of treatment. Individualized, not routine, treatment of each patient is required, and the patient, not just the disease, must be vigorously studied and cared for. Because of the obvious importance of interrelated factors, correction of whatever abnormalities the patient presents is necessary.

[One gladly accepts the choice of a well-rounded internist if he be really interested in the disease. Too often "the well-rounded internist" is conspicuous for his lack of interest in arthritis and by his failure to familiarize himself with the nature of the disease and its victim. Many indulge in half-baked ideas and one-sided methods of treatment, accepting too readily the dicta of faddists. It seems obvious that, in spite of the absence of any specific treatment, best results will be obtained by him who has a broad experience with the disease and who, whether he calls himself a general practitioner, an internist, or even a "rheumatism specialist," has vital interest in the disease. To some extent official medicine in this country has been inclined to oppose the development of arthritic clinics and special institutions for the care of arthritic patients. European governments are frankly partial to such institutions. Certainly therefrom should accrue to the army of arthritic sufferers benefits similar to those which have been derived in the field of tuberculosis and heart disease—Ed.]

At first glance it would seem that treatment of the disease varies markedly in different clinics in one place removal of foci seems to be stressed, in another, postural care, in still another, dietary measures, in others, climatic care, sulphur or gold therapy, sympathectomy, and so on. As a matter of fact most physicians treat patients in much the same way although their writings may be calculated to emphasize some particular idea on treatment or cause. Cecil questioned 15 colleagues in various parts of the country as to their favorite therapy. Replies indicated that rest, removal of foci, physiotherapy and climate were favored, foreign protein, transfusions of blood, drugs and intestinal hygiene, and fever therapy ranked low in their estimate. A diet low in carbohydrate and a streptococcal vaccine won moderate recognition. Controlled experiments with various types of therapy were performed by Holbrook and Hill. Of 100 patients, each was subjected to one of the following: removal of foci, transfusions, administration of vaccine, or heliotherapy, and each was observed for from months to years. Results emphasized the non-specificity of any one measure. In consequence, a coordinated program of those measures found by experience to be most useful is essential. It is suggested that many measures obviously of slight or of questionable value should be discarded and the patient and his physician concentrate their energies and finances on measures of proved worth.

Foci of infection and their removal. Infection in foci may not precede nor be the cause of the disease but may rather be the result of the disease. As a result of basic, general, nutritional and metabolic derangements, producing localized alterations in nutrition, they may appear more frequently after the disease has started. Ducker²¹¹ expressed approval of this viewpoint, put forward by Pemberton, and has noted the tendency for successive foci to develop after the original focus has been removed. Thus, a tooth may become infected as the result of disturbed nutrition incident to arthritis.

Foci of infection were found equally present (17 per cent) in cases of both types of arthritis (3004 of atrophic arthritis, 1335 of hypertrophic arthritis) studied by Steindler²¹². Of those cases of atrophic arthritis and of hypertrophic arthritis in which focal infection was present, the tonsils were infected in 55 per cent and 64 per cent respectively, teeth in 17 per cent and 23 per cent, sinuses in 46 per cent and 57 per cent, the biliary tract in 15 per cent and 7 per cent, and the genito-urinary tract in 6 per cent and 5 per cent. Striking immediate improvement from removal of foci was noted in 35 per cent of cases of atrophic arthritis and in 20 per cent of cases of hypertrophic arthritis. Lasting benefits were obtained, however, in only 15 per cent of cases of atrophic arthritis and in 8 per cent of cases of hypertrophic arthritis. To Key²¹³ it seemed strange that Steindler found foci of infection in only 17 per cent of cases of both types. It has been said that almost no one reaches adult life with normal tonsils and teeth. The effect of removal of foci in these cases was not impressive—many more

than 35 per cent of patients are benefited by other measures or get well without therapy

It is erroneous to believe that tonsillectomy can adequately remove a focus of infection. Infection is not localized in the tonsils but is spread widely over adjacent nasopharyngeal tissue which may appear normal, according to Solis-Cohen²¹⁴. From 95 per cent of normal appearing nasopharynges he got positive cultures for infecting organisms, often the same organisms as those found in removed tonsils. The terms "removal," "eradication" or "elimination" of foci of infection are only relative, and to counteract the toxins elaborated by the irremovable infections, stimulation of antibodies and of bactericidins is necessary. This is done, as previously outlined, by Solis-Cohen's method of vaccine therapy based on pathogen-selection (the use in his vaccine only of organisms which grow in, and are not killed by, the patient's own serum). The dangers of silent sinusitis have been discussed again by Snyder, Fineman and Traeger,²¹⁵ the fourth time a report on this same series of cases has been published.

Early eradication of foci has been to Cecil,^{175, 209} and to many others, the keystone of the arch of treatment. To Cecil removal of infected tonsils is the most important, the care of infected sinuses and teeth next in value. Even tonsils which arouse suspicion should be removed early. Devitalized teeth are removed only when periapical infection is visible, and in the treatment of sinusitis Cecil wrote that he followed the advice of a "none too radical laryngologist". With this plan, Archer,¹⁴⁶ Pemberton and Bach,¹⁶⁶ Climie,⁵ and Sprunt¹⁷⁶ expressed agreement. Foci of infection should be removed early, the sooner the better, and one should not "wait till the patient is stronger". Removal of a focus after it has spent its force cannot repair a joint and not only is of no value but may be dangerous. But foci must be removed "intelligently"²⁰⁷ and "at the proper time"¹⁴⁵. Holbrook¹⁵⁰ expressed the belief that early removal of foci is of much greater value in febrile cases (infectious or "b" group), with a subacute onset, than in cases of the more chronic and insidious type. Removal of foci in the latter group may be disastrous unless proper precautions (a building-up process, measures against fatigue, exhaustion, constipation and malnutrition, preliminary transfusion) are taken. To R and J Kovacs¹⁴⁰ results of removal of foci have been disappointing.

Vaccines. From published reports it is very difficult, if not impossible, to determine the value of vaccines. They are prepared and given in so many different ways, almost always in conjunction with other therapy, and rarely are results with a control series given. Statements relative to vaccines must be considered as statements of impressions, not as declarations of indisputable facts, even though, often, they are made after long experience. The situation is difficult if not impossible to remedy, for few physicians or patients have sufficient faith to rely on vaccines only, and the natural course of the disease is varied by seasonal and other remissions. The majority of investigators now believe that they are attempting desensiti-

zation, not immunization, and therefore favor very small doses, which do not produce significant reactions. Systemic reactions are to be avoided. Minor local and focal reactions may be permissible if followed by a significant period of euphoria (improvement reaction). Some workers even avoid all focal reactions and seek to use the smallest dose which gives relief without reaction.²¹⁶

When vaccines are given, they should be administered for long periods "several months at least,"²⁰⁹ "for 6 to 12 months,"²¹⁷ "for 6 months to 2 years."²¹⁸ Results should not be evaluated until after three or four years,¹⁴⁸ to determine whether a temporary or a lasting effect is obtained. Cecil^{165, 175, 209} expressed himself as favoring administration of his stock, hemolytic streptococcal vaccine intravenously or subcutaneously, in many cases he has obtained gratifying results. Of 35 patients treated by Marvin²¹⁹ with Cecil's vaccine, five were markedly benefited, nine moderately improved, 10 slightly improved, and 11 not improved. Discouraged by previous subcutaneous or intramuscular administration, he gave the vaccine intravenously. No control series was reported. With Cecil's vaccine given intravenously, Higgins'³⁰ results have been far from satisfactory but there was an occasional brilliant result.

Crowe's polyvalent vaccine (staphylococci, streptococci) was favored by Carlson,²²⁰ Nutter and Watson,²²¹ and Nutter,²²² Wright,¹⁵⁰ and Adamson.⁶ Of 137 patients who had chronic (undifferentiated) arthritis, treated by Nutter, 65 became symptom-free and remained so for at least five months.

[No other statistical results were given—Ed.]

Bacterial filtrates, such as are used by Small, were favored by Cohen²²³ and by Lawler.¹¹⁴ The pathogen-selective method of preparing autogenous vaccines was favored by Solis-Cohen,²¹⁴ and by Murphy,²¹⁷ who used vaccines in addition to other measures. Cutter's diluted cold vaccine (staphylococci, streptococci, pneumococci, *Micrococcus catarrhalis*, Friedlander's bacillus, and influenzal bacillus) was used with good results by Sherwood¹⁴¹ in 220 cases of chronic arthritis of various types. "Usually after 12 to 20 treatments the patient will be much relieved."

[Presumably no other treatment was given, but no controls were studied—Ed.]

Of 28 patients treated by Wainwright¹⁷⁹ with vaccines prepared from strains of microorganisms to which patients were skin-sensitive, 75 per cent were benefited. Five of eight bed-ridden patients were able to be about. Subsequent skin tests gave evidence of less sensitivity or became negative, the patients' agglutinins increased and sedimentation rates diminished. Similar vaccines were used by Rogers²²⁴ in 15 cases. In mild cases improvement was marked, in more severe cases less improvement was noted. Anaerobic, as well as aerobic organisms must be included to obtain results. Although one would prefer to use strains presumably responsible for the patient's sensitization, the determination of such strains was, to Hitch-

cock,¹⁷⁸ a formidable matter, consequently stock strains of hemolytic streptococci were used

The methods used in preparation of these various vaccines are to a large extent based on false premises and on assumptions that are not susceptible of proof, according to Short, Dienes and Bauer,¹⁸⁵ who pointed out the inadequacies of skin tests, complement fixation tests, and the pathogen-selective method. Skin tests do not provide a sound method for determining a patient's susceptibility to autogenous organisms. None of the different methods recommended for the selection of strains from which to make specific vaccines has a solid theoretical or experimental foundation. Such results as are obtained are those of the non-specific effect of the vaccines. Buckley^{30, 161} agreed that "specific vaccines" are probably neither specific nor essential. In his hands, Pondorff's cutivaccine has given variable but interesting results. Vaccines have a definite but distinctly limited place in the scheme of therapy according to Holbrook,¹⁵⁹ Irons,²⁰⁷ and Pemberton and Bach.¹⁶⁶ Used alone, they rarely cure patients. Various preparations were administered variously by Holbrook¹⁵⁹ and Holbrook and Hill²¹⁰, only occasionally was improvement noted that was not easily accounted for otherwise. Minute doses of vaccine administered intravenously gave the most favorable results. More cripples than cures may result from indiscriminate and injudicious use of vaccines^{30, 159}. Unsatisfactory results with Cecil's and with Clawson and Wetherby's vaccine were obtained by Archer¹⁴⁶ who expressed the belief that such results as are obtained may be largely psychogenic. No striking results were noted by Shapiro¹⁴⁸. In the study by Cox and Hill,¹⁶⁰ vaccine therapy was not followed by correlated changes in agglutinins.

Regarding the intestines as a focus of infection, and considering the value of "intestinal vaccines," Buckley¹⁶¹ expressed the opinion that the possibility of the infecting organism becoming an inhabitant of the bowel can be ignored. "There is sufficient evidence that bacteria do not normally enter the circulation from this source, and the toxins, if absorbed, are probably greatly modified if not destroyed by passing through the lines of defence."

Foreign proteins These substances seem useful to some investigators^{176, 225}. Brooks¹⁴² continued to favor the use of his hemoprotein, given without reactions, in conjunction with other measures. Lawler¹¹⁴ used typhoid bacilli as the most available means of producing fever in 36 cases of arthritis of various types. Improvement was generally only temporary. Wetherby¹⁴⁷ considered typhoid vaccine of little value.

Diet Attention to the ideas concerning the factor of nutrition and metabolic derangements will explain the supposed rationale of the various popular "rheumatism diets". The same familiar diets or slight modifications thereof are again candidates for approval: the low-carbohydrate, low-calorie diet, the high-vitamin, low-carbohydrate diet²²², the high-calorie, high-vitamin diet^{140, 210}, the individualized diet. To his familiar arguments

in favor of a low-calorie, low-carbohydrate diet Pemberton and his colleagues,^{166, 194} added another, namely, that such a diet exerts a definite dehydrating effect on body tissues in both types of arthritis¹⁶⁶ The loss is in pathologic, not in physiologic fluid Definite reduction in periarticular swelling and articular pain are realized

[This interesting suggestion needs further confirmation The water balance studies in these experiments were approximate, not absolutely controlled—Ed]

Various modifications of the diet just mentioned were favored Avoidance of free sugar by Douthwaite,¹²¹ a starch-free diet and administration of pancreatin by Walker¹⁷⁴

[Has pancreatin ever been shown to have any provable physiologic effect? We do not believe so—Ed]

Pemberton's diet seemed of little benefit to Wetherby's patients¹⁴⁷ Other investigators still restricted purine foods "because the blood uric acid is often high"²²⁶

[We disagree with this, the blood uric acid is rarely high and restrictions of protein generally are not indicated—Ed]

As previously noted a hidden dietary error was corrected by Sladen, Ensign and McColl¹⁹⁵ by rearranging the kinds, not the amounts, of carbohydrates ingested

The majority of investigators expressed the belief that no one diet is of value Constipation, inanition and obesity are all to be avoided or corrected by a diet arranged for the individual patient The details of their diet for anabolic nutrition were outlined by Burnett and Ober¹⁵⁴

Additional intestinal therapy Colonic irrigations were recommended by some,²²² avoided by others^{175, 210} They may be fatiguing if given too often and should rarely be given to people who are on "a low nutritional equilibrium"¹⁶⁶ To control intestinal elimination, mineral oil, agar-agar, oil retention enemas, glycerine suppositories, and abdominal exercises were recommended by some,²¹⁰ but were frowned on by Burnett and Ober¹⁵⁴

Blood transfusions Transfusions of 250 to 500 cc of blood may be indicated in cases in which there is severe anemia^{140, 166} They may be helpful in subacute and early, chronic, febrile cases but are of little value in the very chronic, afebrile cases in which pathologic changes are advanced^{159, 210}

Medicines Many medicinal preparations are used generally as adjuncts to more important measures iron, arsenic, liver extract various analgesic substances, cod liver oil, viosterol, haliver oil, potassium iodide, thyroid extract, wheat germ, yeast, nitrites for vasodilation in selected cases, strychnine or nux vomica for fatigue Cecil¹⁷⁵ agreed with Haden that neoarsphenamine gives good results occasionally, but Moltke¹⁶³ saw no rationale therefor Wheeldon²²⁷ wrote that he used calcium ortho-iodoxybenzoate "to improve peripheral circulation"

Preparations of gold Various preparations of gold (solganol, allo-

chrysin, myocrisin) are being used in continental Europe. Further experience with allochrysin (sodium aurothio-propanol sulphionate) were reported by Forestier,²²⁸ who in five years has treated therewith 500 cases of atrophic arthritis, 70 to 80 per cent responded well. In 50 per cent of early cases, and in from 20 to 30 per cent of those in which the arthritis was of more than two years' duration, permanent cure was reported after two to five series of injections. "Myocrisin" is injected weekly, the individual dose is 0.1 to 0.2 gm and the total dose 1.5 to 2.0 gm in one series. Untoward reactions may be noted in the skin and in the respiratory, alimentary, nervous, and urinary systems. Nephritis has been produced in man and in animals, the gold is excreted mainly through the kidneys. Jaundice, leukopenia, or febrile reactions may be observed. Slot and Deville¹¹⁵ treated 14 patients with solganol and improvement was "great." Buckley used allochrysin "in a certain number of cases with some promising results." The sulphur therein may act synergically with the gold.¹⁶¹ Cecil's¹⁷⁵ results with salts of gold were "not striking."

Compounds of sulphur. A renaissance of sulphur therapy is current. Weekly or biweekly injections of sulphur are generally given intramuscularly, 20 mg in oil or 5 mg intravenously. After 10 or 12 doses have been given, a rest of 10 days is permitted. Two or three courses are generally prescribed. Untoward reactions, aside from occasional, small, cutaneous sloughs or febrile reactions, were not reported, and presumably there are no contraindications. Senturia²²⁰ used sulphur-diasporal in the treatment of 55 patients who had atrophic and hypertrophic arthritis and gave it also to five patients who had fibrositis. Of this total, 75 per cent were "improved", 31 per cent markedly so. From 10 to 76 injections were given. Four of seven patients treated by Sullivan and Hess²⁰² were "appreciably" or "markedly" improved. Later all of six patients were improved.²⁰³

[The same patients?—Ed.]

Sullivan²⁰³ noted definite increases in the cystine content of the nails during therapy. Of 100 patients treated by Woldenberg²⁰⁴ the majority became free of pain after five or six injections. However, all received a variety of other forms of treatment. In seven cases, Argy²³⁰ noted no improvement until after five injections, thereafter, in six improvement was noted. It is suggested that better results are to be expected if the cystine content of the nails is low before treatment. To Cecil,¹⁷⁵ however, injections of sulphur have been disappointing.

[In none of these series, practically all of but a few cases, have control studies been carried out. In the one fairly large series many other forms of treatment were used in addition to sulphur. It seems well to wait for controlled studies before considering that treatment with sulphur deserves to be resurrected from limbo simply because "new" colloidal preparations are available. Our brief note in last year's review, that such therapy was being revived, has already been used in advertising matter praising treatment with sulphur, although not the faintest approval was voiced by us.—Ed.]

Histamine and choline The recent use of histamine for rheumatic diseases was initiated by Deutsch (1931). The claims for such treatment in Germany seem extravagant. From European literature Kling²³¹ collected data on 554 cases of arthritis, neuritis or myalgia so treated by various physicians. Of 316 patients who had myalgia (myositis), 96 per cent were "improved or cured." Of 85 patients who had arthritis, more than 90 per cent were improved. Histamine, given by cataphoresis, ionization, in ointments during massage, or by the scratch method presumably produces capillary and arteriolar dilatation, correcting an altered peripheral circulation. Kling's results^{231, 232} were less striking. Of 32 cases of myositis, in 75 per cent he had a favorable result. Of 14 patients who had hypertrophic arthritis, eight were helped. No conclusions were reached as to results in 24 other cases of arthritis. The use of histamine, byunction or ionization, was praised by Mackenna,²³³ for fibrositis and chronic villous arthritis. It does not change the course of the latter but relieves symptoms for variable periods. With its use, it is "possible completely to cure fibrositis and neuritis." Histamine and thiohistamine are particularly useful in the treatment of periarticular arthritis accompanied by cold, cyanotic fingers, according to Shanson and Eastwood¹¹⁶ who favored intramuscular injections rather than ionization. The benefits of foreign protein therapy, according to Buckley,³⁹ may be attributable to liberation thereby of a histamine-like substance.

[It is to be noted that here again the number of patients treated was generally small, no real control studies were instituted, a confused nomenclature was used, data on the type, severity and duration of the arthritis were almost wholly lacking, and certain of the conditions cured (for example myalgia) were of limited duration—Ed.]

In a series of papers, R and J Kovacs^{140, 234} and J Kovacs^{189, 190} gave the basis for preferring ionization with mecholol (acetyl-beta-methylcholine chloride) rather than oral, subcutaneous, or intravenous use of histamine, acetylcholine or nitrites. The general and local (vasodilating) effects of these were compared. The Kovacs contended that the action of mecholol is more lasting, less unpleasant, and more effective. Of 30 patients who had atrophic arthritis, 90 per cent were improved. Patients who had osteoarthritis were also improved but not more than with more established methods.

Climatotherapy Climate provides no panacea¹⁰⁰. However, a stay in a high, dry climate may be advantageous in some cases²⁰⁹ but not without the use of other forms of therapy^{150, 210}. In and about Tucson, Arizona very few native white people have arthritis. The incidence of the disease among local Indians is less than among those elsewhere. Many patients, unrelieved at home, obtain notable relief in Arizona "but it must be understood that without the proper routine of living (a coordinated program of therapy), arthritis even on the Tucson desert can continue as a sad and crippling disease."

Rest and movement The great value of adequate rest for the inflamed joints, and also for the fatigued body, of the arthritic patient was stressed by many "If one single remedial agent was to be chosen, rest would be the one selected"¹⁵¹ "As in tuberculosis, so in arthritis, rest is the key-stone of the arch"¹⁶⁶ "Motto—no weight bearing on swollen joints"²³⁵ "Rest till signs of inflammation have subsided"²³⁶ As the acute blends into the subacute and chronic stage, rest may be sharply overdone The recumbent patient who has arthritis must not be taught only how to lie correctly but must exercise in bed as the daily condition of the joints permits "A movement a day keeps adhesions away"²³⁵ Early motion is necessary and often too much rest is prescribed When, because of pain and stiffness the patient does not cooperate in the prevention of deformity, the way is paved for the production of arthritic derelicts "The price of comfort is crippling"⁵ Hench and Meyerding²³⁷ have presented examples of these arthritic derelicts—patients who have allowed themselves, or who have been permitted, to become human pretzels from grievous deformities generally induced by rest, often deliberately prescribed A detailed and diagrammatic synopsis of methods of prevention of deformity available for use by physicians in the patient's home was given by Hench and Meyerding Swaim²³⁸ has outlined again the tenets of the Boston school concerning postural and other exercises, and measures for the prevention of deformities

Physical therapy and manipulation As usual, each form of physical therapy has its advocates The value and indications thereof are too well-known to need review here, but the merits of many are cited various forms of heat,^{239, 240} paraffin baths,²⁴¹ infra-red and diathermy,²⁴² effervescing immersion baths,²⁴³ contrast baths,²⁴⁴ fangothrapy,²⁴⁵ hydrotherapy,^{246 247} applications of cold,²⁴⁸ manipulation^{249, 250, 251, 252, 253, 254} The teaching of physical therapy to undergraduates and to the general practitioner who needs to know much more about it was discussed by Cutter and Coulter²⁵⁵ and by Kovacs²⁵⁶ A central registry can inform any physician of the nearest physiotherapists²⁵⁷

Fever therapy, artificial hyperpyrexia This is the newest form of physical therapy Experience with it in treatment of atrophic arthritis has shown that results therein are not nearly as good as they are in gonorrheal arthritis The first dozen reports were analyzed in last year's review Using diathermy-hyperpyrexia (five hours at an oral temperature of 104° F, one to five sessions) in the treatment of 12 patients, Nicholls, Hansson and Stainsby²⁵⁸ noted cures or marked relief of none, moderate relief of 25 per cent and little or no relief of 75 per cent They considered it a trying ordeal for the patient and did not feel justified in continuing its use Osborne and Markson's third and fourth reports^{27, 359} concerned results of 188 treatments administered to 28 patients The usual course was eight treatments (each of 6 to 8 hours at an oral temperature of more than 104° F) Remissions were induced in many cases, and from 50 to 70 per cent of the patients, grouped according to severity of the disease, were

considered improved Merriman, Holmquest and Osborne²⁶⁰ recently have advocated the use of an inductotherm to decrease expense and for the sake of ease in therapy About 75 per cent of 40 patients treated by Simpson²² with radiothermy or in heated cabinets (Kettering hypertherm) were definitely improved Diathermy-hyperpyrexia was advocated by Jones²³ A safe method of producing fever, by hot baths in the patient's home, was outlined by Currence²⁶¹ Cecil¹⁷⁵ preferred injections of typhoid vaccine to fever induced by diathermy For discussions on the relative merits of various methods for producing fever, and for details on the physiologic reactions produced thereby, various new references are available^{26, 262 to 272} Hoverson²⁷⁰ has reported the case of a paretic patient who survived an uncontrollable hyperpyrexia that rose to 110.5° F Short and Bauer,²⁷¹ and Hench, Slocumb and Popp²⁷² recently have reported their results In general the effect of fever therapy in atrophic arthritis was disappointing Satisfactory remissions were occasionally induced About 25 per cent of patients noted definite improvement None were cured Hench²⁷³ also has summarized the entire national experience with fever therapy for atrophic arthritis of about 200 patients so treated less than 10 per cent became symptom-free, about 25 to 30 per cent noted some relief Results with various methods do not differ materially The choice of method resolves itself into the selection of that which is safest, least expensive and most comfortable for the patient Hench expressed his preference for humidified, heated cabinets Untoward reactions are rare when the procedure is supervised, in a hospital, by trained nurse-technicians and an attending physician Severe reactions, even death, are occasionally encountered The Council on Physical Therapy of the American Medical Association recently²⁸ reported on the results obtained by 4809 patients, who had different diseases, treated by various physicians, with different forms of fever therapy Twenty-nine deaths were noted, many of them among neurosyphilitic patients

[With care in selection of patients, and with skilled management, the procedure is essentially safe—Ed]

Surgical Procedures Synovectomy Occasionally synovectomy is indicated for an old, boggy, proliferative, inflammatory process in a knee that is unresponsive to conservative therapy, and if the condition is not accompanied by much arthritic activity in other joints²⁷⁴ Busby²⁷⁵ expressed the belief that synovectomy is at times necessary to correct an otherwise uncorrectable articular focus of streptococci

Sympathectomy This procedure was initiated in selected cases of arthritis by Rowntree and Adson (1927) and its physiologic rationale was further outlined by Hench and Craig (1931) It is a method of value in certain cases²⁷⁶ In Young's²⁷⁷ experience "several cases of distressing and seriously disabling chronic polyarthritis of the hip, knee, and ankle have been relieved almost beyond belief by lumbar sympathectomy" In treat-

nt of a child who had early swelling and deformity of the legs, resection of lumbar trunks by Robertson²⁷⁸ "caused or immediately preceded a rapid complete return to normal" In another "more advanced and severe," after operation, "pain and the vascular condition of the lower limbs were very markedly improved The patient's comfort was greater but that was the net result" Robertson felt that these "results were striking and could encourage one to operate in these cases at as early a stage as they can be found" Unilateral cervicothoracic sympathectomy was performed by Sford²⁷⁹ on an elderly woman who had marked arthritis of the joints of the right arm "Complete pain relief and a considerable increase in the use of the hand and arm" were the results

[Some question the rationale of sympathectomy in a disease presumably infectious Those who initiated and advanced the trial use of this procedure for atrophic arthritis were not proposing a "specific measure" for a disease of supposed neurovascular origin They were advocating a measure designed to counteract a "complication" variably present in differing degrees in a disease which might well be infectious The complication—a vasomotor disturbance presumably responsible for inadequate blood supply to affected and already seriously embarrassed extremities—occasionally be of sufficient severity to warrant attempts for its correction in the most complete and lasting way possible—sympathectomy Sympathectomy is therefore regarded by its proponents as a sort of continuous infusion of the patient's own blood in behalf of just one part of his body—the peripheral portions of his cold, clammy arthritic extremities If thereby the blood flow thereto is significantly augmented (as indirect, not direct, evidence seems to suggest) and if the patient's blood is still sufficiently potent in its concentration of specific and "non-specific" healing substances, good results may be obtained, analogous to repeated transfusions If such is not the case the infusion via sympathectomy will be of no more value than an ordinary transfusion to a hopelessly sick or dying man The crux of the matter lies in the proper selection of the patient

Since the original workers in this field are wisely postponing their final report because others have performed sympathectomy on but three or four cases, the value of sympathectomy in atrophic arthritis is not yet established—Ed]

The selection of cases for sympathectomy was again discussed by Brown, Craig and Adson²⁸⁰ Suitable are young patients who have fairly severe atrophic arthritis, especially in hands and feet, who have cold, clammy extremities and little bony change, and who are unrelieved by conservative measures A higher grade of postoperative vasodilation is obtained in the hands and feet than in less peripheral tissues Several questions are frequently asked What changes are present in excised tissues? Does the operation produce significant vasodilation? Are the postoperative changes permanent? Do ill effects eventually accrue to body tissues? Is there a possibility that sympathectomy might eventually produce neuropathic joint disease?²⁷⁴ Changes in the excised ganglia, according to Craig and Kernof (1933), were comparable to those found in ganglia removed at necropsy in patients unaffected by arthritis or derangements of the sympathetic nervous system Kuntz²⁸¹ found the same changes in ganglia removed from 19 patients who had chronic polyarthritis, but he was inclined to

emphasize their departure from normal and he disagreed with Craig and Kernohan chiefly as to the appearance of normal human ganglia

[Since what is the normal appearance of a ganglion of man has not been established, differences of opinion will arise Kuntz assumed that ganglia of normal human beings and of normal animals are identical but since this has not been established, it, like previous ideas, constitutes only an opinion One might disagree with him when he assumes that the free, intracapsular elements around ganglion cells are phagocytes rather than satellite cells of the ganglion cells At any rate, the changes observed in the ganglia in individual cases were not specific and could not be related directly to arthritis or to other diseases in question—Ed]

Although they were unable, by the injection of an opaque substance, to visualize dilatation of smaller vessels after unilateral sympathectomy of dogs (such as was demonstrated by Horton and Craig, 1930) McMaster and Roome²⁸² found an increased cutaneous temperature most marked distally on the side on which operation had been performed They, therefore, assumed that such vasodilation as occurs probably takes place in smaller arterioles and capillaries

[McMaster and Roome used a thick suspension of vermilion water color Horton and Craig used metallic mercury, a heavier substance of greater penetrability—Ed]

Studying vasomotor reactions of cats on which sympathectomy had been performed, Rosenblueth and Cannon²⁸³ suggested the presence of vasodilator centers and central tracts susceptible of direct stimulation In sympathectomized animals, dilator fibers in dorsal roots are probably efferent paths of response to stimulation of the depressor points, and also to stimulation of the vasomotor reflexes and of the dilator impulses responsible for various reactions such as a fall in blood pressure attending struggle Granting that certain permanent alterations are produced by sympathectomy in man, are they eventually harmful to various organs? In animals 22 to 42 months after operation, Clark²⁸⁴ found no gross changes which could be attributed to absence of the sympathetic system Thymus glands were infiltrated with adipose tissue There was no gross evidence of regeneration of sympathetic trunks or ganglia, and histologic studies disclosed practically no changes except for minor ones in the thyroid glands or testes These, and the studies of Brown, Craig and Adson, would lead to the conclusion that in man permanent vasodilation, but no harmful effects, are produced by sympathectomy

Splenectomy in arthritis with splenomegaly Following the example set by the admirers of Still, from time to time various names have been attached to the combination of arthritis in association with alterations in the blood picture and with involvement of one or more parts of the reticulo-endothelial system (lymph nodes, liver, spleen) The so-called Felty's syndrome is the latest such syndrome (arthritis, splenomegaly, leukopenia) Felty (1924) himself concluded that the syndrome was probably not a new disease and others have felt that it is merely another pathologic combination

of arthritis and reticulo-endothelial reaction, little different from other syndromes reported by Chauffard (1896), Still (1897) and Herringham (1909), and that a new name is therefore unnecessary. We have noted that Moltke¹⁶³ agreed with those who believe that adult or juvenile Still's disease is but atrophic arthritis with a little different physiologic response than usual. Splenectomy has been done occasionally in such cases⁴ recently by Hanrahan and Miller (1932) and lately by Craven²⁸⁵. The patient whose case was reported by Hanrahan and Miller obtained some relief for at least four months. Craven's patient obtained only transient improvement in the arthritis, leukopenia, and hepatic function. In a similar case Price and Shoenfeld²⁸⁶ considered sympathectomy, but this was precluded by fatal pericarditis. The spleen in the latter case, and in that of Craven, presented the pathologic picture of chronic infectious splenitis. Price and Schoenfeld concluded that "Felty's syndrome" is not a new disease or syndrome but merely a single, extended pathologic process.

[It should be pointed out again that the pathologic findings in these various combinations furnish considerable support for the theory of infection as a cause of atrophic arthritis—Ed.]

Thyroidectomy This has been advocated in selected cases of atrophic arthritis by Duncan (1932) and was approved by Ober¹⁵³ if definite hyperthyroidism is present.

Articular bone puncture The evidence in favor of this procedure as recommended by Mackenzie (1932, 1933) has not been impressive to his fellow-countryman, Ducker²¹¹.

[The latter, however, has not so treated any cases himself—Ed.]

Orthopedic procedures When deformity impends, it is as much the duty of the attending physician, as of his orthopedic colleague, to be familiar with simple home methods of preventing or correcting them. If deformities seem inevitable, it is imperative that the affected joints be kept in the best position for optimal function or for subsequent orthopedic procedures. These positions have again been concisely and diagrammatically outlined by Schrock,²⁸⁷ McBride²⁸⁸ and Hench and Meyerding²⁸⁷. The various corrective, non-surgical orthopedic procedures necessary for articular rehabilitation of children were surveyed by Green and Ober²⁸⁹.

Prognosis *Remissions, Spontaneous and Precipitated* The observations of Nissen and Spencer¹⁵² on the course of atrophic arthritis have been noted. Although many investigators would be inclined to agree with Archer,¹⁴⁶ that advanced atrophic arthritis seems to be incurable by the physician and that nature alone is in control of the outcome, nevertheless the majority will not accept so pessimistic a viewpoint. There is ample evidence that a coordinated program made up of those reasonable measures which an intensive study of the victim's physiologic processes will indicate, if carefully instituted and patiently persevered in, is in time followed by distinct

amelioration, and often by complete inactivity of the disease Brooks¹⁴² and others have emphasized the length of time over which it is necessary to carry on treatment to accomplish results To a large extent, the degree of recovery experienced depends on the intelligence of the patient as well as on the skill of his physician

"There is no panacea and none is needed as statistics show that a high percentage of cases properly treated recover"¹⁶⁶ The chief discontent of all is based, of course, on the fact that treatment often takes so long and requires so much of the patient's time, money and endurance before the final natural or induced remission occurs and the disease becomes finally inactive As Pern²⁸⁶ said, "Though the road may wind up hill all the way and the journey take the whole long day, the night will pass and with it its fears and dreads The dawn will break and with the dawn the mists will melt and full day will bring understanding and with it crippled joints and broken lives will belong to the night that is passed" Rather lyrical but none the less true

Since sudden remissions are not the rule, Hench²⁹⁰ was particularly interested in the precipitous remissions induced by intercurrent jaundice in 16 cases of atrophic arthritis and fibrositis In most instances the jaundice was caused by the toxic action of cinchophen but the marked, generally complete analgesia experienced with the onset of jaundice was in no way attributable to cinchophen, for patients who had simple catarrhal jaundice experienced similar relief In the majority of cases, marked reduction in swelling and marked increase in motion accompanied the more or less complete analgesia, and the rheumatic process can be said to have suddenly become inactivated The remissions lasted for variable periods, sometimes only for days or weeks, occasionally months or years Further investigations are under way to see if the obvious therapeutic implications can be realized so that one can repeat nature's miracle, and provide at will a similar beneficence by the use of some non-toxic accompaniment of jaundice effective in available concentration These observations have been confirmed by Sidel and Abrams,²⁹¹ who noted, with the onset of jaundice, abrupt termination of arthritic pain in four cases, in one of which there was also marked reduction of swelling, stiffness and redness In two instances the jaundice was of the catarrhal type, in two, it followed the use of oxyiodide (cinchophen)

HYPERTROPHIC ARTHRITIS

Incidence Recent roentgenographic and pathologic evidence (for example, Heine, 1926) indicates that hypertrophic arthritis (the clinical syndrome as contrasted with a roentgenographic alteration) is universally present among persons whose age is more than 45 or 50 years but that it is symptomatically evident in examination of only a very small proportion of its victims—probably 5 per cent It may very occasionally appear when persons are between the ages of 30 and 35 years, with other evidences of

premature senescence (early grayness of hair, early spontaneous or artificial menopause) In spite of the enormous prevalence of the disease, it is rarely dignified by studies directed primarily to it, but it is usually mentioned only in passing to emphasize some contrasting relationship to, or as a "control" for, atrophic arthritis

[American studies on the pathologic incidence of hypertrophic (degenerative) arthritis are now forthcoming Keefer and Myers (1933), Bauer and Bennett (1933) —Ed]

Symptoms and Course New data on symptomatology have not appeared In the discussion on the course of atrophic arthritis as contrasted to that of hypertrophic arthritis, observations by Nissen¹⁵¹ and Nissen and Spencer¹⁵² on the course of hypertrophic arthritis were noted In 3 per cent (one case) of 30 cases, course A (early functional restitution) developed, in 70 per cent (23 cases), course B (remissions, relapses, steady decline) developed, no cases followed course C, and 20 per cent (six cases), course D (progressive fairly rapid disability until death)

[As we noted heretofore, the idea that hypertrophic arthritis leads to death is not consistent with the facts —Ed]

Röntgenograms and Pathology No new studies were available for this review

Laboratory Data As noted previously herein, the leukocyte count is likely to be lower and the Schilling differential count to be normal in cases of hypertrophic arthritis, as contrasted to alterations in cases of atrophic arthritis^{167, 168} The cell count of synovial fluid in one case of Keefer, Myers and Holmes¹¹ was total cells per cubic millimeter, 600, polymorphonuclears 88 per cent, lymphocytes 8 per cent, monocytes 4 per cent

[A count in one case is of no significance, since so few such counts have been made, however, this case is noted —Ed]

Metabolic rates Among 21 patients who had hypertrophic arthritis of the hips, and who were seen by Kuhns,²⁹² metabolic rates were low in 18 cases

Etiology and Pathogenesis Under general remarks on the etiology of chronic arthritis were noted various ideas concerning the cause of hypertrophic arthritis Those investigators who stressed the prime importance of infection as a factor are in the minority The majority recognized tissue-age and trauma as the most obvious causal agents Few writers were satisfied to consider but one factor responsible for the disease—an interplay of abnormalities is generally incriminated (1) degenerative tissue-changes incident to age—the progressive, uncompensated catabolism of tissue-senility, (2) long continued trauma above and beyond the ability of articular tissues to repair the "microtraumatic" damage, (3) a circulatory derangement, (4) some nutritional abnormality, (5) an endocrine deficiency, or (6) the factor of infection Thus Kuhns,²⁹² from a study of 79 patients who

had hypertrophic arthritis of a hip, concluded that the disease is the product of several factors—trauma, faulty posture, disordered intestinal function, infectious and endocrine disturbances

[Some of us believe that one major cause exists, the discovery of which will result in a realignment of all other factors into their proper secondary position as precipitating or predisposing, not causal factors—Ed]

Factor of tissue degeneration Because of the age-incidence of the disease, the general absence of the usual signs of an infectious process, the frequent association of the disease with recognized evidences of tissue senility, and particularly because of the degenerative nature of the articular pathologic change, hypertrophic arthritis is considered by most investigators to result from an "altered metabolism" [whatever that may be—Ed] incident to age¹⁷⁵. The theory gains some weight from studies by Bruger and Poindexter,¹⁷¹ and by Hartung, Greene and Bruger,¹⁷² on the cholesterol content of blood. There was an increase of plasma cholesterol, not explained by the fact that patients who have hypertrophic arthritis tend to be obese. The range among 50 cases was 140 to 340 mg of cholesterol for 100 cc of plasma. The arithmetic mean was 235 mg (as compared to 195 mg for the control group and 175 mg for a group of 50 patients who had atrophic arthritis). Since similar elevations are found in diseases considered degenerative (hypertension, arteriosclerosis, diabetes), an elevation of plasma cholesterol in cases of hypertrophic arthritis suggests that this is also a degenerative disease.

Factor of trauma Higgins³⁰ and Swain¹⁷³ wrote of the importance of this factor. The importance of occupation as an inciting agent was stressed by Higgins, who stated that laundresses seem particularly prone to the development of Heberden's nodes.

Factor of circulatory alterations Pemberton's ideas on the relationship of sluggish capillary circulation and altered tissue nutrition to the causation of hypertrophic as well as of atrophic arthritis are familiar to all. Of probable etiologic importance, he felt, is this combination of circumstances—capillary constriction with sluggish flow, delay in the normal delivery of certain constituents of the blood, especially oxygen and glucose, to certain tissues, partial tissue anoxemia, further metabolic disturbances at least partly responsible for the pathologic changes in, and the symptoms of, arthritis.¹⁹⁶

Since Wollenberg (1908) launched the "circulatory theory" of arthritis deformans and showed experimentally that interference with the circulation to articular bone was followed by hypertrophy of bone (an experiment more recently repeated by Goldhaft, Wright, and Pemberton, 1930), more obvious evidence of circulatory deficiency, probably from arteriosclerosis, has been sought in cases of hypertrophic arthritis. Of 72 cases, in 78 per cent Nissen and Spencer¹⁹³ found arteriosclerosis demonstrated in

roentgenograms of various sites Of these cases, in 7 per cent the patients were less than 40 years of age

[As we noted before, anatomic correlation was not shown between the arthritis and the arteriosclerotic vessels —Ed]

Kovacs^{189, 190} found small capillaries in 28 per cent, a slow blood flow in 53 per cent of his cases of hypertrophic arthritis, with a decrease in number of capillaries near Heberden's nodes Bick²⁹³ found definite hypertension in 90 per cent and varicosities of lower extremities in 77 per cent of his cases From certain experiments and philosophic considerations, Bick has concluded that most cases of osteo-arthritis demonstrate clinical evidences of circulatory abnormalities, and that "all investigations on the mechanics of osteo-arthritis point to the peripheral vascular system as the *modus operandi* of its etiologic forces" The advent of senile involution produces a systemic passive congestion which results in failure of circulation to the cartilage, thinning, erosion and fibrillation of cartilage and hyperplastic reactions in bone result

[It is difficult to understand how identical circulatory derangements or insufficiency can cause atrophic arthritis in one case, hypertrophic arthritis in another The two pathologic pictures are totally different As one of us has stated, one must distinguish sharply between the application of the theory of circulatory deficiency to atrophic and to hypertrophic arthritis¹⁹² When patellar vessels are ligated and the blood supply is sharply diminished, resulting alterations in bone are chiefly hypertrophic, not atrophic This is what one would expect if one accepts the recent dictum of Jones and Roberts (1934) that bone undergoes increased calcification if its blood supply is decreased, but it undergoes decalcification if its blood supply is increased If this is true, the theory of circulatory deficiency would seem much more applicable to hypertrophic than to atrophic arthritis, and in the latter disease one might better search for an augmented, not a decreased blood supply to account for atrophy of bone in atrophic arthritis Such a state has been suggested as being present in the form of hypéremia and formation of new vessels —Ed]

Factor of altered nutrition In "many cases" Gammon²⁹⁴ and Archer¹⁴⁶ found decreased sugar tolerance However, Archer felt that the evidence of obesity, hypertension and endocrine disturbances probably accounted for it Gammon also mentioned abnormal purine tolerance in many cases

[Statements similar to this last are frequently made, in general without adequate evidence in support thereof By the endless repetition of such unsupported opinions, these ideas become fixed in the literature Exhaustive research has failed to disclose a related purine abnormality —Ed]

Endocrine factors The presence of endocrine abnormalities was vaguely mentioned by many who continued to fail to produce definite evidence of them Thus, we read that metabolic disturbances "unquestionably play a prominent rôle, as manifested by the gratifying response to reduction in weight and compensation for endocrine deficiencies by the use of thyroid extract and ovarian and pituitary hormones" ¹⁷³

[This is another example similar to the one just commented on. It is agreed that reduction of the trauma of obesity is of great importance in hypertrophic arthritis. Therein lies the value of thyroid extract. None but a weight-reducing effect has ever been proved for it, and in a disease presumably the result of catabolism in excess of anabolism, it is difficult to see how the administration of thyroid extract could help matters. The value of other than weight-reducing endocrine substances in this disease remains entirely unproved.—Ed.]

Factor of infection. The ideas of several writers, in this regard, have been noted previously. For example, Brooks¹¹² expressed the belief that the disease is of staphylococcal origin (no supporting data given). Trauma is usually considered the cause of the symptomatic exacerbations of quiescent or relatively symptomless hypertrophic arthritis. Key¹⁸⁴ expressed the opinion that sometimes this idea is scarcely tenable, and that infection of low grade may produce symptoms in cases of the disease which, like the majority of cases, would otherwise be symptomless.

Because cases of osteo-arthritis and spondylitis osteo-arthritica (atrophic spondylitis) presented but few high antihemolysin titers (in contrast to those of atrophic arthritis) Griffiths¹⁰⁶ looked on the disease as noninfective.

Conclusions on etiology. We can but conclude, as formerly, that the disease is of unknown origin but is obviously conditioned by age and is aggravated, pathologically and symptomatically, by trauma and, some would add, perhaps to a less extent by infection and other less well-defined abnormalities of nutritional, circulatory and endocrine nature.

Treatment. Removal of foci. It has been noted that Steindler²¹² found foci of infection in only 17 per cent of his cases and that removal of these foci gave real relief in only 8 per cent of those cases in which it was done. The majority of writers continue to agree that removal of foci does not particularly affect the course of the disease.^{148, 295}

Diet. Sladen, Ensign and McColl¹⁹⁰ rearranged the type, and Scull and Pemberton²⁹⁶ reduced the amount of carbohydrates, ascribing benefit to such dietary measures in cases of hypertrophic, as well as in cases of atrophic arthritis. Tissue edema, also occasionally present in cases of hypertrophic arthritis, may be thus reduced. The majority of writers contented themselves with correction of traumatizing obesity, if present.^{121, 175}

Vaccines. These are but rarely recommended²²⁴, they are generally disapproved.¹⁴⁸

Histamine. This is recommended by some for hypertrophic, as well as for atrophic arthritis.²³²

[No acceptable data indicating its worth are at hand.—Ed.]

Mecholin iontophoresis. In general, the results of this method in cases of hypertrophic arthritis were no better than those derived from simpler measures.^{189, 234}

Blood letting. Kovacs advocated this measure in cases of hypertrophic arthritis in which "a plethoric state and high blood pressure are generally present."¹⁴⁰

[As a matter of fact, plethora is generally absent according to Sparks and Haden (1932), who found the blood volume 7 per cent below normal in 15 cases—Ed]

Physical therapy The usual physical therapeutic measures were advocated²³⁵

Fever therapy This has proved of little value. The early experiences of Tenney, Beiris and King have been reviewed previously.⁴ Simpson²² has treated about 25 patients, with disappointing results. They did not tolerate treatment well, and any relief obtained was transient.

Orthopedic operations When marked stiffness occurs orthopedic operations occasionally are performed.²⁹⁷

Prognosis Aside from those of Nissen¹⁵¹ and Nissen and Spencer¹⁵² no new data on prognosis are at hand. Kuhns²⁹² voiced the general opinion that when adequate therapy and protection are supplied for the joints, progressive deterioration is not inevitable, even among aged persons.

BACKACHE AND SCIATICA

Space for this review does not permit a synopsis of the voluminous but confusing and often contradictory literature on backache and sciatica, which are symptoms of many paravertebral disturbances and diseases. The editors have failed to recognize much that is particularly new in the year's numerous articles on these subjects, but several informative and representative reports are available on the following subjects dealing with the differentiation of types and causes of backache and the sciatic syndrome: backstrain²⁹⁸, postural backache²⁹⁹, traumatic backache⁹, postoperative and parturient backache³⁰⁰, reflex backache³⁰¹, low backache from disease of facets³⁰² or from paravertebral muscular insufficiency³⁰³, sacroiliac strain and subluxation with the treatment thereof by Baer's hyperflexion manipulation³⁰⁴, congenital malformations and spondylolisthesis, the relationship of sciatica to narrowing of the lumbosacral disk³⁰⁵ or to disease (fibrositis) of the piriformis muscle,³⁰⁶ and the behavior of the intervertebral disks in tuberculous, typhoidal or specific infectious spondylitis and malignancy.³⁰⁷ A brief history of backache was given by Wentworth.³⁰⁸

These reports again emphasize the importance of thorough physical and roentgenologic examination and the importance of considering all possibilities before making a diagnosis of rheumatism or arthritis without definite evidence of articular disease. Because bony spurs, large or small, are present, one must not assume that the condition is explained, many large spurs are symptomless, small spurs may cause considerable pain, but one must be sure spurs have not long antedated symptoms. In diagnosing a patient's disease, evaluating symptoms and ruling on compensation cases one must use certain physical maneuvers and therapeutic tests. Buckley³⁰⁹ cautioned that in preparing to testify at a compensation case the physician should remember the dictum "exaggeration is very common—just as common as malingering is rare. Exaggeration is the natural defensive mechanism of

one who fears he presents inadequate external evidence of the pain he feels "

Sciatica This condition was grouped by Burt³¹⁰ thus 1 Root sciatica (36 per cent of his 140 cases) is most commonly attributable to intervertebral arthritis or strain of the lumbar vertebrae and pressure from new growths 2 Trunk sciatica (17 per cent of his cases) is attributable to inflammation of the sciatic sheath, primary or secondary to inflammation in the gluteus maximus or pyramiformis muscles 3 Referred sciatica is attributable to inflammation in some structure supplied by the sciatic plexus (45 per cent of his cases)

The general treatment was outlined by Burt and by Yeomans,³¹¹ physical treatment by Wolf³¹² and the use of injections of alcohol, quinine-urea or thiosinamine by Thomson³¹³

[The complications and untoward sequelae that may attend the injection treatment of sciatica are not sufficiently stressed in these articles—Ed]

The production of 15 to 30 minutes of complete anesthesia by evipan sodium (a barbiturate) for use during the manipulative treatment of sciatica was recommended by Douthwaite³¹⁴

SPONDYLITIS

There is even more confusion in the clinical, pathologic and roentgenographic differentiation of types of arthritis of the spine than in similar differentiation of types of arthritis of peripheral joints There is a tendency on the part of some investigators to recognize two main divisions equivalent to atrophic and hypertrophic arthritis elsewhere and then to subdivide each group further Until better evidence is available, the majority have preferred to ignore subdivisions entirely or to consider them but minor variations of the two main types, namely, atrophic spondylitis (spondylitis rhizomelique or ankylosing spondylitis) and hypertrophic spondylitis (spondylitis osteo-arthritis)

[This viewpoint is favored by us—Ed]

Two reports illustrate these differences of opinion Miller³¹⁵ recognized two main types, Doub³¹⁶ approved of further subdivisions Miller considered "atrophic arthritis of the spine" to be synonymous with "spondylitis rhizomelique," and expressed the belief that the Marie-Strumpell type (spondylitis ossificans ligamentosa of Knaggs) and the von Bechterew type (spondylitis muscularis of Knaggs) are variations of the same process, not worthy of particular differentiation Doub favored Knaggs' separation of atrophic spondylitis under two subheadings spondylitis ossificans ligamentosa (Marie-Strumpell type) and spondylitis muscularis (von Bechterew type) Another type, called "spondylitis senilis," supposedly a variety of spondylitis muscularis as it appears among elderly persons, was listed by some under atrophic spondylitis, by others under hypertrophic spondylitis

Atrophic Spondylitis (Spondylitis Ankylopoietica) This is presum-

ably the spinal equivalent of atrophic arthritis and the same in its cause and general treatment. Miller qualified the synonymy by saying, "Rheumatoid (atrophic) arthritis of the spine is usually followed by pathologic changes recognized as spondylitis ankylopoietica. It is perhaps unnecessary to state that a patient with spondylitis ankylopoietica does not necessarily have rheumatoid arthritis of the spine. However, (the latter) leads to (ankylopoietic) changes." Doubt, using further subdivision, stated that spondylitis ossificans ligamentosa and spondylitis muscularis are similar only in that both are characterized by spinal ankylosis and dorsal kyphosis. "It seems rather odd that they should be considered stages of the same process. Their pathology, signs, symptoms and development are quite different, and the etiology as given by most authors is also distinct."

[No original data are given in proof of these statements—Ed.]

Presumably the differentiation is as given in table 1

TABLE I
Characteristics of Spondylitis

	Spondylitis ossificans ligamentosa		Spondylitis muscularis
Situation	Spinal column, sacro iliac joints, hips, shoulders		Not in hips or shoulders
Progression	Ascending type, from lumbar region		Descending type, from cervicothoracic region
Appearance	Thoracic region	Flat, immobile chest, kyphosis	Flat, immobile chest, kyphosis more marked
	Lumbar region	Generally straight	Generally lordotic
Pathology	Vertebral bodies	No marked change	Fusion at anterior margins
	Intervertebral disks	Little or no change	Atrophic, narrowed, may disappear
	Spinal ligaments	Calcification	No calcification
	Facets	Ankylosis through bony proliferation and ligamentous calcification	Not mentioned in current references
	Other areas	More a periarticular, calcifying fibrositis than an arthropathy	Muscular weakness, followed by secondary spinal changes, calcification is bony, not ligamentous

The incidence of atrophic spondylitis outside of special clinics for arthritis is, according to Miller,³¹⁵ not very great. Miller cited Schmorl and Junghanns (1932) to the effect that only eight cases were found among 10,000 postmortem examinations. Doubt was sympathetic to the idea of

Oppel (1929), of Ballin and Morse (1931) and of others who have included ankylosing spondylitis in the chapter on hyperparathyroidism

[No new evidence is presented We have stated previously⁴ that the evidence is entirely inadequate for us to adulterate the syndrome of hyperparathyroidism with any of these forms of arthritis—Ed]

Nothing new is offered in treatment

Hypertrophic Spondylitis (Spondylitis Osteo-Arthritica) This is similar to hypertrophic (degenerative) arthritis elsewhere in the body and is characterized, early, by flattening of the margins of the vertebral bodies, later by the formation of marginal exostoses or osteophytes, narrowing of the intervertebral spaces and eburnation Bony ankylosis is not the rule, spurs often impinge but do not unite The lumbar and midcervical portions of the spinal column generally are involved, the thoracic portion is much less commonly affected, at least symptomatically The condition has been found, roentgenographically, almost universally to affect patients who are more than 50 years of age (Garvin, 1927) Miller cited Schmorl's statistics on postmortem studies of 10,000 spines and in particular 4,253 macerated specimens Spinal osteophytes were not found in subjects who had been in the first two decades of life They were present in 11 per cent of those in the third, in 36 per cent of those in the fourth, in 78 per cent of those in the fifth, and in 93 per cent of those in the sixth decade

We have commented previously on roentgenographic and postmortem studies of the incidence of hypertrophic arthritis in other joints The studies of Keefer (1933) on knee joints have been extended by Keefer and Myers who cited age and trauma as causes of the condition and outlined a pathogenesis similar to that reported by Schmorl To Keefer and Myers,³¹⁷ the so-called exostosis represents, however, not overgrowth of bone but flattened portions of the margins of joints squeezed out by pressure

[This is not the opinion of most pathologists—Ed]

The accepted cause of hypertrophic spondylitis is degeneration from tissue-senility and trauma, particularly that incident to man's upright posture Ely³¹⁸ has reiterated his view that this form (spondylitis type II) is attributable to a living non-bacterial organism which causes aseptic necrosis, followed by secondary changes of traumatic arthritis Judging from his previous papers, he may mean an ameba He has expressed the belief that the causal organism enters the body from roots of dead teeth and is probably later domiciled in the intestines

[Ely admittedly never has been able to prove his suspicions No new evidence is given—Ed]

Miller traced Schmorl's ideas on pathogenesis as follows (1) loss of fluidity, fibrous desiccation and disintegration, first in the nucleus pulposus, then in the annulus fibrosus, (2) thinning and loss of resiliency of disks,

(3) increased mobility of involved vertebrae, (4) impingement of vertebral rims, producing trauma which leads to formation of osteophytes, and (5) increased strain on vertebral ligaments producing periosteal irritation and formation of new bone

Apropos of the factor of trauma, Buckley and Miller reminded readers of Beneke's (1897) observation that if a man is right-handed the largest lumbar osteophytes are on the left side and vice-versa

The symptoms originating from nerve roots, which may arise about the head, neck and arms, were listed again by Bisgard³¹⁰ (1934) Pseudo-angina pectoris may also originate from cervical involvement³²⁰

Nothing new on treatment has developed Bisgard expressed himself as favoring roentgen therapy Vernon³²¹ recommended paralgesia—para-vertebral block with procaine for relief of pain

THE FACET SYNDROME

In discussions on pathology of the spinal column, the vertebral bodies and intervertebral disks generally command attention—the facets are rarely noted The importance of diseased facets in the production of pain low in the back, with or without sciatica, has been emphasized only recently, in 1927 by Putti, and now by Ghormley³⁰² The articular facets are the only true joints in the spinal column, they may be affected by acute traumatic arthritis from fracture of them, by chronic traumatic arthritis consequent on narrowing of the fifth lumbar intervertebral space, or less commonly by infection The common pathologic findings place most cases of arthritis of the facets in the group of hypertrophic (degenerative) arthritis, resulting generally from trauma Pathologic change of the facets includes degeneration of its cartilages, hypertrophy and eburnation of underlying bone

The patient affected with the facet syndrome may complain of sudden onset of pain low in the back, brought on by some activity, often trifling in its severity but usually involving a twisting or rotary strain of the lumbosacral region Sciatic scoliosis and muscular spasm may ensue, until spasm subsides pain may persist The pains, static in type, can be relieved by assuming a certain posture, or can be exaggerated by assuming other postures, the pain is of a "locking type" Satisfactory demonstration of changes in facets, hitherto impossible, is now possible with the roentgenographic technic of Ghormley and Kirklin, an oblique or three-quarter view is taken³²² Ghormley advised conservative therapy in the form of recumbency with or without traction, physiotherapy, possibly epidural injections If these fail, manipulation or long recumbency in plaster of paris casts may be needed, or even lumbosacral fascetectomy, the technic of which Ghormley described By such a procedure, Mitchell³²³ recently provided relief in a case of sciatica in which there were a narrowed fifth lumbar interspace and subluxation of facets A curious case was reported by Greig³²⁴ A left perinephritic abscess developed Remnants of the abscess were discovered at necropsy

16 years later, with adjacent, localized, unilateral ossifying spondylitis. The chain of events was possibly as follows: recurrent inflammation, alternate hyperemia and congestion, repeated, localized, temporary decalcification with subsequent reformation of bone as the hyperemia subsided, and ultimate sclerosis of bone.

[Apparently roentgenograms were not made at any time—Ed.]

GOUT AND GOUTY ARTHRITIS

Symptoms and Course A very readable synopsis of current ideas on gout has been given by Lichtwitz³²⁵ who wrote that gout is always a chronic disease, a fact that should be recognized in the first attack of acute gouty arthritis, for attacks of arthritis are merely surface explosions of what, in the interim, is a more or less symptomless, but not necessarily a quiescent, disease. Lichtwitz recognized but did not clarify the entity, atonic gout. Modern gout affects the thin, nervous type of person more frequently than formerly.

Two cases were used by Hench³²⁶ to emphasize several points. 1. A history of acute, recurring attacks, with complete remissions, is of diagnostic importance, complete restitution of articular function after numerous early attacks is one of the most characteristic features of gouty arthritis, of itself almost diagnostic. 2. Joints other than those of the great toe may be affected, and those of the great toe may be long unaffected, in one case, in which 150 attacks took place, only 10 affected a big toe, whereas in the other case, in 20 out of 30 attacks a great toe was affected. 3. Roentgenograms may long be non-specific, even negative. 4. Repeal of prohibition already has been followed by an increase in incidence of gouty arthritis as seen at The Mayo Clinic (alcoholic imbibition being a precipitatory, not a causal, factor).

The provocative effect of a high-fat (220 to 300 gm.), low-carbohydrate (20 to 50 gm.) diet in cases of gout was noted by Lockie and Hubbard^{327, 328}. On such a diet, within two to six days, in each of four cases acute gouty arthritis developed. If the diet was maintained, hyperuricemia developed. Ketosis was not sought. A similar diet did not aggravate atrophic or hypertrophic arthritis.

Acute gout occasionally may be precipitated by administration of insulin (Rabinowitch, 1928). In this connection it is interesting to note the provocation of allergic arthritis (symptoms of serum-sickness, not of gout) in the case of a diabetic female after administration of insulin, a phenomenon which, according to the belief expressed by Johnson,³²⁹ may represent an unusual type of insulin allergy.

Associated and Complicating Conditions Acute and chronic gouty arthritis both have their symptomatic and physical differences—some obvious but others subtle—from atrophic arthritis, although the former may simulate the latter in some regards. The association of gouty arthritis with un-

mistakable atrophic arthritis is very rare according to those of wide experience with both diseases Cecil¹⁶⁵ reported the association in two cases

[Both of Cecil's patients undoubtedly had gout, but the diagnosis of atrophic arthritis is based on the presence of fusiform joints and positive agglutination of hemolytic streptococci. The former may occur in gout, the complete diagnostic significance of the latter is not accepted by all. From data given we cannot accept the association as proved in these cases—Ed.]

Gout of adults not infrequently is associated with blood dyscrasia, pernicious anemia when treatment with liver is being given, leukemia, and polycythemia. Some investigators say gout is merely a symptom of destruction of nuclei of blood cells. Vining and Thomson³³⁰ have reported the association of gout with aleukemic leukemia in the case of a boy aged five years.

[No blood chemical studies were reported—Ed.]

A case of erythremia, migraine, gout and intracardiac thrombosis was reported by Weber³³¹

Etiology and Pathogenesis Lichtwitz³²⁵ agreed with the idea that uric acid is nontoxic and not the cause of gout. The symptomatic activity of gout and the production of gouty arthritis do not parallel the degree of hyperuricemia. He favored the allergic theory of gout, allergens are both exogenous (food and drink) and endogenous (tissue substances formed after injuries, surgical operations, sharp vasomotor disturbances). In this connection the opinion of Eaton and Love³³² should be noted: chronic arthritis (especially the atrophic type), may be an allergic disease, with excess of uric acid in synovia and blood acting as the predisposing agent.

[Hyperuricemia is occasionally seen in cases of atrophic or hypertrophic arthritis, but it is the unusual, not the usual, finding. Since the mechanism and significance of hyperuricemia is but little understood and allergy and allergic arthritis even less clear, these remarks must be considered highly speculative—Ed.]

Treatment The patients of Lockie and Hubbard, when placed on a high-carbohydrate (350 to 400 gm.) diet, promptly recovered from their attacks which were induced by high-fat diets. It is advocated, therefore, that patients who have gout avoid fats and accept a generous intake of carbohydrate. The purine-free diet is more highly regarded by the physician than by his patient, according to Lichtwitz, who prescribed it only for four to six weeks after an attack, a low-purine, low-meat diet thereafter. When large tophi are present their removal is indicated to prevent juxta-articular ulceration, which may necessitate amputation of phalanges, and to relieve the kidneys if possible, according to Hench³²⁶. Theoretically, removal of large tophi (weighing 10 to 300 gm.) may relieve the kidneys of the work of many weeks or months. These are but mathematical speculations, Hench admitted, and how much relief is afforded the kidney in gout, by removal of large tophi is problematic, since the factors which govern

resorption and excretion of tophaceous material are but little understood. Cinchophen should be used only intermittently and with great caution, according to Copeman³³³ and Lichtwitz. However, the use of tolysin (neocinchophen) in moderate doses (5 grains three times a day for four weeks) produced in 120 patients who had "traumatic arthritis" or "infectious arthritis" no functional alterations in liver or kidneys detectable by Stein and Minnich.³³⁴

[The editors do not favor the use of cinchophen whenever an efficient substitute is available, such as acetylsalicylic acid, in treatment of atrophic or hypertrophic arthritis. It would appear⁴ that there is no physiologic equivalent for cinchophen in the presence of gout, and since most cases are not long controlled by diet alone, the careful intermittent use of cinchophen seems justified. The doses of cinchophen, in tolysin, were not great enough or given long enough to justify drawing conclusions on the toxicity of tolysin—Ed.]

Quick,³³⁵ who expressed belief that cinchophen poisoning is an allergic manifestation, and acute yellow atrophy a special form of Arthus' phenomenon, wrote that the schedule of intermittent dosage (Graham, 1927) is not protective, indeed may favor the development of hypersensitivity.

In the translation of a fourteenth century French manuscript on gout, Saye³³⁶ found a modern note—a statement promising relief from pain but not complete recovery.

Experimental Gout and the Problem of Uric Acid Spontaneous gout occurred in turkeys raised by Schlotthauer and Bollman.³³⁷ Tophi and hyperuricemia (to 16 mg per 100 c c of blood) were present. Secretion of uric acid varied with the amount of food taken, not with the amount of uric acid in the blood. The latter increased, decreased, or remained unaltered during periods of widely divergent excretion of uric acid. The fertility of eggs from gouty flocks was greatly diminished. Eggs had an increased content of urate, but not in proportion to the concentration in the blood. Factors of sex and age seemed unimportant. Experimental gout was later produced in 20 turkeys.³³⁸ Tophi appeared only in those in which hyperuricemia of 15 mg per cent developed and remained for at least two weeks.

The provocative effect of a high-fat diet in the cases of Lockie and Hubbard was in part explained by Quick.^{339, 340} Excretion of uric acid can be accelerated by various antiketogenic compounds (glucose, glycerol, pyruvic acid, glycine, alanine, aspartic acid, glutamic acid), also by a high-protein diet. It can be depressed by ketosis and by lactic acid, whether fed or produced in excess in the body, also by benzoic acid, phenylacetic acid, and similar compounds. Ketosis probably accounts for the hyperuricemia of fasting, or when a high-fat diet is employed, or in severe diabetes, excess accumulation of lactic acid may explain the high concentration of uric acid in the blood, which often is present in eclampsia, chloroform poisoning, pneumonia, circulatory failure, and other anoxic states. Retention of uric acid after ingestion of sodium bicarbonate probably is attributable to the corrective formation of excess lactic acid.

[Since the patients of Lockie and Hubbard ingested 20 to 50 gm of carbohydrate daily, it is doubtful whether ketosis was present because it is very difficult, if not impossible, to produce ketosis with a high-fat diet unless the intake of carbohydrate is less than 15 to 20 gm—Ed]

Other interesting studies on the problem of uric acid which can only be mentioned are that by Martin and Corley³⁴¹ on the excretion of allantoin and uric acid by dogs on a purine-free and on a protein-free diet, as affected by glycine, the work of Gersh³⁴² suggesting that in rabbits, at least, uric acid is not eliminated by renal tubules but by glomeruli, the inability of Ranganathan³⁴³ to produce uric acid calculi in rats by causing them to ingest an excess of uric acid, the uric acid content of human and animal lymph, blood, aqueous humor, and cerebrospinal fluid, as analyzed by Walker³⁴⁴, and the studies of Pritham and Anderson³⁴⁵ on the comparative value of various methods for the determination of uric acid in blood

HEMOPHILIC ARTHRITIS

A brief but interesting historical sketch was presented by Birch,³⁴⁶ with a summary of accepted clinical and laboratory data on hemophilia, and a restatement of her ideas (1932) on the cause, namely, that it is an ovarian deficiency. This is but theory, and the cause remains unknown. Hemophilia, occasionally occurring when no ancestor has been known to be a bleeder, is called "sporadic" or "spontaneous" hemophilia. Even so it does not arise *de novo* but is undoubtedly inherited from a recessive mother, according to Boggs³⁴⁷ who reported six cases of hemarthrosis in brothers. The likelihood of concealed inheritance seemed precluded, as there was no trace of bleeders in five generations of the mother's ancestry. Therefore the writer, scientifically although not gallantly, raised the question of the mother's illegitimacy. It is generally believed that hemophilia does not exist among females (Bauer and Wehefritz, 1926). Foulis and Crawford³⁴⁸ expressed their inclination to believe that it may, and they presented in evidence the cases of two sisters, members of a known hemophilic family. One sister had a prolonged clotting time, and her two sons were hemophiliacs. The other sister had been in extremis once following extraction of a tooth and recently had had severe postpartum hemorrhage, not of the ordinary type but a vaginal hemorrhage. Purpura was considered unlikely particularly in view of the family history.

[The data were very meager—Ed]

From a total of eight cases, Kahn,³⁴⁹ Rypins³⁵⁰ Solis-Cohen and Levine³⁵¹ confirmed the presence of articular roentgenographic alterations previously noted.⁴ These include when seen early, distention of the capsule, widening of joint space, an articular shadow denser than that encountered in ordinary synovitis and irregular areas of density (blood pigments) suggesting calcification, seen later, there are spotty destruction of

cartilage, broadening of femoral condyles, widening of intercondylar space, formation of cavities or cysts from subperiosteal or subchondral hemorrhages and fibrous or bony ankylosis. Late roentgenograms may simulate those of tuberculous, atrophic, hypertrophic or other types of arthritis. There is no pathognomonic sign.

Treatment To Birch, the rationale of whole ovarian extract is obvious. 40 to 120 grains are given daily by mouth, or 50 to 200 rat units are given subcutaneously or intramuscularly, and have afforded best results. Cotton soaked with ovarian extract is applied to open bleeding areas such as dental sockets. One of Rypins' patients "did remarkably well" under treatment with ovarian extract. Others were disappointed with treatment by ovarian hormone (Stetson, Forkner, Chew, and Rich³⁵², Brem and Leopold³⁵³, Fureen³⁵⁴). Hemarthrosis was not benefited or prevented, and no related alterations in coagulation time of blood or of urinary estrogenic substances were observed in a total of eight cases in which treatment was with ovarian tissue given orally, or various ovarian extracts, estrogenic substances or theelin given parenterally. The relationship between hemophilia and female sex hormones was doubted.

[Further study is necessary to determine whether the use of ovarian extracts is more potent than the use of other non-specific tissue extracts—Ed.]

Pituitary extracts were not helpful in one of Birch's cases. MacFarlane and Barnett³⁵⁵ suggested the local application of sterile solutions of snake venom (*Vipera russelli*) in a dilution of 1 in 10,000 or even 1 in 100,000 parts. Blood of hemophiliacs which clotted spontaneously in 35 minutes, clotted in 17 seconds when one drop of 1 in 1,000 solution was added to 10 drops of blood. In the dilutions used, toxins apparently have been diluted beyond harm. Older methods of therapy were reviewed by Birch and by Kugelmass³⁵⁶: tannic acid dusting powder, application of raw meat or fresh blood, avoidance of disturbing dressings that adhere to wounds, cold applications the first 24 to 48 hours, later warm applications, goat serum given intradermally, transfusion or intramuscular injection of blood, for joints, elevation of the part, absolute rest, application of a posterior splint to prevent contractures, physiotherapy cautiously.

PSORIATIC ARTHRITIS

Many cases are being reported in European continental, few in English or American, literature. One case was reported by Sharma,³⁵⁷ who, vaguely believing that the condition might be of endocrine origin, gave ovarian substance. A month later the psoriasis had cleared up, the joints were "cured," and although psoriasis later recurred, the arthritis did not.

[The data are entirely inadequate to justify conclusions—Ed.]

ALLERGIC, METABOLIC AND ENDOCRINE ARTHRITIS

These terms are appearing less frequently to plague the reader. The year's reports included nothing to clarify their vagueness in any way. The possible predisposing or precipitating importance of such factors as allergic reactions to food (we have discussed bacterial allergy elsewhere), or metabolic or endocrine abnormalities, is worthy of consideration and has been touched on by many investigators, most directly by Johnson³²⁹ in his description of allergic arthritis from insulin, by Eaton and Love³³² in their discussion of the relationship of chronic arthritis and hyperuricemia to allergy, and by Cavadias,³⁵⁸ who concluded that, although chronic rheumatism is a disease which exhibits important metabolic disturbances, it is not characterized by one consistent, classifiable metabolic derangement as is diabetes.

DISEASES OF MUSCLES AND FIBROUS TISSUES (INCLUDING FIBROSITIS AND MUSCULAR RHEUMATISM)

Fibrositis To some this term is merely an impressive name for any vague ache or pain in the neighborhood of muscles or tendons. To others it is the name of a definite pathologic condition, which is an inflammatory exudation in and hyperplasia of white fibrous tissue anywhere in the body, acute or chronic in type, characterized by formation of nodular indurations appearing in various sizes, situations, and manifesting varying degrees of tenderness. Some accept an anatomic differentiation: intramuscular, fascial, bursal, perineural (of which sciatica is often a type), capsular, periarticular, or subcutaneous (panniculitis)^{379, 380}. Since an inflammatory reaction in fibrous tissue occurs in rheumatic fever and various types of arthritis, Jones³⁶¹ would include them also under the general term, and would speak of "fibrositis of rheumatic fever," of "gout," of "rheumatoid arthritis," or of "osteo-arthritis." In general, however, the term is limited to diseases of periarticular and nonarticular structures. Some writers use clinical or etiologic terms: "traumatic," "infectious," "toxic," "senile fibrositis."^{362, 363} The nomenclature of fibrositis thus reveals the same gropings for order amid confusion, the same general etiologic alignments, which exist in arthritis.

Etiology The exact cause is unknown. That trauma of overexertion (exercise or fatigue) can produce the condition seems clear, but traumatic fibrositis or myositis must not be diagnosed in a haphazard manner. A number of conditions may masquerade as traumatic fibrositis or "charley-horse." Elsom³⁶⁴ listed them: simple contusions, muscular strain or rupture, actual myositis with or without calcifying hematoma, periostitis and tenosynovitis. Other presumed causes are chilling or dampness, streptococcal infection, bacterial toxins, "bowel toxins", and acid by-products of fatigue, especially lactic acid. Some consider the condition to be neuralgia of sensory nerves, others believe it is merely a manifestation of neurasthenia^{6, 359, 360, 362, 363, 365}. Many writers are very definite in their opinions,

vague in their terms. Thus, Albee was certain that fibrositis is caused by toxins, particularly those derived from the colon, but he wrote of the condition occurring with the gouty diathesis, with excess of uric acid, with cirrhosis of liver, and so on, and he used estimations of the histamine content of the stools as an index of toxicity.

[Not the least evidence of any sort concerning etiology is offered by many of these writers—Ed.]

Symptoms These may be acute or chronic and may include muscular tenderness and stiffness, muscular spasm (if acute), tenderness over insertions of tendons, small, tender indurations, or actually palpable nodules. Symptoms are exhibited particularly when affected tissues are put on a stretch. The regions chiefly affected are muscular and fibrous tissue about the shoulders (capsulitis) and in the occipital or suboccipital regions, but particularly in the lumbosacral regions (gluteal and hamstring muscles). In the situation last named, which he felt was the major site, Albee wrote that the left side was affected 10 times more often than the right.³⁶³

Pathology The studies of Stockman³⁶⁵ constitute almost the only definite information we have on pathology, and even these were subject to the dubious inquiry of some.²⁷⁷ To some writers nodules are very elusive. Others find them without difficulty.³⁵⁹ At first there is merely a very low grade of inflammatory fibrous reaction, with exudation. Later the exudate may organize, and nodules and indurations may appear.³⁶⁵ In Pennington's cases sensitive nodules were found most frequently in the gluteal muscles, next most frequently in muscles about the shoulders, and less frequently in intercostal or paravertebral muscles. Almost 40 per cent of the gluteal nodules were symptomless. From the fact that such nodules are found so often in normal persons he deduced that fibrositis can be a transient, functional change from overuse of muscles. A second type of fibrositis is the "pathologic form" which may or may not be infectious. Fatigue, loss of muscular resiliency, chilliness, and vague muscular pains are almost universal in senility—signs of senile fibrositis so common that the term "senility" may be said to be synonymous with "fibrositis." In the other forms, the functional pathologic changes are transient, correctable and reversible. In the senile form, they are permanent, according to Pennington.³⁶²

Treatment Proposed methods of therapy concern (1) elimination of foci of infection or of toxins, (2) attention to painful muscles, (3) elimination of sensitive nodules. Albee wrote that he relied on colonic irrigations, acidophilous milk, a diet low in residue and in meat, substitution of lactose for table sugar to reduce production of bacteria and toxin in the bowels. Some rely strongly on physiotherapy, but Stockman expressed the view that although heat is of some service, spa-therapy is useless. Some urge light massage, others insist on firm massage over the nodules as the only way to relieve the condition. If the nodules cannot be dispersed one can "render them hard, callous and insensitive" by massage.^{364, 366} Young,²⁷⁷ however,

found it "difficult to understand how fibrous nodules can be excised by massage" To increase excretion of lactic acid, general sweating was urged by Pennington Some use intramuscular injection of quinine and urea hydrochloride into the tender spots³⁶⁷ Histamine can completely cure the condition, according to Mackenna²³³

[Our information on fibrositis or muscular rheumatism is much more incomplete and contradictory than is the case with other types of rheumatic disease It is indeed curious that excellent pathologic data are at hand on arthritis, in which affected tissues are much less available for biopsy than are those involved in fibrositis Until chemical, pathologic and bacteriologic studies on fibrositis are extended, little hope can be entertained for clarity Practically all articles on the subject give evidence of considerable copy-work, Stockman is one of the few, if not the only, writer who speaks with authority, he at least has made a good beginning The discussions of most of the writers are highly theoretical, and their treatment uncontrolled—Ed]

Epidemic Myositis or Pleurodynia (Devil's Grip, Bornholm Disease) Four reports tell of a recent epidemic of this disease along the Atlantic seaboard of this country and in Yorkshire, England^{368 to 371}

Other names for the condition are "myositis acuta epidemica" and "devil's clitch" Eighty cases are included in the four reports It is an acute infectious disease of unknown cause, characterized by an abrupt onset of excruciating pain in the chest, epigastrium, or along diaphragmatic attachments, fever, aggravation of the pain on deep respirations and movements of the trunk, disappearance of fever in four to 48 hours, in most cases recurrence of pain and fever after two or three days, invariable recovery without sequelae, occurrence among otherwise healthy persons of either sex, especially children, absence of significant pulmonary or pleural signs, a variable leukocyte count (17,000 to 3,000 per cubic millimeter of blood), and often leukopenia No reports on studies of the pathology are available The condition may be mistaken for early acute pneumonia or for an acute abdominal condition Laparotomy often is performed by mistake Absence of vomiting is of diagnostic help Treatment is that of acute pleurisy isolation of the patient, rest, analgesic drugs, reassurance

Myositis Ossificans Progressiva Only about 150 cases are recorded Two have been reported recently^{372, 373} The classical findings were present and do not need repetition here⁴ Interesting roentgenograms were included, and the difficulty of early diagnosis, when roentgenograms are negative, was stressed

BURSITIS

As we have noted, bursitis is pathologically a form of fibrositis However, it may be considered in a separate division here

Subdeltoid or Subacromial Bursitis An inflammation in the general region of one of these bursae generally takes the name of the adjacent bursa The calcareous deposits which often occur, however, are not in the bursae as a rule but in the supraspinatus tendon and, according to Gwynne and Robb,³⁷⁴ probably result from tears of the insertion of the supraspinatus

muscle Grossman³⁷⁵ has reviewed 375 cases and Rogers³⁷⁶ 100 cases Grossman expressed a preference for the term "periathritis," which Rogers rejected, since there is insufficient evidence that infection is present The usual symptoms are recounted and the usual ideas on cause are held—trauma and infection³⁷⁷ We are reminded that the calcareous deposits are often transient, and that the condition generally responds to conservative treatment Aspiration is advised by some

Prepatellar Bursitis and Ganglion In three painful cases of the former and 10 of the latter, the condition was inactivated by Eising³⁷⁸ and by Kaplan³⁷⁹ with a very few injections of sodium morrhuate This substance should not be used if the bursal sacs connect with joints or tendon sheaths

Iliopsoas Bursitis This is an unusual affection, sometimes difficult to diagnose In two cases in which trauma was a factor cure was brought about by Ramage and Morton³⁸⁰ by excision

Information on the development and structure of bursae is all too meager Two reports provided data thereon Since he found no subcutaneous olecranon or prepatellar bursae in fetuses, Black³⁸¹ expressed the belief that they develop after birth Neither subfascial nor subtendinous bursae are present in fetuses but subacromial bursae are Chandler³⁸² found iliopsoas bursae present before birth and rarely absent in adults In 15 per cent of cases, a communication between adjacent bursae and the hip joint exists, this communication is not the result of development but is produced by friction of the iliopsoas tendon

MISCELLANEOUS CONDITIONS

Lymphatic Leukemia Resembling Rheumatic Fever This condition occasionally is seen Articular symptoms resembling those of acute rheumatic fever may be prominent in cases of acute leukemia of children The literature was reviewed by Sutton and Bosworth,³⁸³ who presented the case of a child 32 months old At first fever and swollen joints were associated with enlarged nodes but not with an enlarged liver or spleen Blood counts were normal A diagnosis of rheumatic fever was entertained without satisfaction since salicylates were ineffective and carditis was absent Some months later the liver and spleen became enlarged, biopsy of a lymph node confirmed the diagnosis of leukemia Permission for necropsy was refused

Lipomas of the Articular Capsule These were successfully removed from three patients by Ghormley³⁸⁴

Calcification in Fat Pads about Joints This was noted by Ferguson³⁸⁵ in four cases

PHYSIOLOGY OF ARTICULAR STRUCTURES

Studies on the fundamentals of articular physiology are indeed meager The viscosity of synovial fluid is attributable to its content of mucin When this is removed the viscosity drops to that of a simple exudate Studying

lubrication of joints of horses Jones,³⁸⁶ an engineer, concluded that the coefficient of friction of a joint that has dried is nearly 14 times as high as when it is lubricated by synovial fluid or normal saline solution. A joint of which the surfaces are not lubricated is quickly destroyed when worked under a light load. It is imperative to study the problem of lubrication in joints of human beings in order to understand arthritic changes.

From his studies on the joints of rabbits and of human beings Kuhns³⁸⁷ concluded that lymphatic structures are as abundant as are small blood vessels in the tissues lining joints especially in synovial membrane. Lymphatic drainage of the joints of the lower extremities is through deep lymphatic structures to the popliteal deep femoral and iliac nodes. Synovitis prevents lymphatic absorption of material larger than molecular size, obliteration of lymphatic structures occurs with chronic inflammation. Kuhns and Weatherford³⁸⁸ have shown that colloidal and particulate matter may be carried to joints from body tissues and from the intestines through the action of cells of the reticulo-endothelial system. Such transported substances are stored in histiocytes in subsynovial villi. Large amounts are stored in bone marrow, lesser amounts in intermuscular septa and articular fat pads. Mild inflammation in articular tissues tends to increase the deposition of injected substances. Local blocking of the reticulo-endothelial system is transitory and ineffective in preventing deposition of colloidal and particulate matter injected elsewhere.

The effect of immobilization of normal joints is controversial. After experimental immobilization of the ankles of dogs for from one to three months, Ely and Mensor³⁸⁹ noted the following: frequent periarticular swelling, and thinning irregularity, fibrillation, at times fibrin plaques and vacuolization of cartilages (but no fibrous adhesions) between the joint surfaces, and some encroachment on, and substitution of, cartilage by connective tissue.

BIBLIOGRAPHY

The bibliography contains a few references to articles which should have been commented on in last year's review.

- 4 GADOW, H F The evolution of the vertebral column a contribution to the study of vertebrate phylogeny Edited by J F GASKELL and H L H GREEN, Macmillan, Cambridge University Press, 1934, 356 pp
- 5 KERSLEY, G D The rheumatic diseases a concise manual for the practitioner, William Heinemann, London, 1934, 88 pp
- 6 PEMBERTON, R, and OSGOOD, R B The medical and orthopedic management of chronic arthritis, Macmillan Company, New York, 1934, 403 pp
- 7 SYLVEST, E Epidemic myalgia Bornholm disease, with a foreword by Th Madsen Translated from Danish by Hans Andersen, Levin and Munksgaard, London, 1934, 155 pp

The chairman of the editorial committee for this review will welcome the receipt of reprints from authors of current (1935-1936) articles which will greatly facilitate the preparation of subsequent reviews

CASE REPORTS

VENTRICULAR COMPLEXES OF THE BUNDLE-BRANCH-BLOCK TYPE ASSOCIATED WITH SHORT P-R INTERVALS

By GEORGE H. ROBERTS, M.D., F.A.C.P., and DAVID I. ABRAMSON, M.D.,
Brooklyn, N. Y.

In recent years a number of electrocardiograms have been reported possessing a shortened P-R interval and a bizarre, widened QRS complex of the type usually associated with an asynchronous activation of the two ventricles. Such cases have been described by Wilson,¹ Wedd,² Hamburger,³ Pezzi,⁴ Wolff, Parkinson and White,⁵ Holzmänn and Scherf,⁶ and Wolferth and Wood.⁷

The present report is concerned with an electrocardiographic study of a similar case with some further evidence relevant to the underlying mechanism.

CASE REPORT

A. N., a male, aged 44 years, a patent attorney by occupation, was seen by one of us in September 1932, following his rejection by an insurance company because of an abnormal electrocardiogram. Previously his only complaints referable to the heart were occasional attacks of palpitation since the age of six years, unassociated with effort or excitement, appearing suddenly, and lasting for a few minutes. During the attack his pulse was very rapid but regular, and he discovered early that he could terminate the palpitation by holding his breath.

Examination disclosed a well developed adult male. The heart was regular, rate 82, sounds were clear, and there were no murmurs, blood pressure 122 systolic and 80 diastolic. Fluoroscopic examination revealed the heart inclined transversely, but otherwise normal in contour and size.

Electrocardiographic Study. The first electrocardiogram, taken in September 1932, showed a normal sinus rhythm with a rate of 80 per minute. The P-waves were upright in all leads but very close to the ascending limb of the R-wave (P-R interval 0.12 sec.). The QRS complex was widened, being 0.15 sec. in duration and splintered at its apex. The terminal deflection was oppositely directed to the main deflection, the latter being upright in the three leads and similar to the type of complex seen in left bundle-branch-block (new classification) (Figure 1).

Despite an electrocardiogram usually associated with, and indicative of myocardial damage, it was thought, in view of the apparent good health of the patient, that the electrocardiographic alteration was not the result of organic involvement. Quinidine sulphate, gr. III q. i. d., was given for three days, and another record was taken. The latter showed a definite change from the first (figure 2, A). In all three leads, the abnormal complex had been replaced by normal R-waves associated with lengthened P-R intervals. Except for a left axis deviation, the electrocardiogram was normal in contour. Comparison of the two types of complexes revealed that the

FIG 1 Usual type of electrocardiogram with short P-R interval and wide QRS complex
Time, one-fifth second 1 cm = 1 millivolt

FIG 2 A Effect of quinidine medication—normal P-R interval and QRS complex present in the three leads

B Effect of subcutaneous injection of atropine sulphate, gr 1/50 Increase in heart rate noted with no change in contour of QRS complex

C Effect of digital pressure applied to carotid sinus Decrease in heart rate noted with no change in contour of QRS complex

distance from the beginning of P to the end of the QRS wave was approximately the same in both the normal and abnormal groupings (0.274 to 0.279 sec), and the contour of the P-wave was similar in both

In order to be certain that the changes recorded in the second tracing were not merely coincident with the quinidine medication, the latter was discontinued and one week later another electrocardiogram taken. This showed only the abnormal type

of QRS complex together with the short P-R interval. At two other periods, quinidine was again administered with approximately the same effect as in the above instance. The withdrawal of the drug always resulted in the return of the abnormal type of curve. At times without any treatment a spontaneous transition from the abnormal complex alone to alternate grouping of abnormal and normal complexes occurred (figure 3).

In the course of one examination the effects of exercise, digital pressure on the

FIG 3 Electrocardiograms showing alternation of normal and abnormal groupings

carotid sinus and the subcutaneous injection of atropine sulphate were studied (figure 2, B and C). The rate decreased with carotid stimulation and increased after atropine and exercise. There was no change in the time relations and contour of the abnormal groupings. Electrocardiograms taken at intervals up to the present still reveal one or the other of the above states, but at no time except during quinidine medication have normal groupings been present more often than every other cycle. Unfortunately, no records were obtained during any of the attacks of paroxysmal tachycardia.

DISCUSSION

Twenty-eight cases possessing short P-R intervals associated with widened QRS complexes are described in the literature. The patients were all comparatively young and in only a few could an abnormal cardiovascular history be obtained. However, many had suffered from paroxysms of tachycardia, auricular fibrillation, or flutter.

Recently Wolferth and Wood reported nine such cases and reviewed the previous attempts to explain the mechanism. They further presented an hypothesis based upon the assumption that an aberrant conduction tissue connection (i.e., one besides the Bundle of His and its two branches) was present between the right auricle and right ventricle in these patients and that it was functionally able to conduct impulses. Such a structure has been described by Kent⁸ (Bundle of Kent), who presented histological evidence of the existence of a muscular connection between the right auricle and ventricle in the lateral wall. He demonstrated further that when all the structures which connect the auricles and

ventricles in a mammal are severed with the exception of this bridge of tissue, impulses still may be conducted from auricle to ventricle resulting in response of the latter

In some of Wolff, Parkinson and White's series, factors producing inhibition of vagal impulses brought about a transition to normal. Wolferth and Wood, and Holzmänn and Scherf found on the contrary no change under similar conditions. In our patient also, exercise, carotid sinus stimulation, and atropine had no effect upon the characteristics of the abnormal grouping. On the other hand subsequent to the administration of quinidine a normal electrocardiogram was obtained. This drug decreases the rate of impulse spread through conduction tissue as has been noted by numerous investigators, among them Cohn and Levy,⁹ Lewis,¹⁰ Schott,¹¹ Wolferth,¹² and Korns.¹³ If we assume therefore that the Bundle of Kent is able to conduct impulses in these patients (as have Wolferth and Wood, and Holzmänn and Scherf), a further assumption is reasonable that this tissue, which ordinarily does not have the properties of irritability and of conductivity as highly developed and as well stabilized as the Bundle of His, responds more markedly to depressants like quinidine. Following its administration the impulses tend to be conducted through normal channels. On withdrawal of the drug, the refractoriness of the Bundle of Kent again diminishes and impulses are conducted over it. Measurements made on the normal grouping over a period of three years consistently revealed a prolonged P-R interval (0.222 sec). Since such an increase is usually the result of a decreased rate of spread through the auriculo-ventricular node, it can be assumed that this is the explanation here. This may in part account for the fact that the effective impulse in most instances is the one traversing the aberrant pathway.

It seems likely that under these conditions the Bundle of His is able to conduct impulses and does so, but when the abnormal complex occurs, the conduction wave passes over two pathways: (1) via the Bundle of Kent, hence reaching the right ventricle prematurely, and (2) via the Bundle of His and its two branches. However, the impulse arriving at the right ventricle by way of the normal route (right branch) finds the ventricle already activated and therefore refractory. In the case of the left ventricle there is evidently a race between the impulses spreading down the left branch of the Bundle of His and those spreading across the septum from the prematurely activated right ventricle.

SUMMARY

An electrocardiographic study of a case is presented possessing ventricular complexes of the bundle-branch-block type associated with a very short P-R interval.

The effects of carotid sinus stimulation, exercise, atropine and quinidine upon the abnormal electrocardiogram are described.

EXCESSIVE SMOKING AS A POSSIBLE PRECIPITATING FACTOR IN DIABETIC GANGRENE, WITH A CASE REPORT *

By HARRY BLOTNER, M D , *Boston, Massachusetts*

TOBACCO smoking became of interest to me as a result of the work by Wright and Moffat¹ who found that smoking produced in the great majority of normal individuals a marked drop in the surface temperature at the tips of the fingers and toes, and frequently a slowing and stoppage of the blood flow in the capillaries of the nail fold. Shortly after their paper was published I saw a young man with diabetic gangrene who gave a long history of smoking a great many cigarettes each day. The case of this man is recorded to suggest that excessive smoking may be injudicious for the diabetic and even may be a factor in helping to precipitate fatal gangrene.

Mr S B was a Jewish business man, 34 years old. He entered the hospital on August 11, 1934, complaining of non-healing gangrene of the right foot. His family history was striking in that his mother died of diabetes at the age of 34 and a sister, now 29 years old, has had diabetes for several years. He had been married for six years and his wife and one child were living and well. He began to smoke at the age of 17 and used 30 to 40 cigarettes a day up to two years ago when he started to smoke more heavily. Since then he has smoked 40 to 80 cigarettes a day, a daily average of about sixty. For the past three years he has noticed at times on exertion numbness and tingling in his right leg. Three years ago he had weighed 223 pounds, but his weight had decreased to 150 pounds when he came under observation.

He was always well until 1931 when he began to feel easily fatigued and noticed that he was losing weight. His diabetic sister recognized the possible significance of these symptoms and got him to visit a doctor who confirmed the diagnosis of

* Received for publication June 20, 1935

From the Medical Clinic of the Peter Bent Brigham Hospital

diabetes At first the patient was treated with diet only, but after three months he began to take, in addition, 10 units of insulin three times a day, and for a year remained sugar free He then grew careless and omitted the insulin for a time, but his symptoms returned so that he resumed treatment

About eight months before entry to the hospital he began to have a noticeable amount of pain in the back of his right leg when walking At first the pain was trivial but as time went on it became more severe and more frequent Finally he could walk only for half a block before pain would compel him to stop He had no pain in bed at night

About four months before entering this hospital a small ulcer developed on the right little toe There was no history of any antecedent trauma He was then hospitalized elsewhere for 10 days and while in bed another ulcer appeared spontaneously on the sole of the right foot After this period of rest he got up and about and was able to walk a short distance with crutches The ulcers, however, failed to heal Four weeks before entry to this hospital he noticed that these ulcers had become black and foul with a purulent discharge and gradually they became so large and uncomfortable that he took to his bed, and entered our institution for treatment

His general examination was not remarkable except for evidence of loss of weight and gangrene of the right foot The blood pressure was 100 mm of mercury systolic and 60 diastolic

The Wassermann and Hinton tests were negative The hemoglobin was 94 per cent (Sahli), the red blood count 5,030,000, and the white blood count ranged from 25,000 to 13,000 The blood cholesterol was 185 and 140 mg on two occasions and the blood sugar varied from 276 mg to 160 mg The patient had rare insulin reactions, but no blood sugar determinations were made during them The urine was essentially negative and it seldom contained even the slightest possible trace of sugar even when the blood sugar was elevated

The radial arteries were not sclerotic but very soft and easily compressible The temporal and retinal arteries were normal The pulsations in the dorsalis pedis artery were present in the left foot but were absent in the right The popliteal pulse was felt on the left but not on the right The right foot showed swelling and redness on the lateral aspect The small toe was black On the sole of the foot there was an ulcerated area about 8 cm long and 4 to 6 cm wide over which the skin was black, crusted, indurated and somewhat peeling Beneath the crustation there was a foul purulent discharge Around this area of gangrene the skin was red, angry and edematous There was also a small ulcer over the external malleolus which was almost completely healed

Because of the patient's age there was doubt as to the underlying cause of the gangrene In the previous experience of this hospital diabetic gangrene has been encountered only once in so young a patient This was a man of 32 who developed gangrene apparently as the direct result of trauma and superimposed infection

At first it was thought that obliterative endarteritis (Buerger's disease) might be playing a part However, a number of tests were made which tended to exclude such a diagnosis Roentgen-rays of the feet, legs and thighs showed an osteomyelitis involving the distal end of the fifth metatarsal and the proximal end of the proximal phalanx of the right small toe In addition, there was marked calcification of the arteries of the feet and of the posterior tibial arteries of the legs up to the level of the proximal end of the fibula

Oscillometric studies of the arms and legs gave normal tracings over the arms and the left leg down to the lower part of the calf In contrast, on the right side there was decrease of the amplitude of the oscillations over the thigh and practically absence of oscillations from just above the knee downwards This indicated a very poor circulation on the affected side

FIG 1 Views of gangrenous foot of Mr S B, a diabetic patient

FIG 2 Oscillometric tracings of the arms and legs of a patient with diabetic gangrene, who smoked on an average of 60 cigarettes a day

Skin temperatures of the legs were determined with a thermocouple at frequent intervals during a control period until the temperatures remained constant and subsequently during a period of two and one-half hours while the patient was smoking cigarettes continuously. During all that time the patient lay flat in bed in a small room at a constant temperature. The temperature readings were taken at the tibial tubercle, the anterior ankle and the base of the great and small toes. Tobacco smoking produced a gradual decrease in the temperature at the various points during the

FIG 3 Skin temperatures of legs of Mr. S. B., a diabetic patient with gangrene of the right foot, while smoking cigarettes for 2½ hours

period of observation. The maximum drops in temperature occurred over the right and left tibial tubercles and these amounted to 7.1 and 5.3 degrees F respectively. The decrease in temperature at the other points was less striking. In Wright and Moffat's cases using tobacco, the average drop in skin temperature was 5.3 degrees F in one hour, the maximum drop was 15.5 degrees F. However, their experiments were conducted on normal individuals.

The patient was given a diet of 150 gm carbohydrate, 70 gm protein and 80 gm fat and 15 to 20 units of insulin three times a day before meals.

The leg was treated conservatively with a heat cradle and the wounds were kept clean. The foot improved and the toe became demarcated. However, in two weeks there developed suddenly a rise in temperature and some lymphangitis of the right leg. A mid-thigh amputation seemed indicated and was performed at once, and the patient progressed very satisfactorily until the ninth day postoperatively when the temperature again rose suddenly and the wound broke down and became infected. The infection progressed and invaded the subcutaneous tissues, producing necrosis of the fascia and muscle over the entire stump. Subsequent operations on the hip failed to be helpful and the patient died on October 10, 1934.

The essential pathological changes in the amputated leg consisted in a thrombosis of the posterior tibial artery. The clot filled the lumen of the vessel and extended from its origin to the region of the external malleolus. It was well organized and was evidently of long duration. Distal to the clot the plantar arteries and the peroneal artery showed considerable atheromatous change. The popliteal artery was not remarkable. Microscopic examination of sections from various parts of the arterial tree of the limb showed arteriosclerotic lesions of varying type. In some of the smaller vessels occasional fibrinous thrombi were encountered. However, the general picture was that of arteriosclerosis and not of thromboangitis obliterans.

The findings of the postmortem examination were otherwise irrelevant. There was extensive infection of the right hip and an abscess in the right side of the pelvis which extended around the rectum and was in direct connection with the muscles of the anterior thigh. Bronchopneumonia also was present in both lungs. The blood vessels in various organs and other parts of the body were in surprisingly good condition.

COMMENT

It is of practical interest to attempt to trace the etiology of the gangrene in this case. Certainly the fundamental lesion, as usual, was arteriosclerosis with superimposed thrombosis and infection. In line with the work of Wright and Moffat it is not unreasonable to suggest that the excessive use of tobacco by this patient may have been an important factor in precipitating the gangrene. The lowering of the skin temperature after the use of tobacco is thought to be caused by a slowing or stoppage of the circulation in the capillary bed. Such an effect in an extremity with an already diminished arterial blood supply may well play a considerable role in the early development of gangrene. Although the greatest drop in temperature observed after smoking was not more than 7.1 degrees Fahrenheit and hence not as marked as in some of the normal individuals used by Wright and Moffat, nevertheless it is possible that such a fall in temperature so induced, day in and day out over a long period of time in an individual with marked arteriosclerosis, was very harmful.

Since now it is known that the excessive use of tobacco produces definite effects on the peripheral vascular system, it will be of value in the future to investigate carefully the history of excessive smoking in diabetic patients. Diabetics who are ardent smokers should be advised moderation in smoking, since if they will avoid this deliberate insult to a peripheral circulation which already is likely to be diseased and easily vulnerable, they may thereby escape the vicissitudes of unnecessary gangrene.

EDITORIAL

THE RÔLE OF THE LIVER IN HEMOPOIESIS

THE rôle of the liver in hemopoiesis has aroused increasing interest since the discovery by Minot and Murphy of the curative action of liver when fed to patients with pernicious anemia. It is now well established that liver contains some substance necessary for normal red cell production, which is produced in the normal body, but is lacking in pernicious anemia. A deficiency of this material results in an arrest of the maturation of the red blood cells and in the delivery into the blood stream of cells which are abnormal and functionally defective.

The work of Cohn et al., of West, and many others has shown that chemically this anti-anemic principle of liver is a relatively simple substance quite distinct from the vitamins, proteins and other nutrient materials present in liver. The development of methods of purification by Gansslen, and by various American workers, which permit intramuscular and even intravenous administration, is of great practical importance as well as of theoretical interest.

We owe to the work of Castle and his associates the first clear insight into the nature of the deficiency in pernicious anemia, as well as the source of the active substance. The action of some ferment-like constituent of normal gastric juice, the "intrinsic factor," on some substance present in certain foods (muscle meat, yeast, etc.), the "extrinsic factor," results in the production of a new substance which, after absorption by a patient with pernicious anemia, acts like liver extract in stimulating a reticulocyte crisis and a rapid production of red blood cells. The gastric juice of patients with pernicious anemia shows a lack (or a great reduction) of this intrinsic factor.

The fact that liver extract is also therapeutically effective in such diseases as tropical sprue, the "hemolytic" anemias of pregnancy and fish tape worm anemia, which show a macrocytic hyperchromic anemia morphologically similar to pernicious anemia, has led some to the generalization that macrocytosis is an indication of some disturbance in the production (or utilization) of this anti-anemic principle of liver. This assumption has received some apparent support from the observation of macrocytic anemia in some cases of advanced liver disease (Wintrobe and Shumacker,¹ Goldhamer et al.,² etc.).

Intensive study of these various diseases has shown that the conditions giving rise to the anemia may be complex. In some cases of sprue, the intrinsic factor is absent, as in pernicious anemia. In others the intrinsic

² GOLDHAMER, S. M., ISAACS, R., and STURGIS, C. C. The rôle of the liver in hemopoiesis, *Am. Jr. Med. Sci.* 1934, **CLXXXIII**, 193.

factor is present, and another explanation must be sought. In some cases of sprue and tropical anemia feeding large amounts of vegex or marmite (autolyzed yeast) relieves the anemia, and a lack of the extrinsic factor seems to be responsible for failure to form the active substance. In some cases of sprue, idiopathic steatorrhea, etc., deficient absorption seems to be the explanation. The intrinsic factor is present, oral administration of marmite or liver is uncertain in its effect, but parenteral injection of liver extract is highly effective.

In the case of anemia in disease of the liver, it is natural to assume that there is an inability of the liver to store, or possibly to elaborate the anti-anemic principle in a normal manner. There is considerable evidence that a defect of storage may exist. The intrinsic factor is probably not usually at fault. Achlorhydria is inconstant in these cases, and in one case¹ demonstration of the intrinsic factor in the stomach juice has been reported. Additional information of great interest has been obtained by a study of the content of anti-anemic principle in individual livers. By suitably preparing extracts of the liver of patients at autopsy, injecting them into patients with pernicious anemia, and observing the reticulocyte response, the presence or absence of the anti-anemic substance can be determined. This is regularly present in patients dying of unrelated diseases and in well treated cases of pernicious anemia in remission, but it is absent in untreated cases dying in an active stage of the disease. In some fatal cases of cirrhosis with macrocytic anemia, absence of the active principle in the liver has been demonstrated. Furthermore, parenteral injections of liver extract have relieved the anemia in some of the cases.

In one case of cirrhosis with anemia reported by Goldhamer et al the liver did contain the anti-anemic principle. The anemia in this case was attributed to an inability of the liver to mobilize the substance normally. Furthermore, Wilkinson and Israels² have reported a small series of cases of macrocytic anemia of unknown etiology whose gastric juice contained free acid, who showed no evidence of gross liver disease, who were not benefited by injections of liver extract, and whose livers contained the anti-anemic principle. They assume here an inability of the hemopoietic tissues to utilize the active principle, even when it is present in the body in adequate quantities.

Such conclusions are based largely on the assumption that because the anemia is macrocytic, it must be related in some way to a disturbance in the production or utilization of the anti-anemic principle of liver. However, as Minot has pointed out, anemia with macrocytosis occurs occasionally in a variety of diseases (leukemia, aplastic anemia, hemolytic jaundice) in which there is no evidence that this substance is involved, and it is quite possible that the macrocytic anemia of liver disease also is unrelated to it. Injections of liver extract are ineffective in some cases. As yet there are no adequate studies of the bone marrow.

² WILKINSON, J. F., and ISRAELS, M. C. G. Achresthic anemia, *Brit Med Jr*, 1935, 1, 139, 194.

That the liver may play some part in the elaboration of the active material as well as in its storage is suggested by the fact that the active material as extracted from liver differs significantly from that in the gastrointestinal tract (and in "ventriculin") "Liver extract" is thermostable, it can be sterilized and is effective on parenteral injection. Its potency is increased by autolysis and by digestion with hog's stomach or normal gastric juice. The active material as it exists in the gastrointestinal tract cannot be extracted by the methods applicable to liver. It is destroyed by autolysis or prolonged digestion, it is thermolabile, and (except perhaps as "addisin") it has not been obtained in a potent form suitable for parenteral injection. There is, however, no direct proof that the liver is the site of this alteration, plausible as this appears. The change might occur in the intestinal mucosa during absorption. The fact that the material is stored in the liver does not prove that it is elaborated there. It is also abundant in kidney, and it is present in lesser concentration in other tissues (brain, placenta, etc.)

The study of these problems has been hampered by serious technical difficulties. The only available method (Castle's) for demonstrating the intrinsic factor is extremely cumbersome and quite impracticable except in large hospitals with an abundance of clinical material available. Demonstration of the active principle has been possible only by observing the response to it of untreated patients with pernicious anemia, who are now inconveniently rare. Hitherto the experimental production of the disease in animals has not been satisfactorily accomplished. Recent experimental work, however, offers hope that some of these difficulties may be eliminated. Thus Singer⁴ has reported a reticulocyte response in rats following injection of gastric juice containing intrinsic factor but negative responses with that from patients with pernicious anemia. Jacobson⁵ obtained a definite reticulocyte response in selected normal guinea pigs following the administration of active principle, and he has used this as a means of detecting and measuring the amount of the active principle. While quantitatively the responses reported are not impressive, his work receives confirmation from the observations of Miller and Rhoads,⁶ and it offers definite promise that animals will soon replace patients for this purpose.

Miller and Rhoads,⁷ utilizing swine because the gastric juice of these animals contains intrinsic factor, have recently produced a disease condition closely resembling tropical sprue and (less closely) pernicious anemia by feeding a diet similar to that by means of which Goldberger produced black tongue in dogs. These animals showed a severe anemia (usually

⁷ MILLER, D. K., and RHOADS, C. P. The experimental production of loss of hematopoietic elements of the gastric secretion and of the liver in swine with achlorhydria and anemia, *Jr. Clin. Invest.*, 1935, *xiv*, 153.

macrocytic), gastrointestinal disturbances with stomatitis, achlorhydria, loss of the intrinsic factor, disappearance of the active principle from the liver, and a hyperplastic megaloblastic bone marrow. The administration of liver extract caused a typical reticulocyte crisis, and clinical and hematological improvement. The possibilities for study which such experiments offer is obvious.

In summary, the only part played by the liver in erythropoiesis for which positive proof exists is that of a storehouse for the antianemic principle. The latter appears not to be an essential constituent of the liver cells. It is possible that the liver participates in the elaboration of the final product. It is also possible that a disturbance of its capacity to store or even to elaborate the active principle is responsible for the occasional development of macrocytic anemia in grave liver disease. That the liver may be found to exercise other important functions in the process of blood cell production is probable, but this is still pure speculation.

BOOK REVIEWS

Radium Treatment of Skin Diseases, New Growths, Diseases of the Eyes and Tonsils
By FRANCIS H WILLIAMS, M D 118 pages, 13 × 19 cm Stratford Company,
Boston 1935 Price, \$2 00

This is a delightful and simply written little book of one hundred and eighteen pages divided into three sections Part One consists of four chapters dealing with the nature and properties of radium and the use of radium in diseases of the skin and superficial new growths Part Two includes seven chapters dealing with radium in diseases of the eyes, and Part Three is made up of five chapters dealing with the treatment of tonsils and lymphoid tissues in the throat The twelve illustrations are simple and clear, although more illustrations could have been added to advantage

One of the attractive features of this book is its author—a pioneer in the field of radium therapy, who began his work in 1900, when little was known about the biological effect of radium and its usefulness as a therapeutic agent He was required to develop instruments to measure the penetration of tissues by the various rays in order to apply radium intelligently to clinical cases This meant detailed careful experimentations The book is a lasting record of Dr Williams' fundamental discoveries and is of real practical value

Parts Two and Three, dealing largely with clinical uses of radium in the specific fields covered by the book, are illustrated by typical cases, adding interest and clarity to the text The sphere of clinical use, of course, is limited, but the book is concise and valuable for a ready reference text

G E W

Classical Contributions to Obstetrics and Gynecology By HERBERT THOMS, M D ,
Associate Professor of Obstetrics and Gynecology, Yale University, and HOWARD
A KELLY, M D 265 pages, 15 × 23 5 cm Charles C Thomas, Springfield,
Illinois 1935 Price, \$4 00

In this book the author tells about the great specialists in women's diseases, beginning with Soranus of Ephesus who lived in the Second Century The contributions of any gynecologists or obstetricians now living have been omitted as has all material published since 1900 There has been no attempt to make this volume encyclopedial in type but rather the author has exercised the right of personal choice in selecting those men to write about who in his opinion have made the most important contributions to the development of gynecology and obstetrics

The general practitioner, as well as the specialist, will be glad to become better acquainted with the great obstetricians, who lived in the Eighteenth Century, among whom might be mentioned Mauriceau and Smellie but probably the most interesting part of the book is that which deals with the accomplishments of Charles White, Oliver Wendell Holmes, Semmelweiss and Pasteur, all of whom lived in the Nineteenth Century It is to these men that the human race should be always grateful for giving the medical profession a clearer understanding of puerperal infection

The last part of the book tells of the lives and achievements of those pioneers in pelvic surgery, who lived in the last Century, among whom we Americans are proud to claim as our own—Ephraim McDowell, Nathan Smith, Marion Sims and many others

Dr Thoms work should be of special interest to those who instruct medical students in obstetrics and diseases of women A little medical history interspersed through a lecture or clinic often adds interest, and the students through learning what

their forebears have accomplished in the struggle against disease may be stimulated to "carry on the torch"

L B

Gynecological and Obstetrical Tuberculosis By DR EDWIN M JAMESON, B S, Fellow of Trudeau Foundation, Attending Surgeon, Saranac Lake General Hospital and Reception Hospital 256 pages Lea and Febiger, Philadelphia 1935 Price, \$3 50

This monograph coming from the Trudeau Foundation should be of great interest not only to the gynecologist and obstetrician but also to the whole medical profession. The book is divided into three parts. The first deals with the alterations in the physiology of the female genital apparatus brought about by pulmonary tuberculosis. The second covers the various forms of female genital tuberculosis, while the third or last part of the book is given over to a discussion of the problem of pregnancy in the tuberculous woman.

The author has thoroughly reviewed the literature and there is a 36 page bibliography. However, what makes this monograph of such distinct value are the conclusions that Dr Jameson himself has reached, based on his own studies of the tremendous amount of clinical material available in the Trudeau Clinic. This is, indeed, a book well worth having.

L B

Pediatric Treatment By PHILIP S PORTER, M D 578 pages, 16 × 24 cm Macmillan Co., New York 1935 Price, \$5 00

The organization of material is excellent. Following the necessary basic review of general, local and emergency treatment, plus a chapter on pharmaceuticals, the diseases according to systems are then presented by a brief resume of clinical symptoms and signs with the therapeutic indications, followed by the therapeutics proper, under the subdivisions of general and symptomatic measures. Whenever prophylactic or quarantine measures are requisite they are described in the appropriate subdivision. Prescriptions are amply supplied and a final chapter consisting entirely of prescriptions of outstanding pediatricians is presented. The book is most complete, nearly every possible subject regardless of the value of treatment has been devoted space.

A therapeutic text almost uniformly reflects the climatological location of the author and likewise methods that are common usage in his (the author's) location. To the preceding, Dr Potter of California, is no exception, as may be evidenced by the statement on Page 220 (Treatment of Anorexia), "the child should be held upright after feeding and then taken out in the sunshine for an hour."

The author is a firm advocate of purging, even in many cases in which it would seem that this measure was of questionable value. The inclusion of practices in vogue elsewhere would have been a helpful addition to this volume.

The treatise is easily read. There is an excellent bibliography. It contains much of interest but cannot be said to constitute an advance over more familiar texts.

E B

Mouth Infection By OLIVER T OSBORNE, M D 119 pages, 14 × 21 cm 1934 Price, \$2 00

This book is an interesting treatise on the importance of mouth infection, its relationship to disease and the necessity for cooperation between physician and dentist in treatment. According to the author, many diseases, such as boils, neuritis, stomach and intestinal ulcers, endocrine disturbances, endocarditis, etc are often caused by oral infections.

In discussing devitalized or pulpless teeth, the author states that even when teeth are negative to roentgenographic examination, upon removal the *Streptococcus viridans* may be found within the root canal

Many case histories are included which are classed in several groups. With each history, there is a report of the oral examination. The reports of reexamination following medical and dental treatment reveal many interesting reactions.

The relationship of infected tonsils to systemic disorders is discussed and supplemented with actual case histories showing reactions following their removal.

Vincent's infection, its dangers and treatment are described.

The book closes with a discussion as to the possibility of the tooth brush, which is in general use today, causing continued reinfection of the mouth by being improperly kept.

The author's point of view is often stimulating even though his conclusions may not be fully supported.

INVITATION

Detroit, one of the oldest of the large cities of the country and, in a sense, one of the newest, joins with Ann Arbor, the home of Michigan's great University, in extending for the second time a cordial invitation to the American College of Physicians to hold in these cities the Twentieth Annual Session of the College

The Michigan State Medical Society, the Wayne County Medical Society, the Detroit Academy of Medicine, the Medical Departments of the University of Michigan and Wayne University have, through their officers, assured the College of their hearty cooperation with the local committee to make the Session a success. The Department of Health and the Welfare Department with the wealth of clinical material under their control will give us their unqualified support.

The seven hospitals, at which will be given the clinical and demonstration programs, have a total bed capacity of 4051. The clinical amphitheatres and assembly rooms of these hospitals will accommodate 2000 persons.

Many distinguished clinicians from other cities of the United States and Canada will aid the local physicians, and this will give to the clinical program a truly cosmopolitan character.

The day in Ann Arbor will give to members the opportunity to visit the University of Michigan and to have a close-up view of the activities of its teaching hospital and laboratories.

The features of historic interest of older Detroit have been largely overgrown during the present century by its rapid rise to the position of the fourth city of the country in population and by the change in its character from a gracefully growing community to the greatest industrial city of the world.

While Detroit cannot rival the old cities of the East in structures and objects

GENERAL INFORMATION
HEADQUARTERS
BOOK-CADILLAC HOTEL
Washington Blvd

The Book-Cadillac Hotel will be not only the headquarters hotel for Officers, Regents, and Governors of the College, and so far as facilities permit, for members and guests, but also the general headquarters for registration, technical exhibits and all general scientific sessions

Wolverine, Witherell at Elizabeth	500	6	2 00 up		3 00 up			

of national historic interest, it can entertain its guests with the marvels of modern industrialism. It is the world's center of automobile production. Ninety per cent of the passenger car output of the country is made in the city and its environs. A visit to one of the great factories is an education in the methods of quantity production.

Belle Isle Park is one of the beauty spots of the city. Among the outstanding objects of interest are the Art Museum and Public Library at the Art Center, the unique American Museum at Greenfield Village at Dearborn and the Cranbrook School at Bloomfield Hills.

Since the Session of 1926 the hospitals of Detroit have doubled their capacity with modern buildings and equipment, and brought their laboratories and research departments to a high state of efficiency.

It is the hope of the local committees that their efforts will make the coming Session memorable for its educational value and for its enjoyable entertainment.

DIRECTORY

Headquarters	Book-Cadillac Hotel
Registration	Fourth Floor, Book-Cadillac Hotel
Technical Exhibits	Fourth Floor, Book-Cadillac Hotel
General Scientific Sessions	Ballroom, Book-Cadillac Hotel
Convocation	Ballroom, Book-Cadillac Hotel
Annual Banquet	Ballroom, Book-Cadillac Hotel

WHO MAY REGISTER—

- (a) All members of the American College of Physicians in good standing for 1936 (dues, if not paid previously, may be paid at the Registration Bureau)
- (b) All newly elected members
- (c) Members of the Wayne and Washtenaw Counties Medical Societies, without registration fee, upon presentation of their 1936 membership cards
- (d) Medical students pursuing courses at the Wayne University, College of Medicine, and the University of Michigan Medical School, without registration fee, upon presentation of matriculation cards, or other evidence of registration at these institutions, exhibits and general sessions
- (e) House Officers of the hospitals participating in the program, upon presentation of proper identification, exhibits and general sessions
- (f) Members of the Medical Corps of Public Services of the United States and Canada, without registration fee, upon presentation of proper credentials
- (g) Qualified physicians who may wish to attend this Session as visitors. Such physicians shall pay a registration fee of \$12.00, and shall be entitled to one year's subscription to the ANNALS OF INTERNAL MEDICINE (in which the proceedings will be published), included within such fee.

REGISTRATION BUREAU—Temporary Registration Bureau will be open at the Book-Cadillac Hotel on Sunday afternoon and evening, March 1. The permanent Registration Bureau will be located on the fourth floor of the Book-Cadillac Hotel. Hours: 8:30 a.m. to 6:00 p.m., daily, March 2 to 6.

REGISTRATION BLANKS FOR ALL CLINICS AND DEMONSTRATIONS will be sent with the formal program to members of the College. Guests will secure registration blanks at the Registration Bureau during the Session.

THE CASHIER'S DESK at the Registration Bureau will receive payment of dues still delinquent, and accept orders for Banquet tickets, the College Key, the framed Fellowship Pledge, the Fellowship Certificate Frame and subscriptions to the ANNALS OF INTERNAL MEDICINE.

BULLETIN BOARD FOR SPECIAL ANNOUNCEMENTS will be located near the Registration Bureau at the Book-Cadillac Hotel

TRANSPORTATION—Round trip tickets may be procured on the basis of one and one-third of the current one-way first class fares, with minimum excursion fare of \$1 00 for the round trip, upon presentation of identification certificates to be procured from the Executive Secretary of the American College of Physicians. The reduced fares apply for physicians and dependent members of their families.

Members are privileged to make the going journey by one route and return by another route. The fare for children of five and under twelve years of age will be one-half of the round trip fare for adults, children under five years of age free when accompanied by parents or guardian. Stop-overs will be allowed at all stations within final limit on either going or return trip, or both, upon application to conductors.

Before purchasing tickets, members must secure from the Executive Secretary an Identification Certificate, to entitle them to the reduced fares.

In general, tickets will be sold from February 19 to March 4, depending upon the relative distance from Detroit, with a return limit of thirty days in addition to date of sale.

All tickets must be validated by a special railroad agent at the Detroit Headquarters at the Book-Cadillac Hotel from March 2 to 6.

LOCAL TRANSPORTATION—Transportation to the University Hospital, Ann Arbor, on Wednesday, March 4, will be by buses. Fare for the round trip will be \$1 80. Tickets should be purchased at the desk near the Registration Bureau before 8 00 o'clock, Tuesday evening, in order that a sufficient number of buses will be available.

Buses will be stationed at the Book-Cadillac Hotel at 8 00 o'clock, Wednesday morning, and will start for Ann Arbor as rapidly as filled. Running time—1 hr., 20 min.

Street cars of the Hamilton Avenue line pass the Henry Ford and the Herman Kiefer Hospitals. These cars cross Washington Boulevard at Grand River Avenue, two blocks north of the Book-Cadillac Hotel. The Woodward Avenue cars going north pass within two blocks of Harper, The Grace and The Children's Hospitals.

THE GENERAL BUSINESS MEETING OF THE COLLEGE will be held at 5 30 p m., Thursday, March 5, immediately following the general scientific program of the afternoon. All Masters and Fellows of the College are urged to be present.

There will be the election of Officers, Regents and Governors, the reports of the Treasurer and of the Executive Secretary, and the induction to office of the new President, Dr Ernest B Bradley, Lexington, Kentucky.

BOARD AND COMMITTEE MEETINGS—The following meetings are scheduled as indicated. Special meetings will be announced and posted.

A special dinner will be tendered to the Board of Governors by members of the Board of Regents at the Book-Cadillac Hotel, Sunday evening, March 1. An announcement of the time and place will be made later. Members of the Board of Governors are cordially invited.

COMMITTEE ON CREDENTIALS

Sunday, March 1, 10 00 a m

Parlor C, Fourth Floor, Book-Cadillac Hotel

BOARD OF REGENTS

Friday, March 6, 12 00 m *

BOARD OF GOVERNORS

Parlor C, Fourth Floor, Book-Cadillac Hotel

Monday, March 2, 5 00 p m

Wednesday, March 4, 12 00 m *

** Buffet luncheon served*

SPECIAL FEATURES

MONDAY, MARCH 2, 1936

THE ANNUAL SMOKER will be given immediately following the scientific program, about 10 20 o'clock in the evening, in the Grand Ballroom of the Book-Cadillac Hotel. An unusual program of music and other entertainment will be given. Ladies are invited.

WEDNESDAY, MARCH 4, 1936

CONVOCATION OF THE COLLEGE—8 15 p m, Ballroom, Book-Cadillac Hotel. All Masters and Fellows of the College and those to be received in Fellowship should be present. Newly elected Fellows who have not yet been received in Fellowship are requested to assemble in the Reception Room to the rear of the Grand Ballroom of the Book-Cadillac Hotel at 7 30 o'clock, preparatory to the formation of the procession. They will occupy especially reserved seats in the central section of the Ballroom, to which they will be conducted by the Convocation marshal promptly at 8 15. As this is the most formal meeting of the College, it is suggested that all appear in evening dress.

The Convocation is open to all physicians and their families generally. A cordial invitation is also issued to such of the general public as may be interested.

Following the Convocation Ceremony, the President will present the John Phillips Memorial Medal for 1935-36. Thereafter will follow the Convocational Oration, "The Role of Emotion in Disease," by Dr. Walter B. Cannon, Professor of Physiology, Harvard University Medical School, Boston.

The President, Dr. James Alex. Miller, of New York City, will then deliver the annual presidential address, "The Changing Order in Medicine," to the Masters, Fellows and Associates of the College.

The Presidential Reception, in the Reception Room to the rear of the Grand Ballroom, will follow immediately after the program. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the Reception. All members and guests are invited to remain for dancing in the Grand Ballroom following the Reception.

THURSDAY, MARCH 5, 1936

THE ANNUAL BANQUET OF THE COLLEGE will be held in the Grand Ballroom of the Book-Cadillac Hotel at 8 00 p m. All members of the College, physicians of Detroit and Ann Arbor and visitors attending the Session, with their families, are cordially invited to attend. Consult the banquet program to be printed later for announcement of the toastmaster and speakers.

PROGRAM OF ENTERTAINMENT FOR VISITING WOMEN

The headquarters of the visiting ladies will be in the Founders Room on the fifth floor of the Book-Cadillac Hotel, near the Grand Ballroom.

The program for their entertainment has been arranged to give ample time for sightseeing, shopping and recreation. A folder giving points of interest, shops, theaters, concerts, etc., will be issued by the local committee.

ART CENTER—The Detroit Public Library and the Detroit Institute of Art, Woodward Avenue between Farnsworth and Kirby Streets. The Public Library contains the celebrated murals of Gari Melchers and the Art Institute the much discussed murals of Diego Rivera.

THE WAYNE COUNTY MEDICAL SOCIETY BUILDING 4421 Woodward Avenue. This is the meeting place of the medical men of the city and county. Its club features make it very popular both to members of the Society and the Women's Auxiliary, which has a large and active membership. An excellent restaurant serves luncheon and dinner at moderate prices.

Members of the College are cordially invited to visit the Society's home and inspect its work in the field of medical economics.

ANN ARBOR

LIBRARIES OF THE UNIVERSITY OF MICHIGAN contain about one million volumes, and include many notable collections. 6000 listed items of Greco-Egyptian papyrus, in size and importance surpassed only by the collections in London, Berlin and Cairo, a collection of Persian and Arabic manuscripts once owned by the Sultan Abdul Hamid, the Macmillan Shakespeare Library, 6525 volumes, the Parsons Library of Political Science, 6076 volumes, the Goethe Library 1131 volumes, the William L. Clements Library of American History with its collection of books, manuscripts, maps and newspapers relating to early American history.

THE LAW QUADRANGLE will be found of especial interest. It consists of the Lawyers' Club, the dormitories attached to the Club, the Legal Research building and the Law School building, Hutchins Hall.

THE MUSEUMS BUILDING houses the zoological, anthropological and paleontological collections of the University, including a number of important special collections, such as the Stevens Oriental Collection and the Chinese Government Exhibit from the New Orleans Exposition.

THE EXPOSITION AND TECHNICAL EXHIBIT will be located on the fourth floor of the Book-Cadillac Hotel, on the way to registration and General Sessions.

Because of limitation of room and the impossibility of expanding the number of booths, many firms were unable to obtain space. Many of these firms have exhibited before the College previously, have established contacts among our members and would be in the exhibit again this year if possible. Among them are the following: The Doak Company, Cleveland, Kellogg Company, Battle Creek, Gradwohl School of Laboratory Technique, St. Louis, The Burdick Corporation, Milton Wis. Aznoe's National Physicians' Exchange, Chicago, Ayerst McKenna & Harrison Ltd., Montreal, The Battle Creek Food Company, Battle Creek, Ciba Company, New York, Spicer and Company, Glendale, Ernst Bischoff Company, Inc., New York, S. H. Camp & Company, Jackson, Westinghouse X-Ray Company, Inc., Long Island City, Austin, Nichols & Co., Inc., "Vichy Celestins," Brooklyn.

However, the exhibit will be very representative, and will include medical literature and texts, pharmaceutical products, apparatus and appliances, and many other items of special interest to physicians, especially internists. These exhibits will afford an opportunity for physicians to keep informed of the latest literature and the newest products in the field of medicine generally, the educational value of these exhibits should not be overlooked. Furthermore the exhibitors contribute much not only to the interest of the meeting, but to the financial support of these scientific sessions. Every physician is urged to visit each of the booths, for he will certainly find something new, interesting and scientifically valuable. The exhibits will be closed on Wednesday, Ann Arbor Day. Special intermissions in the general program will be arranged, providing additional time for the inspection of exhibits.

GENERAL SESSIONS

In arranging the program for the General Sessions this year, an effort has been made to present a summary of the progress of medical knowledge in a few selected fields, and in carrying out this plan we are very fortunate to have secured the co-operation of outstanding leaders in various branches of medicine

This review plan of presentation will be followed in the consideration of the following diseases

Cardiac Disease, Diabetes, Virus Diseases, including Common Colds, Silicosis, Arthritis, and also the treatment of Pneumonia, of Pulmonary Tuberculosis and of Syphilis

In addition, the program contains special contributions to other phases of medicine

OUTLINE OF SESSION

TIME	MONDAY	TUESDAY	WEDNESDAY	THURSDAY	FRIDAY
	March 2	March 3	March 4	March 5	March 6
9 00 a m to 12 00 m	Morning free Registration, Exhibits, etc	1st Clinical Session	" ANN ARBOR DAY " 2nd Clinical Session (beginning at 10 00)	3rd Clinical Session	4th Clinical Session

8 00 p m to 10 00 p m	2nd General Session followed by Smoker	4th General Session	Convocation, followed by President's Reception and Dance	ANNUAL BANQUET	

Medical History—It has been thought desirable to include one paper upon this cultural subject as distinct from the purely clinical aspects of medicine

Neurology—The subject of the neuroses is considered from the standpoint of their causation and also of their treatment, and a very recent procedure of great value in the diagnosis and location of brain tumors will be described

Vascular Disturbances will be discussed from the standpoints of physiology and of hemodynamics

Diseases of Children—The subject of the use of convalescent serum in the treatment of acute infectious diseases, and also the treatment of the sequelae of birth injuries will be presented with the aid of motion pictures

Endocrinology—Some of the problems connected with the internal secretions, in addition to those of diabetes, will be discussed

Preventive Medicine and Public Health—In the presentation and discussion of both syphilis and silicosis, the preventive and public health aspects of these diseases will be emphasized

Medico-Dental Problems will be discussed both from the standpoint of medicine and of dentistry

The *Organs of Digestion* are considered in the discussion of certain conditions of the liver and of the intestines, including the treatment of constipation

Respiratory Diseases—In addition to the reviews of the treatment of pneumonia and of pulmonary tuberculosis, special phases of respiratory diseases, both tuberculous and non-tuberculous, will be presented

Experimental Studies of the Revived Human Heart will be presented in a fascinating manner by means of a motion picture

Ann Arbor Session—An unusual and unique feature of our program is the assignment of one entire day to the medical staff of the University of Michigan at Ann Arbor. The program for that day is very varied and promises to be of exceptional interest

The *Convocational Oration* will be delivered by Dr. Walter B. Cannon, Professor of Physiology at the Harvard University Medical School. This address will present a physiological approach to some of the important problems of medicine, under the title, "The Rôle of Emotion in Disease." Professor Cannon's reputation as a scientist and public speaker assures us of a most instructive and enjoyable evening. This address, as well as that of the President of the College, which will be delivered on the same evening, will contain much of general as well as of medical interest, so that it is hoped that many of our lay guests will find it both interesting and enjoyable to attend this session.

GENERAL SESSIONS

Ballroom, Book-Cadillac Hotel, Detroit, Mich

FIRST GENERAL SESSION

Monday afternoon, March 2, 1936

p m

2 00 Addresses of Welcome

CHARLES G. JENNINGS, General Chairman of the Twentieth Annual Session

GROVER C. PENBERTHY, President Michigan State Medical Society

ROBERT C. JAMIESON, President, Wayne County Medical Society

HENRY F. VAUGHAN, Commissioner of Health, City of Detroit

Response to Addresses of Welcome

JAMES ALEXANDER MILLER, President of the American College of Physicians

- 2 30 The History of Hospitals, with Special Reference to Some of the World's
Oldest Institutions
HENRY R CARSTENS, Detroit Mich
- 3 00 Viruses and the Diseases Caused by Them
THOMAS M RIVERS New York N Y
- 3 30 INTERMISSION
- 4 15 Recent Advances in the Study of Common Cold and Influenza
A R DOCHTZ, New York, N Y
- 4 45 Treatment of Birth Injuries and Allied Problems (Illustrated with Motion
Picture)
EARL R CARLSON, New York N Y
- 5 05 The Localization and Diagnosis of Tumors of the Brain by Olfactory Tests
CHARLES A EISENBERG New York N Y
- 5 35 ADJOURNMENT

SECOND GENERAL SESSION

Monday Evening March 2, 1936

Presiding Officer

JAMES E PAULLIN, Atlanta, Ga

p m

- 8 00 Diabetes Today and Tomorrow
ELLIOTT P JOSLIN, Boston, Mass
- 8 30 Disturbances of the Endocrine Balance and Their Relation to Diseases of
Metabolism
C N H LONG, Philadelphia, Pa
- 9 00 Ulcerative Conditions of the Small Intestine
PHILIP W BROWN and J DEJ PEMBERTON, Rochester, Minn
- 9 20 Use of Foods in the Treatment of Constipation
WILLIAM H OLMSTED, St Louis, Mo
- 9 40 Chronic Arthritis—A General Disease Requiring Individualized Treatment
ERNEST E IRONS, Chicago, Ill
- 10 00 ADJOURNMENT

10 20 o'clock

SMOKER

Ballroom, Book-Cadillac Hotel

An unusual program of music and other entertainment has been arranged
Ladies are invited

Admission by registration badge

THIRD GENERAL SESSION

Tuesday Afternoon, March 3, 1936

 Presiding Officer

 ERNEST B BRADLEY, Lexington, Ky

p m

- 2 00 Errors in the Interpretation of Cardiovascular Symptoms and Signs
PAUL D WHITL, Boston, Mass
- 2 30 Errors in the Clinical Application of Electrocardiography
WILLIAM B BREED, Boston, Mass
- 2 55 Errors in Cardiovascular Roentgen-Ray Interpretation
HUGO ROESLER, Philadelphia, Pa
- 3 20 A Survey of the Newer Methods of Cardiac Therapy
WILLIAM D STROUD, Philadelphia, Pa
- 3 45 INTERMISSION
- 4 25 Studies of the Revived Human Heart (Motion Picture)
WILLIAM B KOUNTZ, St Louis, Mo
- 4 45 Some Factors in the Etiology of the Psychoneuroses
LOUIS CASAMAJOR, New York, N Y
- 5 15 The Treatment of Psychoneuroses
AUSTEN FOX RIGGS and HORACE K RICHARDSON, Stockbridge, Mass
- 5 45 ADJOURNMENT
-

FOURTH GENERAL SESSION

Tuesday Evening, March 3, 1936

 Presiding Officer

 WILLIAM J KERR, San Francisco, Calif

p m

- 8 00 The Public Health Control of Syphilis
THOMAS J PARRAN, JR, Albany, N Y
- 8 30 Modern Treatment Methods of Early Syphilis
JOSEPH EARLE MOORE, Baltimore, Md
- 9 00 The Prophylactic and Therapeutic Value of Convalescent Sera in Some of
the Acute Infectious Diseases
WILLIAM THALHIMER, New York, N Y
- 9 20 Medico-Dental Relations A Dentist's Viewpoint
J T O'ROURKE, Louisville, Ky
- 9 40 The Interrelations of Dentistry and Internal Medicine
SIDNEY R MILLER, Baltimore, Md
- 10 00 ADJOURNMENT

ANN ARBOR SESSION

Wednesday, March 4, 1936

The entire program, exclusive of the Convocation in the evening, will be conducted at the University of Michigan, Ann Arbor

FIFTH GENERAL SESSION

Wednesday Afternoon, March 4, 1936

Conducted by the Staff of the Department of Medicine of the University of Michigan
Ballroom of the University of Michigan Union

Presiding Officer

JAMES D. BRUCE, Ann Arbor, Mich

p m

2 00 Address of Welcome

ALEXANDER G. RUTHVEN, President of the University of Michigan

2 10 The Medical and Economic Advantages of an X-Ray Chest Survey of All Hospital Admissions

FRED J. HODGES

2 35 Clinical Aspects of Water Balance and Dehydration

FREDERICK A. COILER

3 00 The Relation between Emotion and Disturbance of Physiologic Function

CARL D. CAMP

3 25 The Present Status of Pernicious Anemia, Experience with 600 Cases over Eight Years

CYRUS C. STURGIS

3 50 The Surgical Treatment of Hypertension

MAX M. PEET

4 05 ADJOURNMENT

ANNUAL CONVOCATION

Wednesday Evening, March 4, 1936

8 15 o'clock

Ballroom, Book-Cadillac Hotel

The general profession and the general public are cordially invited. No special admission tickets will be required.

1 Convocation Ceremony

2 Presentation of the John Phillips Memorial Medal

3 Convocational Oration "The Role of Emotion in Disease"

WALTER B. CANNON, Professor of Physiology, Harvard University Medical School, Boston, Mass

- 4 Presidential Address "The Changing Order in Medicine"
JAMES ALLAN MILLER, New York, N Y
-

President's Reception

Reception Room, Ballroom, Book-Cadillac Hotel

The Reception will follow immediately after the program. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates during the Reception.

Dancing

SIXTH GENERAL SESSION

Thursday Afternoon, March 5, 1936

Presiding Officer

JAMES B. HERRICK, Chicago, Ill

p m

- 2 00 Clinical Manifestations and Studies in Parenchymatous Hepatitis
HUGO A. FREUND, Detroit, Mich
- 2 20 Treatment of Pneumonia
RUFUS I. COLE, New York, N Y
- 2 50 Adolescent Disturbances of Endocrine Function, the Importance of Their
Recognition and Treatment
CHARLES H. LAWRENCE, Boston, Mass
- 3 20 Vascular Physiology and Clinical Medicine
EUGENE M. LANDIS, Philadelphia, Pa
- 3 45 INTERMISSION
- 4 30 The Diagnosis of Silicosis with Special Reference to Roentgenologic Mani-
festations
LEROY U. GARDNER, Saranac Lake, N Y
- 4 50 Silicosis from the Public Health and Economic Viewpoint
A. J. LANZA, New York, N Y
- 5 10 Some Combinations of Certain Tuberculous and Non-Tuberculous Pulmonary
Lesions
F. MAURICE MCPHERDAN, Philadelphia, Pa
- 5 30 ADJOURNMENT

The *Annual General Business Meeting* of the College will be held immediately after the last paper. All Masters and Fellows are urged to be present. Official reports from the Executive Secretary and Treasurer will be read, new Officers, Regents and Governors will be elected, and the President-Elect, Dr. Ernest B. Bradley, will be inducted into office.

Thursday Evening 8 00 o'Clock

Ballroom, Book-Cadillac Hotel

THE ANNUAL BANQUET OF THE COLLEGE

(Procure Tickets at the Registration Bureau)

Consult Special Banquet Program

SEVENTH GENERAL SESSION

Friday Afternoon March 6, 1936

Presiding Officer

GEORGE MORRIS PIERCE Philadelphia Pa

p m

- 2 00 Tuberculosis among Student Nurses, a Five-Year Study at Bellevue Hospital
J BURNS AMBERSON, JR., and H McLEOD RICCINS New York N Y
- 2 20 The Present Status of the Treatment of Pulmonary Tuberculosis
LAWRASON BROWN Saranac Lake, N Y
- 2 50 Postural Pulmonary Emphysema
WILLIAM J KERR and JOHN B LAGEN, San Francisco, Calif
- 3 10 Clinical Problems of Hemodynamics in Nephritis and High Blood Pressure
ARTHUR R ELLIOTT, Chicago, Ill
- 3 30 INTERMISSION
- 4 15 The Lethal Effect of Solar Radiation on Guinea Pigs
MAX PINNER and AARON E MARGULIS, Oneonta, N Y
- 4 25 Acute Syphilitic Myocarditis—Simulating Myocardial Infarction, With a
Case Report
EDWARD C REIFENSTEIN, Syracuse, N Y
- 4 45 ADJOURNMENT

THE CLINIC SESSIONS

The program of the Clinic Sessions—from 9 00 a m to noon at Detroit (10 00 a m to noon at Ann Arbor)—has been modelled on those which have proved so successful in recent years. Emphasis has been placed on clinics in the true sense of the word, and there is scarcely a field of medicine which is not fully represented on the program. In addition to the various aspects of internal medicine, there are ample offerings in the subjects of pediatrics, psychiatry, neurology, roentgenology as well as in certain more distant fields which are still of importance to the internist, as for example bronchoscopy and certain surgical subjects. Ample opportunities in ward walks are offered for those who wish to see patients at close range and hospital methods in Detroit and Ann Arbor. Scientific demonstrations are offered on some programs that the visitors may see the research work actually being carried on at this time in the various laboratories.

The clinic program offers daily a capacity of over 2,000, scattered over six hospitals in Detroit and one in Ann Arbor. These hospitals are the following

- A* Harper Hospital was opened for the care of patients on January 1, 1866. It has grown steadily until now it has a capacity of 625 beds caring for medical, surgical and obstetrical patients. Last year 13,478 patients received 117,376 days' hospitalization. It has well equipped pathological and x-ray departments and a large Outpatient Department Clinic with an average daily attendance of 294.
- B* The Receiving Hospital is a city institution under the supervision of the Department of Public Welfare. It was opened in 1915 for the care of needy general hospital cases and the temporary detention of mental patients. In 1921 and again in 1927 notable additions were made to the hospital building. It now has a capacity of 650 beds.
- C* The Henry Ford Hospital was incorporated under the laws of the State of Michigan on October 15, 1915. It is a general hospital with a bed capacity of 608, offering services to both in-patients and out-patients in all branches of medicine, surgery, pediatrics and obstetrics. In 1925 a school of nursing and hygiene was opened and operates in conjunction with the hospital.
- D* The Grace Hospital was founded in 1888 by a group of public spirited citizens. In 1889 a Training School for Nurses was organized. A large Memorial Unit erected in 1931 increased the capacity to 529 beds. The hospital is a non-profit institution governed by an independent Board of Trustees. It cares for all forms of disease, except contagious and insane.
- E* The Herman Kiefer Hospital, owned by the City of Detroit, controlled by the Board of Health. It has a capacity of 1,400 beds—services for all stages of tuberculosis in any form, contagious diseases, and maternity cases. A teaching hospital affiliated with the Wayne University, College of Medicine, houses the Department of Health Laboratories and the department's Outpatient Tuberculosis Clinics.
- F* Children's Hospital of Michigan. The Children's Free Hospital Association was founded in 1886 by a group of Detroit women. In 1922 it was merged with the Michigan Hospital School, an organization for the care of crippled children, to form the Children's Hospital of Michigan. The city hospital with a capacity of 239 beds is for the care of acute medical and surgical patients. The hospital school, capacity 240 beds, is located in the country and is used as a convalescent home.
- G* The Hospital of the University of Michigan opened in 1925 with a capacity of 825 beds, to increase the facilities of the old University Hospital which was built in 1869 and served as a teaching hospital for 56 years. There are now a total of 1,312 beds available for the care of the sick and for teaching, as well as ample provision for research.

The detailed programs at each of these hospitals are not printed herein. At the time this copy goes to press, it is too far in advance to name the actual cases that will be presented and to give the detailed titles of clinics and demonstrations. Furthermore, the full program of clinics and demonstrations would occupy too great space in this issue of the ANNALS. The official program, complete in all respects, will soon be distributed from the Executive Offices of the College.

COLLEGE NEWS NOTES

NOMINATIONS FOR ELECTIVE OFFICERS

The Committee on Nominations of The American College of Physicians, in accordance with the provisions of the By-Laws, presents the following nominations for the elective officers of the College for 1936-1937

President-Elect JAMES H. MANS, M D, Boston, Massachusetts
First Vice-President, O. H. PERRY PIPPER, M D, Philadelphia, Pennsylvania
Second Vice-President, DAVID P. BARR, M D, Saint Louis, Missouri
Third Vice-President, WAITER L. BIRRING, M D, Des Moines, Iowa

Respectfully submitted

Committee on Nominations,
SIDNEY R. MILLER, Chairman,
FRANCIS M. POTTLENGER,
JAMES D. BRUCE,
ROBERT A. COOKE,
THOMAS KIRIN

NEW LIFE MEMBERS

Dr Willard J. Denno, New York City, and Dr Lewis B. Bates, Ancon, Canal Zone, Fellows of the College are new additions to the Life Membership Roster of the American College of Physicians

The Life Membership plan of the College is worthy of very careful consideration by each Fellow at this season of the year. The plan affords the member an opportunity of protecting his membership during his productive years and while his income is greatest, thus avoiding the burden of dues later in life. It provides for underwriting dues years in advance, but of receiving active membership throughout one's entire life. A member pays no more for Life Membership than he would pay for ordinary active membership to 65 years of age, without active membership thereafter, yet he receives active membership not only until 65, but for the balance of his life. Many members can readily afford Life Membership during their active, productive years, but, with changing conditions or ill health, find annual dues a burden in later life.

It is especially appealing to some members to take out Life Membership purely from an altruistic standpoint, namely, to make this contribution to the Endowment Fund of the College, putting the organization in position, financially, to broaden its activities along lines which are clearly suggested at this time, when there is so much conflict of thought and opinions on the subjects of medical practice, medical education, certification of specialists and other topics which are of primary interest to internists. Full details of the Life Membership plan, along with illustrations of the Life Membership Certificate, appear in the 1935 Directory of the College, pages 47 to 50.

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following gifts to the College Library of publications by members

Fellows

Dr Malcolm T. MacEachern, Chicago, Ill.—1 book, "Hospital Organization and Management"
Dr Walter A. Bastedo, New York, N. Y.—4 reprints
Dr Ralph O. Clock, New York, N. Y.—1 reprint

Lt Col George B Foster, Jr, (MC), U S Army—10 reprints
 Dr Benjamin H Frayser, Lexington, Ky—1 reprint
 Dr D Waldo Holt, Greensboro, N C—1 reprint
 Dr D O N Lindberg, Decatur, Ill—1 reprint
 Dr Harold C Ochsner, Waukegan, Ill—9 reprints
 Dr Henry A Rafsky, New York, N Y—7 reprints
 Dr William B Rawls, New York, N Y—1 reprint
 Dr Jesse D Riley, State Sanatorium, Ark—4 reprints
 Dr H C Robinson, Grand Rapids, Mich—1 reprint
 Dr Walter M Simpson, Dayton, Ohio—1 reprint
 Dr R Garfield Snyder, New York, N Y—3 reprints
 Dr Percy Harry Sprague, Edmonton, Alberta—6 reprints
 Dr August A Wernei, St Louis, Mo—3 reprints

Associates

Dr C Kelly Canelo, San Jose, Calif—2 reprints
 Dr Hyman I Goldstein, Camden, N J—3 reprints
 Dr W B Grayson, Little Rock, Ark—2 reprints
 Dr M Coleman Harris, New York, N Y—4 reprints and one book, "Normal Facts in Diagnosis"

CORRECTION TO 1935 DIRECTORY

Dr Charles Leonard Brown (Fellow), Philadelphia, is Professor of Medicine and Head of the Department of Medicine of Temple University School of Medicine, instead of Associate Professor of Internal Medicine, as printed in the new Directory

Dr Francis M Pottenger (Fellow) delivered the second Annual John W Bell Lecture on tuberculosis, at Minneapolis, December 2, 1935, under the auspices of the Hennepin County Tuberculosis Association and the Hennepin County Medical Society. Dr Pottenger's title was "The Responsibility of the General Practitioner in the Tuberculosis Program of the Future"

Dr A C Griffith (Fellow), Governor of the College for Missouri, was recently elected President of the Kansas City Southwestern Clinical Association

Dr Edward W Krumbhaar (Fellow) Philadelphia, and Dr Howard Dittick, Cleveland, were appointed by the Department of State of the United States Government as delegates from the United States to the Tenth International Congress of the History of Medicine, at Madrid, September 23-29, 1935. They, with Dr Henry E Sigerist, Baltimore, also served as delegates of the American Association of the History of Medicine at the same Congress

Dr Joel J White (Fellow), Lieutenant Commander, has been selected for, and promoted to Commander, Medical Corps, U S Navy. Dr White has been detached from duty on the Staff of Commander Aircraft, Base Force, U S Fleet, based at San Diego, California, and assigned to duty with the Mayo Foundation, Rochester, Minnesota, for a special course in internal medicine

Dr Louis Faugeres Bishop, Jr (Fellow) presented a paper on "Recent Advances in Diagnosis and Treatment of Coronary Thrombosis" on November 20, 1935, at the meeting of the Southern Medical Association in St Louis. On the same day a paper on "A Report of Correspondence with Physicians in the Tropics on In-

vestigation of Coronary Thrombosis" was presented before the American Society of Tropical Medicine, St Louis, by Dr Louis Faugeres Bishop (Fellow) and Dr Louis Faugeres Bishop, Jr

Dr L D Sargent (Fellow), Washington, Pa, was elected Councilor of the Eleventh Pennsylvania District and a Censor of the Pennsylvania State Medical Society at its last annual meeting in October

Dr William Egbert Robertson (Fellow) was made President-Elect of the Philadelphia County Medical Society at its last annual meeting Dr Robertson is Emeritus Professor of the Theory and Practice of Clinical Medicine at the Temple University School of Medicine Dr Louis H Clerf (Fellow), Philadelphia, was elected Vice-President

Sir Aldo Castellani (Fellow), formerly Professor of Tropical Medicine of Tulane University of Louisiana School of Medicine, is supervising the Italian Medical Corps in Ethiopia

Dr Salvatore Lojacono (Fellow), Superintendent of Morgan Heights Sanatorium, Marquette, Michigan presented a paper on "Tuberculosis in Finns of Marquette County" at the November meeting of the Trudeau Society at Howell, Michigan

Dr John I Marker (Fellow) has been elected Vice-President of the Mississippi Valley Medical Society This Society covers the States of Illinois, Missouri and Iowa

Dr Fred C Oldenburg (Fellow), Cleveland, Ohio, was recently promoted to Assistant Clinical Professor of Medicine in the Western Reserve University School of Medicine

OBITUARIES

DR GEORGE ELGIE BROWN

George Elgie Brown of the Mayo Clinic, and Regent of the College for two terms (1929 to 1933), died in Rochester, Minnesota, November 28, 1935, after an illness of two weeks with pneumonia He is survived by his wife, Irma, and his mother, Mrs Ella Brown, also by a sister, Mrs Esther Frost, and two sons, George, Jr, a medical student at the University of Michigan, and Hugh, a student at Carleton College, Northfield, Minnesota

He was born in Grand Rapids, Michigan, July 16, 1885, and received his degree of Doctor of Medicine at the University of Michigan in 1909 He served an internship under the late Dr Walter Courtney at the Northern Pacific Hospital at Brainerd, Minnesota, and it was at Brainerd that he married Irma Parker July 22, 1911 Together they went to Miles City, Montana, where he engaged in an extremely active practice of general medicine, later developing internal medicine up to 1921 His interest in accurate scientific diagnoses was exemplified from the very first He was the first to develop in that part of Montana the complicated laboratory tests such as the Wassermann reaction, and introduced the first fluoroscope He

sought out special opportunities for clinical study, as well as extension of his knowledge in the basic sciences, as was shown by several months' study at Harvard in 1914 and at Johns Hopkins University in 1916. The war-time found him associated in France with the Rockefeller Foundation in 1918 and 1919.

Coming to the Mayo Clinic at Rochester, Minnesota, as First Assistant in medicine in 1921, he advanced rapidly in the Clinic and the Mayo Foundation (Graduate School of the University of Minnesota) to the position of Associate Professor of Medicine in 1927.

George Brown had a wide association and membership in the usual and especial medical societies. In addition to the local, county, state and national, he had membership in the American College of Physicians, American Society for Clinical Investigation, Association of American Physicians, American Association for the Advancement of Science, Central Interurban Clinical Club, Central Society for Clinical Research, Minnesota Society of Internal Medicine, Minnesota Heart Society, American Heart Association, Sigma Xi, and Phi Rho Sigma. In addition, he took an active interest, both as to attendance and program building, and was a prolific contributor—approximately one hundred and fifty articles in periodicals, systems of medicine and textbooks, and two monographs, and during his last illness and while sick in bed was working upon a number of manuscripts. His bibliography manifests the widest range of interest, as did his clinical interests and contacts, but in recent years he delved deeply into the problem of peripheral vascular disease, and in this field he became an international authority. At the time of his death he was working upon a monograph on vascular diseases and hypertension. He approached these problems evaluating the functional influence of the sympathetic nervous system, and his work is too well known to need further comment here.

He was gifted with a judicious balance of confidence in his own powers, with sufficient respect for traditional opinion, but not enough to insulate him against original thinking. This combination, fortified by a fine personal capacity to stimulate assistants and associates, led to his very productive years and the fullest utilization of his great opportunities, with the wealth of clinical material at the Mayo Clinic at his disposal. At the same time, while working as an original investigator, he was fully able to carry on as a clinician, to please and charm people, and give them the full benefit of his wide therapeutic experience. Never, however, did he lose sight of the duty he felt—to add all he could to the understanding of our medical problems. It is proverbial, in all walks of life, that many attain their ambitions by ruthless appropriation of the opportunities, the actual work, or the resources of others. Never could this be said of Dr. Brown. He beautifully exemplified the glory of our guild—the desire to share not only with humanity but with all of his fellows the best of his mind, his heart and personality. These powers helped him to become one of the best of traveling companions.

He was meticulous in his dress and personal appearance. He enjoyed relaxation, music, good food, stimulating reading, and he had a wide interest in world affairs.

It is thus, in his untimely passing, that his multitude of friends feel a crushing loss.

E. L. TUOHY, M.D., F.A.C.P.,
Governor for Minnesota

DR. LEWIS MANN SILVER

Dr. Lewis Mann Silver (Fellow), New York City, died August 14 of a fractured skull, as a result of a fall, aged seventy-five years.

Dr. Silver was born in Brooklyn in 1860, attended Phillips Academy at Andover, Mass., and was graduated from Yale University with the A.B. degree in 1882. He received his medical training at Bellevue Hospital Medical College, graduating in 1885. He did postgraduate work in Munich and Vienna. At the time of his death he was a member of the courtesy staff of the Babies' Hospital and assistant at the Vanderbilt Clinic of Columbia University College of Physicians and Surgeons. He was the author of a number of publications.

Dr. Silver belonged to the New York County Medical Society, the New York State Medical Society, the New York Academy of Medicine, the Medical Society of the Greater City of New York, the American Medical Association and the Society of Alumni of Bellevue Hospital. He had been a Fellow of the American College of Physicians since 1921. In addition to his medical societies, he was a member of the Yale Club, the Yale Alumni Association, the New England Society, the Vermont Society, the New Hampshire Society and the Sons of the Revolution.

ROBERT A. COOKE, M.D., F.A.C.P.
Governor for Eastern New York

DR. EDWARD W. JACKSON

Dr. Edward W. Jackson was born in Albion, N. Y., June 21, 1877, and died on October 2, 1935, in Rochester, New York, of his third cerebral hemorrhage.

Dr. Jackson graduated from Albany Medical School in 1907 and practised in Little Falls, N. Y., for three years. A severe automobile accident caused him to give up his work and after his recovery he devoted two years to study in various medical centers in Europe, notably in London with Drs. MacKenzie and Lewis. Returning to the United States he began the practice of cardiology and internal medicine in Rochester.

During the World War he served as Captain in the Medical Corps and acted as cardiologist at Camp Greenleaf and in Carlisle, Penna. After the war he resumed his work and continued as cardiologist and chief of the Heart Clinic at the Genesee Hospital, having first received his appointment

in 1913. He was a member of the state and county medical associations and of the A M A, the Rochester Academy of Medicine and was elected a fellow of the College of Physicians in 1924. He was a member of the Yonondio Lodge, F and A M of the Damascus Temple, and the American Legion.

Cardiovascular disease forced him to give up his practise in Rochester, and during his latter years, his life was a long struggle with ill health. He went, successively, to California, Texas and Florida, attempting twice to resume a small amount of work in his specialty, but each time his reserve was insufficient, and he was forced to give up.

Dr. Jackson was a very earnest student of medicine and a man of tremendous capacity for work. His sympathetic and kindly nature endeared him to his patients to whom he gave his time and energy unstintedly, and thereby, no doubt, hastened his untimely death.

ROSCOE H. KNOWLTON, M D, F A C P

DR. THOMAS CHALMERS

Dr. Thomas Chalmers (Fellow, 1919) deceased, November 16, 1935, was the son of an eminent New York physician, and a member of an old and important New York family. His mother was a Virginian of long American lineage and distinguished family.

Dr. Chalmers received his preliminary education in various private schools in and about New York City, and finally entered Princeton University, from which, however, he did not graduate. During his youth he was deeply interested in athletics, and took an active part in school and college work of this character. He graduated in medicine from Bellevue Hospital Medical College in 1897, substituted for a time on the Third Division of Bellevue Hospital, afterward serving in one of the out-patient departments of that institution.

In his youth Dr. Chalmers became a member of Company F of the Seventh Regiment of the New York National Guard, and remained with this organization at the time of the Spanish American War when he was transferred to the Twelfth Regiment of the New York National Guard as Captain and Assistant Surgeon. He served with this organization and on the Brigade Staff in Puerto Rico, and remained with the Army during the Philippine Wars, serving with distinction, and with the rank of Major, Medical Department.

On his return from the Philippine Islands, he again opened practice in West Ninth Street, New York City, where he remained until the formation of the colony at Forest Hills, Long Island, and he was one of the earliest physicians in this colony, and did much to establish a high standard of ethical and professional life in this part of Long Island.

Dr. Chalmers was actively interested in medical politics and for many years was a delegate to the American Medical Association. He was presi-

dent of the Queene County Medical Society, and was largely instrumental in the building of the Queene County Medical Building. He acted on numerous committees in connection with the health activities in this part of Long Island, and was a member of the New York Academy of Medicine, of the Advisory Council of the Commissioner of Hospitals, and on numerous other committees of professional organizations.

Dr. Chalmers married Miss Elizabeth Ducat on August 1, 1911. He was the father of three children.

Dr. Chalmers was well known for his high professional ability, his public spirit, his generous friendships, particularly to the younger members of the profession, and for his unswerving devotion to the highest standards of ethical medical practice. More than usual he possessed the power of attracting friends, both in and outside of his profession. Up to the very day of his death, he was actively engaged in public duties of many kinds beyond that which he gave to his own profession, and his patients. He was a fine citizen, a good soldier, and a high representative of his profession.

HARLOW BROOKS, M.D., F.A.C.P.

DR. ALEXANDER MCNIEL BLAIR

Dr. Alexander McNiel Blair was born in Buffalo, N. Y., July 30, 1873, and died at his home in Southern Pines, N. C., November 27, 1935.

Receiving his early education in the public schools of Buffalo and Niagara University, he graduated from the Medical Department of the University of Niagara in 1897. He settled in Southern Pines, N. C., in 1903, where he was actively engaged in practice save for the summer months, which he spent in Bethlehem, N. H., also in active work. His postgraduate work was done at Harvard University, Polyclinic Postgraduate Hospital in Philadelphia, Children's Hospital in Boston, and the Royal Victoria Hospital in Montreal. He was a member of the Volunteer Medical Service Corps during the World War, and at the time of his death was a member of the staff of the Lee County Hospital, Sanford, N. C. He became a Fellow of the American College of Physicians in 1925, and in addition held membership in the Moore County Medical Society of which he was President, the N. C. State Medical Society, the Tri State Medical Society, and the Southern Medical Association, as well as being a Fellow of the American College of Radiology.

Dr. Blair was actively interested in social and civic matters in his community, was a director in the Citizens Bank & Trust Co., and a member of the Presbyterian Church. His chief medical interests were diseases of the chest and stomach, though his work was not entirely limited to these phases of internal medicine. At the time of his death, he was the oldest practitioner in service in Southern Pines.

C. H. COCKE, M.D., F.A.C.P.,
Governor for North Carolina

DR ALBERT EDWARD ROUSSEL

Albert Edward Roussel (Fellow) was born in Philadelphia, September 17, 1863. He attended public and private schools and also studied under private tutors, later passing entrance examinations, admitting him to Annapolis. In 1882 Dr. Roussel was graduated from the Jefferson Medical College of Philadelphia, he served as interne in the Philadelphia Orthopaedic Hospital and Infirmary for Nervous Diseases, 1882-83, interne, Philadelphia General Hospital, 1883-84, served as externe in neurology, Hospital de la Salpetriere, Paris, 1885-87, and as externe in internal medicine and venereal diseases, St. Louis Hospital, Paris, 1887-88.

In 1888 Dr. Roussel pursued postgraduate studies in neurology and internal medicine at Heidelberg, Berlin, London and Paris. Upon his return to America he was appointed lecturer in physical diagnosis, Medico-Chirurgical College (1889-90), he became Associate Professor of Medicine and Clinical Medicine in the same institution in 1900, a position which he held until the merger of the Medico-Chirurgical College and Hospital with the University of Pennsylvania in 1916. He was elected Assistant Professor of Medicine in the University of Pennsylvania Graduate School of Medicine in 1916, and in 1920 was elected Professor of Medicine, ably filling that chair until 1932, when he became Professor Emeritus.

Dr. Roussel had served as Visiting Physician to the Polyclinic and Howard Hospitals, and held the position of President of the Staff at the latter institution for a number of years. He was also Visiting Physician to the Eagleville Sanitarium and to the French Consulate and Foreign Benevolent Society of Philadelphia. During the World War he became a member of the Medical Advisory Board and Special Medical Examiner for the French Government for the State of Pennsylvania. In 1907 Dr. Roussel received from the Government of France, the decoration, Officer d'Academie, and in 1924 also that of Chevalier de la Legion d'Honneur, from the same source.

Dr. Roussel was an honored member of numerous medical organizations, e.g., the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the Philadelphia Pediatric Society, the American Medical Association (Fellow), and the American Association for the Advancement of Science. He was President of the American Therapeutic Society in 1929, and First-Five-President of the Philadelphia Medical Club, and since 1916 a Fellow of the American College of Physicians. Dr. Roussel contributed a number of articles to current medical journals and he was the first to point out that Brill's disease and typhus fever were the same disease.

Dr. Roussel had an attractive personality and his presence would cast a shadow of dignity over any gathering of physicians. From personal observation, during frequent and more or less prolonged contacts, the writer is convinced that he had a clearly demonstrated ability for straight thinking.

and reliable clinical observation that enabled him to reach an accurate diagnosis. His services in the capacity of teacher were highly appreciated by the Board of Trustees of the University of Pennsylvania, as shown by the fact that upon being retired from his professional duties he was immediately made Emeritus Professor of Medicine. His career as a whole is destined to endure for a long time in the minds of his pupils and medical practitioners who sought his services as a consultant. The subject of this sketch was quite familiar with French medical literature, on which he drew freely while teaching his medical classes.

Dr Roussel was a member of the Board of Governors of the Penn Club, with which he was prominently connected during many years. He was fond of hunting and, exceedingly so, of fishing.

Dr Roussel is survived by his widow, Mrs Albert E Roussel, who was a Miss Finn, and belonged to a socially prominent family of Baltimore, a son, Albert E Roussel, Jr, and a daughter, Mrs J Graham French.

J M ANDERS, M D, M A C P,
Philadelphia, Pa

NOTES ON MEDICAL EDUCATION AND MEDICAL INSTITUTIONS IN MICHIGAN

THE approaching General Session of the American College of Physicians, which is to be held in Detroit and in Ann Arbor, will give to the members of the College an opportunity to acquaint themselves with the present status of medical education and of medical institutions in the two chief medical centers of the State of Michigan. This approaching event should, therefore, lend interest to the following brief sketch of the development of the schools of medicine and of the hospitals which will furnish the clinical features of the program.

The long and stormy history of the early settlements and trading posts in the wilderness which has since become the State of Michigan, punctuated by warfare between the white settlers and the Indians, and between the forces of the French, the English, and later the Americans, contains little that is pertinent to the later development of medical institutions. Though Detroit was settled over two hundred years ago, the great hospitals and schools now existing were all founded within the last century.

Yet, lest the medicine and surgery of those earlier pioneer days in the wilderness should be too readily considered as unimportant, it should suffice to recall that it was towards the close of this period (1822), when Michigan was still a Territory, that William Beaumont, a surgeon in the United States Army stationed in the post at Mackinac, began his long series of scientific observations and experiments on gastric function on the trapper, Alexis St. Martin, who had been left after recovery from a gunshot wound with a permanent gastric fistula. This classical investigation must be looked upon as Michigan's first great contribution to scientific medicine. It still ranks in world medical history as one of the major advances in our knowledge of human physiology.

The history of medical education in Michigan is essentially that of the development of the medical school of the University of Michigan at Ann Arbor and that of the various medical schools in Detroit which have been continued as the recently formed Wayne University College of Medicine.

During the era of proprietary medical colleges, small schools were organized at various times in Detroit and other cities of the state, but they were short lived and of little importance.

The University of Michigan Medical School opened its doors to students in 1850 at Ann Arbor, and in 1869 the Detroit Medical College was incorporated. For half a century a fusion of these institutions was under consideration. Ann Arbor, in those earlier years a small city, had limited clinical facilities and, although the medical school was outstanding in the quality of its preclinical departments, many medical men both in Ann Arbor and Detroit believed that medical education in Michigan would be advanced

by the attachment of the Detroit school, with large hospitals and a wealth of clinical material under its control, to the Medical Department of the University

From the early eighties a number of conferences took place between the faculties of the two colleges looking to an amalgamation. The last conference met with the Council on Medical Education of the American Medical Association in Detroit in 1916.

A plan of union was proposed by the Council which was accepted by the Regents of the University and the Trustees of the Detroit College. The entry of the United States into the World War arrested the negotiations and they were not resumed. After the war the University of Michigan built its great teaching hospital and it now has the clinical facilities necessary to give a well rounded medical education.

WAYNE UNIVERSITY COLLEGE OF MEDICINE

The first attempt to give systematic medical instruction in Detroit was the organization in 1864 of a preparatory medical school by the staff of Harper Hospital, which was then used by the Government as a hospital for wounded soldiers of the Civil War. The instruction was almost entirely

FIG 1 Wayne University College of Medicine

clinical. The venture was a success and in 1869 the school was expanded and incorporated as the Detroit Medical College, with a faculty of fourteen members.

Two of the pavilions of Harper Hospital were remodeled and made the college building. Harper and St. Mary's Hospitals, with a college out-patient department, furnished the material for clinical teaching. The success of the college and the professional advantage which a teaching position may give excited the envy of other medical men of the city. In 1879 a rival college, the Michigan College of Medicine, was organized and, after a stormy

period of competition, the two institutions amalgamated in 1882, under the name of the Detroit College of Medicine

The charter of the Detroit College of Medicine expired in 1913. Under a new charter and name, the Detroit College of Medicine and Surgery, the college was reorganized with faculty, equipment and curriculum brought up to modern requirements. The institution, however, did not have an adequate endowment and it had difficulty in maintaining the desired standard of medical education. In 1918, in order to save the college, its charter and property were taken over by the city. This ended its proprietary character and it became a unit of the public school system of Detroit under the control of the Board of Education.

The City of Detroit established Wayne University in 1933, and the medical college became the medical department of the University in 1934, under its present name, Wayne University College of Medicine.

Through all its changes in name and administration the present institution is a direct continuation of the Detroit Medical College organized in 1869.

The municipally owned Receiving Hospital and the Herman Kiefer Hospital, with a combined capacity of 2,050 beds, are the main teaching hospitals of the college.

THE RECEIVING HOSPITAL

The Receiving Hospital is operated by the City of Detroit and supervised by the Public Welfare Commission. It was founded in 1915 for the care of the indigent and emergency cases. It was re-organized in 1921 into a general hospital to include all services except obstetrics and contagious diseases, and was enlarged to its present capacity of 650 beds in 1927. The hospital still maintains a completely equipped emergency department supervised by the staff physicians. During 1934, 62,984 cases received treatment in the emergency room, 20,892 of which were subsequently hospitalized. These hospital admissions were distributed among the different services as follows:

General surgery	6564
Psychiatry	5653
Medicine	5252
Urology	1039
Gynecology	1609
EENT	1007

The hospital also maintains an out-patient department for the follow-up care of discharged patients, to which there were 106,692 visits during 1934. The hospital also houses the City Physician's Clinic which during 1934 had 368,239 visits. Much of this clinical material is utilized for teaching purposes.

The Receiving Hospital is the chief teaching unit of the Wayne University College of Medicine. Senior students serve as clinical clerks seven

hours daily for a total of twelve weeks in internal medicine, including psychiatry, neurology and dermatology, for four weeks in gynecology and for eight weeks in general surgery, including urology, orthopedics, and proctology. Junior students are taught physical diagnosis and pediatrics on the wards, and surgery and internal medicine in the out-patient department. Obstetrics and contagious diseases are taught at the Herman Kiefer Hospital.

THE HERMAN KIEFER HOSPITAL

The Herman Kiefer Hospital is a specialized institution, having services for all stages of tuberculosis in any form, all acute communicable diseases and maternity cases. There are 500 beds for contagion, 65 maternity beds and 65 bassinets, and 763 beds for tuberculosis. The institution is municipally owned and operated by the Board of Health.

FIG 2 The Herman Kiefer Hospital

The contagious service is built on the unit, or pavilion plan, and the first building was erected in 1910. Construction of the new tuberculosis unit was begun in September 1927, and the building was opened for the reception of patients in December 1928.

This unit, with a capacity of 680 beds, is devoted to the care and treatment of tuberculous patients, who are admitted through the tuberculosis clinic of the Detroit Department of Health, housed in this building.

The structure is seven stories in height. On the first floor are the administrative offices, the social service department, library, record room,

physicians' offices, offices of the nursing executives, tuberculosis clinic and health department laboratories, as well as a modern and well equipped x-ray department

The second, third, fourth, fifth and sixth floors are devoted to the housing of patients. The rooms are either single rooms or for two patients, there being no wards, and most of them have porches. In fact, about 80 per cent of the patients can be placed on porches at one time. Each room, in addition to having prettily decorated furniture, is equipped with a radio head set. A microphone placed in the auditorium will enable speakers to give health talks to the whole patient population.

The surgical service occupies the entire seventh floor, excepting the wings, which are devoted to heliotherapy. There are five operating rooms, one of which has an amphitheater which seats 50 persons. Advances in the study and treatment of tuberculosis have brought forth corresponding advances in tuberculosis surgery, and the instrument, dressing and sterilizing rooms on this floor are equipped in the most up-to-date manner.

The space devoted to heliotherapy is divided into two sections, one side for women and the other for men. Each section is divided into compartments, one to be used for artificial sunlight and equipped with carbon arc lamps, and the other with an open roof for treatment by direct sunlight. Ultra-violet ray transmitting glass is also used in all of the patients' bedrooms.

The value of the grounds, buildings and equipment is \$9,000,000.00. Operating expenses are in excess of one million dollars per year.

The hospital is a part of the teaching service of the Wayne University School of Medicine and affiliates with the various general hospitals in teaching their internes contagious diseases, tuberculosis and obstetrics. It also has a three-months' course in contagious diseases and tuberculosis for senior nurses, and has affiliations with 16 different hospitals.

In addition to the Wayne University College of Medicine and its two chief hospitals the members of the College will be interested in a number of other medical institutions in Detroit which will contribute valuable features to the program of the meeting.

HARPER HOSPITAL

Harper Hospital, one of the largest and oldest institutions in the city, was founded in 1859 through the generous gift of Walter Harper, whose name the hospital bears. At that time, an additional contribution was made by Nancy Martin, who gave a tract of five acres on Woodward Avenue (on which she had a market garden), together with other lands, to the new institution. During the Civil War, the Federal Government decided to establish a hospital for soldiers and sailors in the city, and the land was leased to the government for this purpose. The wooden buildings which

1864

FIG 3

were then erected housed the sick and wounded soldiers until 1865, when the buildings were turned over to the trustees, and the institution has been conducted as a general hospital ever since. In continuation of the tradition of war-time service, Base Hospital No. 17 was sponsored by Harper Hospital in 1917. It went overseas in July of that year, and was stationed in Dijon until 1919. This reserve unit has been continued as 17th General Hospital.

With growth of the city, and under the guidance of a Board of Trustees which has ever been keenly interested in medical progress, expansion followed, and in 1883 the new building (facing John R. Street) was completed. Later years saw the completion of many other units which were made possible by the generous gifts from citizens. In 1913, the Hudson Building (containing private rooms and wards), and the Buhl Building (housing the out-patient department) were completed. In 1918, a new operating pavilion was occupied, and 1928 saw the completion of the eight story building facing Brush Street.

The Fairland Training School for Nurses (one of the first established in this country) was opened in 1883, at first occupying the "Swain Home." As these quarters became inadequate, McLaughlin Hall was erected in 1921 to house the nursing staff and pupil nurses.

The laboratory, equipped for both routine work and research work, occupies the entire seventh floor of the center building. The department of roentgenology occupies extensive quarters on the first floor. Its equipment includes super-voltage therapy apparatus (700 K V Constant), as well as experimental x-ray diffraction and neutron-ray apparatus.

The out-patient department was formally established in 1883, it outgrew its old quarters, and in 1914 occupied the new Buhl Building. About

10,000 to 12,000 new patients are treated yearly, the number of daily visits being 300 to 400

The hospital is completely equipped as a general hospital, and receives every type of case, excepting contagious diseases. It has a capacity of 625 beds, including private rooms and endowed ward beds

FIG 4 Harper Hospital Building erected in 1928

HENRY FORD HOSPITAL

In the year 1909 it became manifest to the medical profession and public-spirited citizens of Detroit, that the city's hospital facilities had not kept pace with the amazing progress made in other fields. There was then formed the "Detroit General Hospital Association" of which body Mr Henry Ford was a member, and of which he later became Chairman of the Board of Trustees. The purpose was the development of a hospital for Detroit under the name of the "Detroit General Hospital."

Two years later, namely, in 1911, ground was broken for the new institution and a building program begun. The work did not progress as was expected, so that with incompleting buildings, and with about one-third of the needed sum in hand, the original plan was enabled to continue only through Mr Ford's vision and generosity.

In June 1914, five years after the incorporation, and three years after the building program had begun, Mr Ford made an offer to take over full responsibility for the development of the new hospital. This offer was immediately accepted.

These chronological details tell the story of how the Henry Ford Hospital came into existence.

The Henry Ford Hospital was incorporated under the Laws of the State of Michigan on September 15, 1915. It is a general hospital with a bed capacity of 600, offering services to both in-patients and out-patients in all branches of medicine, surgery, pediatrics and obstetrics.

The hospital has been registering about 15,000 persons as patients a year. Recently the 227,300 mark was passed.

In 1925 a School of Nursing and Hygiene was opened and operated in conjunction with the hospital.

In the laboratories of the hospital facilities for research have been provided and from these laboratories as well as from the clinical departments a program of unusual interest may be expected.

THE GRACE HOSPITAL

The Grace Hospital was founded in 1888 by a group of public spirited citizens who contributed the cost of the original buildings and established an endowment fund of \$100,000, which was later increased to \$300,000. The site of the Hospital, at the corner of John R St and E Willis Ave., was contributed by one of the founders.

In 1910 an addition of four stories was built which included an x-ray suite, a group of operating rooms, a pediatric service, and a group of laboratories, together with accommodations for 50 additional private and semi-private patients.

The growth of the city soon placed added responsibilities on the Board of Trustees. In 1919, directly after the War, the Board instituted a construction program to cover a period of ten years and to involve the expenditure of \$2,500,000.

Between 1914 and 1930 the original Main Hospital Building on John R St. was extensively reconstructed and improved. An obstetric ward and a urological unit were provided, and the roentgenologic equipment was modernized. In 1926 a third addition to the Main Hospital was built, which included an out-patient clinic service and 30 additional private rooms.

In 1929 a campaign for \$1,850,000 was carried through successfully for the purpose of increasing the bed accommodations in the main hospital, and as a result of this campaign the Memorial Building of the main hospital was constructed on the Brush St. frontage.

In 1912 a member of the Board of Trustees donated a site and a building on West Grand Blvd., as a memorial to his deceased daughter. After alterations, 57 beds were provided, and thus a branch hospital, known as the

FIG 5 The Grace Hospital

Miriam Memorial Branch of the Grace Hospital, was opened, which has given a much needed community service to the West Side for many years

In 1919 a Nurses' Home for the Miriam Memorial Branch was built In 1929 the first unit of a new hospital building at this branch hospital was constructed

In 1889 the Training School for Nurses was organized and the first Nurses' Home, constructed later, was the gift of a public spirited woman

In 1931 a new Nurses' Home was erected at a cost of \$600,000 This addition was occupied first in 1932

The building of the new Nurses' Home permitted the expansion and improvement of the School of Nursing, with installation of modern pedagogic equipment The development of the Training School and the standards in nurse-teaching have kept pace with the growth of the Hospital

In the 47 years of its existence, the Hospital has cared for over 325,000 bed patients In 1935 the capacity of the Hospital was 527 beds In 47 years it has given relief to over 1,000,000 ambulatory indigents The cost of the latter has been partly provided by the Detroit Community Fund through the Council of Social Agencies

For more than two generations some of the leading representatives of the medical and surgical profession have served on the staff of this Hospital, and many of the prominent citizens of Detroit have been members of its Board of Trustees

CHILDREN'S HOSPITAL OF MICHIGAN

On November 12, 1886, a group of Detroit women who were interested in child welfare met and organized the Children's Free Hospital Association The first hospital work of this Association was begun on a ward in Harper Hospital Two years later, however, a temporary hospital was established in a house at Seventh and West Fort Streets In 1896 a generous gift from a prominent citizen of Detroit made possible the construction and endowment of the present building In 1922 a merger was effected with the Michigan Hospital School which possessed a building in the country at Farmington, and the merged institutions assumed the name of the Children's Hospital of Michigan This made it possible for the acute medical and surgical cases to be cared for in the city hospital, while the Hospital School building at Farmington was used as a convalescent home

Since this merger, many new facilities have been added New wings have been constructed to the main hospital and additional buildings have been erected at Farmington A nurses' home, a new out-patient department, a new roentgenologic department and new laboratories have all been added to the facilities of the city hospital The city branch now has a capacity of 239 beds and the country branch has 240 beds The hospital cares for all illnesses of children excepting pulmonary tuberculosis and contagious diseases The hospital is governed by a permanent Board of Trustees It

is supported by the income from its endowment fund, contributions from patients, receipts from the care of city, county and state patients, and by funds allotted by the Detroit Community Fund

FIG 6 Children's Hospital of Michigan

In 1934, 6,449 patients were admitted to the hospital and 73,822 days' care were given, 7 800 new patients were cared for in the out-patient department and 84,000 patients' visits were made there, 550 patients were admitted to the Convalescent Home and were given 65,846 days' care

The hospital maintains a school for teaching pediatric nursing to senior students from accredited training schools and to postgraduate students

THE WAYNE COUNTY MEDICAL SOCIETY

The Wayne County Medical Society was organized as a branch of the Michigan State Medical Society in 1849. The law under which it operated was repealed in 1851. The Detroit Medical Society functioned as its successor until 1866, when it was reorganized under its old name. In 1876 the Society was incorporated and had an active period of several years. Professional interest became divided by the organization of the Detroit Academy of Medicine by the faculty of the Detroit Medical College and the Detroit Medical and Library Association.

The Wayne County Society was kept alive by a small socially congenial group.

The Medical and Library Association, at that time the dominant society of the city, was compelled, by the adoption of the present membership requirements of the American Medical Association, to disband and transfer its membership to the Wayne County Society, which then became the powerful organization that it is today. In 1909 it purchased a property and added to

it a library building and an auditorium. Later the library was put in charge of the public library of the city, and with the organization of Wayne University it was transferred to the medical department and is now housed in the college building. In 1932 the Society removed to its present building acquired through the generosity of a public minded citizen. It is now the center of medical activity in the city. It has a membership of over 1,500, the fourth largest county medical society in the country. Its club features

FIG 7 The Wayne County Medical Society Building

make it a popular daily meeting place for medical men. Through its various committees it takes a prominent part in civic affairs of medical interest, especially in the fields of social service, the medical care of the indigent and the safeguarding of the proper interests of the medical profession.

THE UNIVERSITY OF MICHIGAN MEDICAL SCHOOL, ANN ARBOR *

The University was founded in 1817 when the Governor and the Judges of the Territory of Michigan, which then had a population of less than

* Contributed by Frederick G. Novy, M.D., Sc.D., LL.D., Dean Emeritus of the Medical School

7,000, passed an Act establishing the Catholepistemiad or University of Michigan. This Act provided for thirteen professorships, designated as didaxia, one of which was specified as iatruca or medical sciences. The sponsors of the Act were John Monteith, a Presbyterian minister, Gabriel Richard, a French priest, and A. B. Woodward, a Judge. The germ of the idea of a medical school thus was incorporated in the proposed structure, possibly the sponsors had in mind the case of Nathan Smith who first at Dartmouth and later at Yale constituted the whole medical faculty.

A new Act was passed in 1821, repealing the former one, and creating a University of Michigan at Detroit. The Trustees of the new University did little more than to secure from Congress the grant of valuable lands for its support, some of which they promptly sold at a very low figure.

On January 26, 1837, Michigan, then having a population of about 100,000, was formally admitted as a State into the Union. Shortly before this date, the Superintendent of Public Instruction, the Reverend J. D. Pierce, a graduate of Brown, presented a comprehensive educational plan, based on the Prussian system. As a result, the Legislature of the new state, on March 18, passed the Organic Act establishing the University of Michigan, and two days later another Act was passed locating the University at Ann Arbor. In the first Act it was specified that the University was to consist of three departments. The Department of Literature, Science and Arts, the Department of Law, and, the Department of Medicine. The first of these departments was opened in September 1841.

The Department of Law, perhaps, should have been the next to be established, but in January 1847, a petition was presented to the Board of Regents asking for the organization of the Medical Department. Owing to an adverse legal opinion no action was taken at the time. However, a year later, the Board formally adopted a report whereby the School was established, money was appropriated for a laboratory building, and professors were appointed. After some delay, due to lack of funds, the Medical Building was finally completed and when its doors were opened to students in the fall of 1850, a faculty of five professors were on hand to give instructions.

The Medical Department was the first professional school established at the University. This example of Michigan in providing for medical education at a university was taken up, largely by the newly formed western states. At the present time 30 state universities have medical schools. Moreover, the new Medical School was an integral part of the University and not a merely nominal connection as was often the case. The professors were salaried and the equipment was provided by the University.

Because of its financial independence, the new medical school was able to carry out policies which otherwise might have been very difficult. Thus, it started out with a course of two years of six months each. In those days the course of instruction in the medical colleges of the country, almost without exception, extended only over four months. The apprenticeship system was

FIG 8 University of Michigan Hospital

in vogue and since the instruction was given largely by lectures and recitations it was required for graduation that the student exhibit evidence of having pursued the study of medicine and surgery for the term of three years with some respectable practitioner of medicine (including lecture terms) This preceptorial system lasted for three decades

FIG 9 University of Michigan Medical School, West Medical Building

In 1878, the course was lengthened to two years of nine months each, and in 1880 to three years of nine months each. This increase in time was brought about by the introduction of laboratory courses and hospital instruction. In 1890, the course was extended to four years of nine months each, thus permitting the further development of a graded course for the teaching of the rapidly growing basic sciences and the expanding clinical work. Another step taken at this time was the establishment of the first Combined Course in Arts and Medicine. This combination, though criticized at the time, has since been generally adopted by other universities.

The entrance requirements for the Medical School in 1850 were much the same as those for entrance to the Literary College but gradually they were modified so that only "the elementary branches of an English education" remained.

With the increase in the length of the course and the teaching of the new sciences it became evident that the requirements for admission should be raised. Hence, it was that in 1890 they were advanced to a diploma from

the classical course in an approved high school, and a little later, in 1896, the requirement of certain languages and science subjects was made effective

In 1909, the minimum requirement for admission was placed at two years of collegiate work, and in 1929, this was increased to 70 hours, and, in 1931, it was advanced to 90 semester hours

The School which opened in 1850 with five professors now maintains a staff of 24 professors, 19 associate professors, 23 assistant professors, 78 instructors and 82 assistants, or a total of 226. The dean is A. C. Furstenberg.

Laboratories were not a conspicuous part of the medical schools of 1850. True, rooms for dissection were provided but the other sciences were either in their infancy or as yet unborn. The chair of Anatomy at the University was first filled by Moses Gunn who later became professor of surgery and eventually was called to Rush Medical College. He was followed by Corydon L. Ford who held the position for 40 years. Then came J. P. McMurrich who after 12 years of service accepted the chair at Toronto, his successor was G. L. Streeter who after a few years left to take charge of the newly organized Carnegie Institution in Baltimore. The department was then combined with histology under G. C. Huber and R. E. McCotter.

Histology as an offshoot of anatomy was recognized in 1877 as a separate study when a laboratory was equipped, and in 1879 by the appointment of C. H. Stowell, but in 1889 it was temporarily combined with physiology under W. H. Howell. After a short time the work was taken over by G. C. Huber who carried on until his death in 1934.

At Michigan, some laboratory chemistry was at first given in the old Medical Building and with such success that it led, in 1856, to the construction of the first chemical laboratory in a state university, if not the first in the country. The original small building was repeatedly enlarged and finally in 1909 the present laboratory was completed and occupied. It was in the old chemical laboratory that physiological chemistry developed in the seventies. The first chairs in this subject were filled at Yale by Chittenden and at Michigan by V. C. Vaughan at about the same time. After a few years the chair was combined with hygiene, and Vaughan held the dual position until his retirement in 1921. His successor in physiological chemistry is H. B. Lewis.

Physiology was first an appanage of anatomy under C. L. Ford and a laboratory was established in 1877, but the modern experimental phase began with Henry Sewall who entered on his work as professor in 1881. Because of ill health he was forced to retire and was succeeded in 1889 by W. H. Howell who held the position until 1892 when he went to Harvard and a year later to Johns Hopkins. He was followed by W. P. Lombard who retired in 1923 to be succeeded by R. Gesell.

Pathology was likewise in the early days combined with another chair,

namely medicine, under A. B. Palmer. After his death in 1887, an independent chair was created under H. Gibbs, and laboratory work was instituted. In 1895, the chair was recombined with medicine under George Dock, the actual instruction being carried on by A. S. Wainthun who filled the chair until his death in 1931. His successor is C. V. Weller.

Materia medica and therapeutics were at first tied up with chemistry, later passed on to anatomy, physiology, ophthalmology and, again, with medical chemistry, or given independence for a short time. In 1890, however, the chair of Pharmacology was established under J. J. Abel who, in 1893, left to join the Johns Hopkins faculty. He was followed by A. R. Cushny who, in 1905, was called to London and later to Edinburgh. His successor is C. W. Edmunds.

In 1888, the Hygienic Laboratory was built from a special appropriation of the Legislature, and the first systematic instruction in bacteriology given in this country was begun under F. G. Novy who retired in 1935 and was succeeded by M. H. Soule.

It will be seen from the above that the importance of the sciences was early recognized and every opportunity was given for their development. Today the School is provided with three large and commodious buildings for instruction and research in the basic sciences.

Of clinical instruction in the present sense, there was but little during the first two decades. At first, some effort was made to give such instruction in a summer session in Detroit but this was attended with little success. The location of the medical school in a small city, such as Ann Arbor at that time, was decidedly unfavorable from a clinical standpoint and repeated attempts were made to have the school removed to Detroit but with no success. In the absence of hospital facilities the clinical staff invited physicians to bring in their patients on three mornings in the week for diagnosis and demonstration. This custom had a beneficial result for before long patients did present themselves at these modest clinics. They were then brought into the lecture room of the old Medical Building where they were examined before the class and, if need be, operated upon and then carried to a private house for subsequent care.

In 1869, the beginning of a hospital was made when one of the four professors' houses on the campus was fitted out for that purpose. This did not relieve the situation materially and, in 1875, the Legislature was prevailed upon to appropriate a small sum of money for a wooden pavilion hospital, of the type used during the Civil War, which was to be connected with the former building. It was argued that a hospital would become so infected in time that it would be necessary to burn or demolish it and replace it with a new one. However, the new pavilion hospital proved its need and the Legislature of 1879, 1881, and 1883 was prevailed upon to make further appropriations, at no time exceeding \$7,000, for additions such as a women's ward, a ward for eye and ear cases, and a clinical amphitheater.

By 1889 the wooden hospital on the campus had more than reached its

limit and again the legislature was called upon to relieve an intolerable situation. This time it appropriated what seemed to be a very large sum (\$100,000) for the erection of a new brick hospital on the hill overlooking the Huron River. In the following years repeated additions and extensions were made, but the conditions became far from satisfactory because of the increasing demand for medical and surgical service on the part of the citizens of the state. Serious thought was given to the building of a new and thoroughly modern hospital. The Legislature was again appealed to and this time a grant of one million dollars was made. Before construction was entered on we were involved in the World War and the matter was postponed. After the War it was clear that the amount appropriated would be insufficient and further requests were presented to the Legislature with the result that enough funds were provided to erect the present new hospital which was opened in 1925. It has a capacity of 835 beds and since some of the old buildings have been retained the entire hospital has a capacity of 1,312 beds. It is essentially a teaching hospital and as such is unique. The most recent addition is a therapeutic pool primarily intended for cases of poliomyelitis.

A state psychopathic hospital was erected on the hospital grounds in 1906. It was the first University building for psychiatric teaching to be established in this country. It has a capacity of 62 beds and in the near future it will be enlarged to provide 90 beds.

Adjoining the main hospital is the Simpson Memorial Institute for Medical Research, opened in 1927, and primarily devoted to the study of pernicious anemia and other blood diseases.

As might be expected, of the five original appointments to the faculty, three were clinical, namely, surgery, medicine and obstetrics, including diseases of women and children. The specialties were to come later.

In surgery, in the interval of 63 years between Gunn and the present incumbent, F. A. Collier, there were six professors. The surgery staff at present numbers 37 of whom 10 hold the rank of professor. With two exceptions all are on full time. Besides general surgery, there are subdivisions of neuro-surgery, orthopedics, thoracic surgery and urology.

The head of the Department of Medicine is C. C. Sturgis who is also the eighth appointee to the chair. The staff consists of 27 full-time men, of whom 9 rank as professors.

The Department of Obstetrics and Gynecology is in charge of N. F. Miller who is the fifth to hold that chair.

Ophthalmology and aural surgery was one of the first specialties to be recognized (1872). It was divided in 1904 and the present head of the former is F. B. Fraulick while the Department of Otolaryngology is headed by A. C. Furstenberg.

Neurology was recognized as an entity in 1888. This work is in charge of C. D. Camp.

Dermatology was introduced into the curriculum in 1890 and is headed by U J Wile

The Department of Pediatrics was dissociated from Obstetrics in 1901 and ever since has been conducted by D M Cowie

The chair of Psychiatry was established in 1906 and given to A M Barrett who is the present head of the Department

Roentgenology was the last of the special chairs to be created and the work is now in charge of F J Hodges

A Department of Postgraduate Medicine is maintained for the purpose of giving instruction to practitioners. Special courses are given in different parts of the state. This work is in charge of J D Bruce

NUMBER 8

GROWTH AND DEVELOPMENT OF FUNCTION IN BLOOD VESSELS AND LYMPHATICS

By ELIOT R. CLARK, M.D., *Philadelphia, Pennsylvania*

PROBLEMS relating to the growth and development of function in blood vessels and lymphatics are not restricted to the period of embryonic development and the growth period, but are met with throughout the entire life of the individual. They play a particularly important role in the reparative stages of inflammation, in the reaction to various forms of injury, and in the healing which follows surgical operations. The development in our laboratory of a special technic enables us to make observations of many continuous hours daily, extending over weeks and months, with the highest powers of the microscope, in which we can observe directly the minutest morphological details of the growth of blood capillaries, the differentiation of arteries and venules and their behavior in relation to function, and the growth and behavior of lymphatic vessels.

The method, first worked out with the assistance of Mr. Sandison and perfected and extended by a group including Drs. R. G. Williams, H. T. Kirby-Smith, R. O. Rex, R. G. Abell, W. J. Hitschler, Mrs. Clark and myself, consists of the permanent installation in the ear of a rabbit or other mammal of a double-walled transparent chamber, in which there is left a central round "table" space, in relation with the living tissue of the ear. This space fills with exudate, blood cells and fibrin, which in turn is invaded by new tissues—including blood-vessels, lymphatics, connective tissue, and nerves—from the surrounding living tissues. The thickness of the space varies in different chambers from 45 to 75 micra. Modified types of chamber are also in use which permit the study of the original tissues of the ear, the introduction of chemical substances (Abell and Clark), and the access to the living tissue for experiment, transplantation or manipulation (R. G. Williams). No anesthesia is required during the observation period.

First the rate of growth of new blood capillaries will be considered. They appear at the edge of the "table" at an average of seven days after the installation of the chamber and advance at a rate which varies from 0.2

* Received for publication April 29, 1935.
From the University of Pennsylvania, Philadelphia, Pa.

to 0.6 mm a day, under favorable growth conditions. There is evidence that the rate of advance may be influenced by temperature, at least to the extent that marked lowering of the room temperature may result in slower growth. There is also evidence that the rate of advance is affected by the condition of the substances into which the capillaries are growing. Thus in chambers with a minimum of disturbance, in places where no hemorrhages or inflammatory exudations have occurred for several days, the rate of growth is appreciably reduced. However, there is much still to be learned regarding the physical and chemical factors which regulate the growth of new capillaries, and studies in this direction are going on in our laboratory.

Regarding the manner of growth of new blood capillaries, it has been possible to establish definitely that they grow by the sending out of sprouts from preexisting capillaries, in a manner similar to that established years ago in the transparent tails of amphibian larvae. Pointed endothelial processes are pushed out from the side of a circulating capillary or venule into the base of which the lumen gradually extends, and into which the nuclei are carried by the amoeboid activity of their surrounding endoplasm. The tip is constantly extended until it comes in contact with a blood capillary, venule or another sprout, when it forms a connection through which the lumen gradually extends. The nuclei increase in number by mitotic division—a process which has been observed in the living rabbit. No outside cell contributes to this endothelial extension. In fact, such sprouts have been seen to grow through a fibrin network—which no fibroblasts had yet penetrated and in which leukocytes could be easily excluded as possible contributors. The number of new sprouts for a given area varies enormously—from an occasional single sprout to a density so great that the neighboring sprouts are almost in contact with one another. Many sprouts may grow out from the wall of a single capillary or venule. Since this property of growth is probably common to endothelium of all capillaries and veins, it may be stated that, if suitable growth conditions are introduced, the number of capillaries of any region of the body may be increased many-fold within a period of two or three days.

However, growth processes also operate in the reverse direction, and many of the newly formed capillaries retract or disappear, in some instances by a process which is the reverse of sprouting, in others by what appears to be a dissolution of the endothelium. Thus, in places not more than one out of 10 of the newly formed capillaries survives, while in others nearly all may survive. Loss of capillaries is greater in the neighborhood of arterioles than in that of venules. This process of reverse growth, while varying in rate, may occur so rapidly that short capillaries may narrow and retract within 24 hours.

Nearly as rapid as the growth of new capillaries is the development of arteries and veins, both of which are formed by the enlargement of capillaries or parts of capillaries. Within a few days a newly formed capillary

may enlarge to form part of an arteriole or venule. The determining factors as to which of four fates may befall a capillary (retention as a capillary, disappearance, or enlargement to form part of an artery or vein) lie chiefly in the two hydrodynamical forces, blood pressure and amount of blood flow, as pointed out by Thoma in his histomechanical principles, the former regulating the thickness of the wall and the latter the size of the lumen.

While the endothelium is the essential tissue of the vascular system, forming a complete lining probably for all parts of it, leading the way in all its growth extensions and constituting a membrane through which occurs all interchange between the blood stream and outside cells and spaces, there is an elaborate development of accessory or adventitial cells outside, which ranges from the smooth muscle, connective tissue, elastic tissue wall of the larger arteries to scattered adventitial cells on capillaries and venules. These layers act as mechanical supports to the system and also, in connection with the nervous system, as local regulators of the flow of blood. Regarding these tissues outside the endothelium we have been able to make certain interesting observations.

The first adventitial cells on blood capillaries appear very early in their formation, often on new sprouts which have not yet connected with other capillaries and practically in all cases soon after circulation starts in the new capillary. In the tadpole's tail their formation from the surrounding connective tissue cells has been established by Mrs. Clark and myself, and we have observed in the mammal the flattening on the newly forming capillary of cells from outside—from the army of fibroblasts which usually invades the space along with the blood capillaries. Persistent study of some 40 such cells carried out during the past three weeks on a set of about a dozen capillaries indicates that the original early quota may remain unchanged for weeks, although one cell was seen to undergo division into two. In the capillaries in the rabbit's ear they are as inert as we had found them in the tail of the tadpole, and we cannot agree with Krogh, who has rather unfortunately termed them "Rouget" cells, that they play any part in capillary contraction.

On the arterioles there is a rapid increase in the number of cells outside the endothelium, the exact origin and development of which have not yet been worked out. However, the tempo and certain other details of development are of interest. Within two or three days one sees on the arterioles, in place of the longitudinally arranged cells, a continuous layer of cells which encircle the arteriole. Coincident with or following soon after this the arteriole becomes narrower. Just how soon this cell may be called a muscle cell we do not know. It apparently does not perform definite contractions and dilatations unless and until a vasomotor nerve reaches it. Regarding the latter, Dr. R. G. Williams, Mrs. Clark and I have been able to link up the inauguration and extension of definite contractions and dilatations with the ingrowth of nerves, by the use of intravital methylene blue

staining, and have proved the presence of active muscle cells which performed nerve controlled contractions on a vessel which 10 days before had been a newly formed capillary sprout. We also observed the extension of this undoubted contractility to muscle cells on parts of the vessel which ranged between 10 and 18 days of age. We have evidence of definite muscle contractility on arterioles 8 and 9 days old, respectively, which must for the present stand as the minimum time in which a new smooth muscle cell may develop. While muscle cells develop on all arterioles and apparently maintain a persistent partial contraction, only a variable fraction of the new arterioles in a regenerated region are reached by vasomotor nerves, and it is only the latter which develop typical contractions and dilations. Thus we have some chambers in which not a single arteriole showed this activity even after months. However, we have seen active contractility develop as late as $7\frac{1}{2}$ months after the growth of the arteriole.

While capillaries ordinarily intervene between artery and vein, it has long been known that in the ears of rabbits, as in certain regions of other animals, there are direct connections, or arterio-venous anastomoses. It has been possible in our chambers to observe the behavior of such structures, to watch their development and to discover some of the factors which regulate their formation and persistence. They are regulated in part, at least, by circulatory conditions.

In speaking of the development of the arteriole we have referred also to its function. Let us return briefly to consider the development of function in the capillary. We may exclude the development of contractility in the capillary, since the most prolonged observation and rigid testing, first by Sandison and later by Miss Clark and myself, have convinced us that neither in the ear of the rabbit nor in that of the dog does endothelium possess any such power of contractility as is usually associated with control of blood flow. This is of extreme interest and importance, of interest because the endothelium of capillaries in the tail of amphibian larvae has undoubted active contractility (and suggests an evolutionary loss of this property following the elaborate development of the nerve-muscle apparatus on the arteries in mammals), and of importance because it directs the physiologist back to smooth muscle and nerve in analyzing the control of peripheral circulation, perhaps saving him from a wild-goose chase in an attempt to discover the details of an endothelial contractility which probably does not exist in the mammal.

Regarding the essential function of the capillary, however, that of furnishing a membrane through which interchange of substances takes place, it is interesting that this function apparently starts as soon as circulation begins in a new capillary—perhaps earlier. However, the newly formed capillary differs slightly from the older capillary in its consistency, for it is obviously softer and more tender. Thus newly formed capillaries frequently become widened to a diameter three or four times the usual capillary size and are so tender that small hemorrhages from them are easily produced.

by slight external pressure or even by increased blood pressure. This soft consistency changes rapidly, especially in those capillaries with abundant blood flow, and within a day or two the new capillary grows narrower and is more resistant to injury.

The soft consistency of the young capillary is a property which may be manifested by well-established capillaries under the influence of chemical substances. There is evidence that blood-vessel endothelium may at any time, in reaction to certain chemical or mechanical stimuli, undergo progressive changes in consistency which are evidenced by (1) mild sticking of leukocytes to the endothelium, (2) prolonged leukocyte sticking, (3) emigration of leukocytes, (4) localized bulgings and hemorrhages, and (5) disintegration of endothelium. Such changes are most conspicuous in but not confined to inflammation.

The growth of lymphatics as observed in the rabbit's ear shows both similarities and differences when compared with blood vessels. Like blood vessels, growth takes place by the sending out of endothelial sprouts, into the bases of which the lumen gradually extends. All new lymphatic endothelium forms from preexisting lymphatic endothelium, and nuclei increase in number by mitotic division. The lymphatic is *normally* closed, both during growth and subsequently.

On the other hand, the growth of lymphatics is much more sporadic than that of blood vessels. Thus in the many chambers which have been observed, there have been great variations in the time and extent of ingrowth of lymphatics. In some cases one or more lymphatics have grown along with the most advanced blood capillaries, in others the first lymphatics have not appeared on the table until a week or more after the space has been completely vascularized. When lymphatics advance after blood vessels and connective tissue have differentiated, they show a decided tendency to grow along a clear space next an artery or a vein. They may continue a slow growth for weeks. Because of the almost negligible pressure in lymphatic capillaries they may be compressed along their course, and terminal stretches may be left completely isolated. Such isolated lymphatics may persist for weeks, retaining their typical lymphatic endothelial properties. They may eventually reunite with other lymphatics or may gradually shorten and disintegrate.

While lymphatics are normally closed, their contents may be forced through the wall by light pressure. If surrounded by the normal semigelatinous intervascular material, openings so made close at once. If, however, there is free fluid surrounding them, we have observed such artificial openings to persist for days, with an in-and-out movement of fluid and floating cells.

The frequent close proximity of venule and lymphatic makes possible a break of the double endothelial wall, with hemorrhage into the lymphatic. Such openings have, in our observations, always closed immediately, leaving a mass of blood in the lymphatic. While such a mass of erythrocytes in

the lymphatic may be cleared out within 24 hours, some of the erythrocytes may, in the absence of massage, remain in the bulbous tips for many days.

As for the development of function in the lymphatic, we have been impressed with the very slight amount of activity manifested by the lymphatic capillaries as watched in the living, under the conditions of our observations. There is some passage of fluid into the new vessels, but it is apparently slight in amount. Thus floating cells in the lymph may be seen bobbing back and forth for minutes or even hours without progressing. We have frequently seen not only erythrocytes but immigrated leukocytes remain in a lymphatic tip for weeks. The lymphatics play no significant part in the removal of the enormous amount of extravasated erythrocytes and other debris which is present following the insertion of the chamber or after a hemorrhage, and which is removed without their assistance. In inflammatory conditions with edema the lymphatics become distended but usually show even a diminution in flow indicating a blocking. There is no noticeable difference in the rate or amount of connective tissue growth in our chambers, whether lymphatics are present or absent. Regions without lymphatics show no evidence of disturbed physiology. In short, our own observations on the behavior of living lymphatics corroborate other studies on the sluggishness of lymph flow from peripheral parts of the body in mammals, in the absence of muscular activity. They even raise the question as to whether, in such regions, lymphatics play any useful role whatever.

The observations which have been presented in this paper regarding the growth and behavior of blood vessels and lymphatics as seen through the microscope in the living mammal represent but samples of the studies which a new method has made possible. They form a mere beginning of a new analysis of that region which is of such fundamental importance in the anatomy and physiology of health and disease, namely, the peripheral region which includes the arteriole and venule, the blood and lymphatic capillary, the cells of the tissues, and, scarcely less important, the extravascular, extra-cellular tissue spaces.

The paper was illustrated by lantern slides and by an eight minute motion picture film made with the assistance of Dr. E. A. Swenson, which showed the circulation in new-growing and recently formed blood vessels, movement of blood cells in an isolated lymphatic, and contraction and dilatations of a new-formed arteriole and of a new-formed arterio-venous anastomosis.

THE PRESENT STATUS OF BRONCHOSCOPY IN BRONCHIAL ASTHMA

By LOUIS H. CLERG, M.D., F.A.C.P., *Philadelphia, Pennsylvania*

IN a discussion of bronchial asthma one should bear in mind that patients sent as cases of asthma for investigation or treatment often present signs or symptoms that do not conform to the textbook description of this condition. In other words, there are many pathologic conditions that simulate asthma and may be regarded clinically as such. It is only by a careful study that the correct diagnosis is made. The rôle of bronchoscopy in bronchial asthma therefore includes the investigation of the tracheobronchial tree to rule out certain conditions that might simulate asthma. In addition bronchoscopy permits the collection of bronchial secretions for autogenous vaccine, and it affords relief by removal of obstructing secretions from the air passages. The interest of the bronchoscopist is limited largely to that form of asthma associated with evidences of tracheobronchitis, the so-called bacterial asthma. Hypersensitiveness and the part played by bacteria as an etiological factor in asthma are problems for the allergist.

The matter of diagnosis is often difficult. Not infrequently patients with dyspnea, wheeze or cough of obscure origin are referred to the bronchoscopist for investigation and it is found these are clinical manifestations of hypersensitiveness. On the other hand patients with a foreign body in the air passages or even in the esophagus not infrequently have been studied carefully from an allergic standpoint, and only later has it been discovered that there was a good foreign body history with quite typical signs and symptoms.

One of the common and often most misleading symptoms which suggest a provisional diagnosis of asthma is wheezing respiration. It is usually described as "asthmatoïd wheeze," a term which promptly offers a diagnostic possibility to those who are readily influenced by suggestion. The wheeze, heard best at the open mouth and towards the end of expiration, should be considered as an audible manifestation of *narrowing of the airway*. Mechanical conditions producing the wheezing sound are perfectly obvious to the bronchoscopist, namely, air being forced through a narrowed lumen. In the patient with foreign body the narrowing is produced by the foreign body, swollen inflammatory mucosa and secretions, in the asthmatic patient air is being forced through a lumen narrowed by congestive or inflammatory changes, and with thick mucoid secretion adherent to its walls. It has been described also as a symptom of laryngeal disease, of foreign body in the trachea or bronchi, of foreign body in the esophagus, of malignant or benign tumor of the trachea or bronchi, of compression stenosis or of stricture of a bronchus. Why not describe it as "wheeze" or "wheezing

* Received for publication November 25, 1935

respiration" without reference to asthma and then proceed to investigate it as a symptom indicative of partial obstruction to the airway? It is in this connection that bronchoscopy and at times esophagoscopy have given valuable aid in establishing a correct diagnosis and often effecting a cure. Illustrative cases are cited.

Case 1 A woman, aged 31 years, reported to an Allergy Clinic for investigation of wheezing respiration and a slight cough of three weeks' duration. Routine skin tests were carried out and the patient was requested to bring in a quantity of house dust. Following the third visit she was advised that all of the tests were negative and that she did not have asthma. Curiously, the wheeze disappeared at about that time being replaced by slight dyspnea and an aching sensation in the left chest. She consulted another physician who examined her chest and referred her to the Bronchoscopic Clinic of Jefferson Hospital for investigation of atelectasis of the left lung. Completed studies revealed a malignant tumor of the left bronchus.

Comment The symptom "wheezing respiration" led the patient to believe that she had asthma. This provisional diagnosis apparently was accepted at the Allergy Clinic, for no chest studies were carried out. When the bronchial obstruction became complete, producing atelectasis, the wheeze disappeared.

Case 2 A child, aged two years, began to wheeze during August. This was noted particularly during sleep. There was also some dysphagia for solid food. Later, slight dyspnea developed. After several months it was observed that paroxysms of dyspnea with wheezing occurred whenever the child took any food. A diagnosis of asthma was made and several foods were suspected. Avoidance of these gave no relief. The symptoms became progressively worse, epinephrine afforded some comfort. On careful questioning it was found that the child had swallowed a large button about three weeks before the onset of symptoms. Roentgen studies of the swallowing function revealed a non-opaque object in the cervical esophagus. At esophagoscopy this proved to be a button. Its removal seven months after it had been swallowed was followed by prompt relief of the asthmatic symptoms.

Comment The large size of the foreign body together with the periesophageal swelling produced compression stenosis of the trachea which was responsible for the wheeze and later the dyspnea. The dysphagia apparently was overlooked.

Foreign body as a diagnostic possibility should be excluded in every child presenting symptoms suggesting asthma. A careful study of the history and symptoms, a thorough physical examination of the chest supplemented by a roentgen study will rule out foreign body in a majority of cases. If in doubt a diagnostic bronchoscopy is indicated. Wheezing respiration is a common symptom of bronchial foreign body.

Bronchoscopic observations in the cases of true asthma are of interest. The noteworthy findings are collapse of the trachea and bronchi during cough and forced expiration, and the presence of abnormal secretions.

Collapse of the Trachea and Bronchi Moderate forward bulging of the membranous wall of the trachea during cough is often observed in children, occasionally in adults, and is not considered pathologic. In the normal person there is a rhythmic movement of the trachea and bronchi during respiration. The bronchi elongate and dilate during inspiration, during expiration they shorten and contract. These changes are participated in by the entire bronchial tree. The collapse observed in certain cases of asthma differs from the normal phenomenon both in appearance and in the mechanism involved in its production. At the beginning of expiration in many cases there is noted marked collapse of the trachea. In some the collapse is limited to the posterior tracheal wall, which, bulging forward, becomes convex, and fits into the concavity of the anterior wall of the trachea, the resulting lumen is crescentic. The forward bulging occurs during expiration and cough, and is in proportion to the force of the expiratory effort. Occasionally the lateral tracheal walls also participate in the collapse, giving the lumen a triangular appearance. The lumen promptly returns to its normal more or less rounded appearance at the beginning of inspiration. In many of these cases there is an associated collapse of the walls of the bronchi including the orifices of the bronchial subdivisions. These changes often are sufficiently marked to interfere with the introduction of the bronchoscope which can be advanced only during inspiration. This is not bronchial spasm. The collapse is undoubtedly passive in nature, and one gains the impression that the tracheal and bronchial walls are being forced shut by some external influence. This phenomenon was discussed by F. J. Kaltefleiter in a previous report. While not absolutely characteristic of the average case of asthma, it is unquestionably a pathologic state that is present in certain of the different conditions clinically described as asthma.

Treatment In my experience bronchoscopy has been employed only in cases that did not present any demonstrable etiological basis for their symptoms or did not respond to treatment based on supposed causative factors. With an occasional exception our patients had been studied from the standpoint of allergy, and the nasal accessory sinuses, the teeth and other possible foci of infection had been investigated. Their status as to the presence or absence of serious organic disease had been determined.

These patients could be divided roughly into two groups. The first consisted of adult patients who, previously well, dated the onset of asthmatic symptoms to an acute respiratory infection. The second group consisted largely of children. In these the asthmatic symptoms were sudden in onset and often were considered as of foreign body origin.

In the first group the more commonly observed symptoms were a sense of tightness or constriction about the chest and cough. Paroxysmal attacks of coughing often initiated the asthmatic attacks. Mucoid or thick mucopurulent sputum was present. When sputum was readily coughed up the patient seemed comfortable. From a description of the paroxysms of asthma one gained the impression that the inability of the patient to get rid

of secretions was followed by subjective sensations in the chest, paroxysms of cough with dyspnea and wheezing. The hypodermatic use of epinephrine often gave little relief, occasionally it produced a feeling of depression with severe headache. Atropine and morphine often were helpful. Burning of "asthma powders" seemed to give greater temporary relief than any of the commonly employed measures. Attacks would continue for hours, even days. Relief was secured following expectoration of secretions. The patients commonly exhibited the clinical and roentgen findings observed in chronic laryngotracheobronchitis. Suppuration of the nasal accessory sinuses often was present but no relief was secured from treatment. A history of many nasal operations was the rule. It was not uncommon to find allergic reactions to certain substances including house dust. Attempts at desensitization either failed to give relief or produced only slight amelioration of the attacks.

The bronchoscopic findings consisted of moderate inflammatory changes involving the mucosa of the larynx, trachea and larger bronchi with thick mucoid or mucopurulent secretion adherent in small clumps to the walls. One always could secure an additional quantity of this by exploring the smaller bronchial subdivisions with a small flexible tipped aspirating tube. Narrowing of the orifices of the smaller bronchial subdivisions was no greater than would be expected in the presence of chronic inflammatory swelling of the mucous membrane. Collapse of the trachea and larger bronchi during expiration occurred. Patients observed during a paroxysm did not yield any additional information unless dyspnea was marked. Then the expiratory collapse of the airway was increased and the mucosa appeared more cyanotic.

The following fairly typical case is cited

Case 3 A female, aged 25 years, had asthmatic attacks for six years. There was a history of an acute pulmonary infection about two years previously, but recovery was apparently complete. Shortly before the onset of the asthmatic attacks the patient had a severe "head cold" which continued for about two months. During the past six years she had been under the care of many physicians, 10 operations on the nasal accessory sinuses had been performed, and in addition the tonsils had been removed. A number of skin tests were carried out with negative results and vaccine therapy was employed with little benefit. During the year prior to admission to the Bronchoscopic Clinic, Jefferson Hospital, she had secured little relief from attacks. On admission she had not been free from wheezing and dyspnea for practically three months. The usual forms of medication gave slight relief. A roentgen study of the chest revealed little change. Although the patient's condition was not good bronchoscopy was proceeded with. A large quantity of thick tenacious mucopus was found in the trachea, main bronchi and their subdivisions. There was a generalized tracheobronchitis. Collapse of the trachea and large bronchi was noted during expiration and cough. The patient developed a severe paroxysm of asthma during the bronchoscopy, with removal of a large quantity of secretions there was marked alleviation of symptoms. Vaccine made from the bronchoscopically removed secretions was given with no apparent benefit. Repeated bronchoscopic treatments have been carried out in this patient, in fact, she has been reporting to the Bronchoscopic Clinic

every three or four weeks for the past four years. She is willing to continue since this is the only mode of treatment that has afforded relief.

The second group of cases was characterized by the abrupt onset of the asthmatic symptoms, often suggesting foreign body aspiration. All of the patients observed were children. In one case the attacks occurred only during rainy weather. In others no predisposing factors could be elicited. The acute onset with wheezing respiration, alarming dyspnea both expiratory and inspiratory, a moderate febrile reaction and clinical and roentgen findings of bilateral obstructive emphysema warranted bronchoscopic investigation to rule out tracheal or bilateral bronchial obstruction, notably foreign body. Through the bronchoscope there was found a subacute tracheobronchitis with a large quantity of tenacious, greyish secretion in the trachea and bronchi. The relief secured following bronchoscopic aspiration of the secretions was not unlike that observed after removal of a partially obstructing tracheal foreign body. In the subsequent studies of these cases nasal accessory sinus disease and positive skin reactions, particularly to foods, often were found present. I do not recall a single case in this group, however, that was benefited by removal of suspected foods or by attempts at desensitization.

The following case is typical.

Case 4. A child, aged two years and nine months, daughter of a physician, was brought to the Bronchoscopic Clinic with wheezing respiration and severe dyspnea. There was moderate fever. The onset had occurred quite abruptly 24 hours previously. A provisional diagnosis of asthma had been made, and epinephrine, atropine and morphine had been given without relief. Foreign body was then suspected although there was no history of foreign body aspiration. On admission the dyspnea and wheezing were both expiratory and inspiratory. There was no cyanosis. Cough was absent. The findings suggested tracheal obstruction. Roentgen study by Dr. W. F. Manges showed overdistention of both lungs with air throughout the entire respiratory cycle suggesting either a foreign body in the trachea or any condition that would produce partial obstruction to both main bronchi.

At bronchoscopy a large quantity of thick mucoid secretion was removed from the trachea and both main bronchi. There was no evidence of aspirated foreign body. A roentgen study made following bronchoscopy indicated that there was a marked decrease in the degree of overdistention of the lungs. Wheezing and dyspnea were absent. There was roentgen evidence of nasal accessory sinus disease. Skin tests were carried out and were found positive for two foods, namely chicken and beef. Their use, however, did not produce symptoms. On close questioning it was learned that this patient had slight dyspnea lasting for about one hour three weeks previously. Treatment of the sinuses has since been carried out and the patient has had only occasional slight attacks of wheezing.

It is believed that in both of these groups, one occurring in adults, the other in children, there was an intrinsic cause for the asthmatic attacks. Sinus disease was present in a majority of cases.

In the first group there was found evidence of a chronic infection of the

mucosa of the tracheobronchial tree. Treatment of the sinus infection when present and attempts at desensitization gave slight relief and to only a few cases. Bronchoscopy with removal of secretions gave prompt relief. When bronchoscopy was repeated at intervals the attacks either did not recur or produced only slight distress.

In the second group the findings suggested an acute inflammatory process. Bronchoscopic aspirations afforded prompt temporary relief. Treatment of a sinus infection when present gave the best ultimate results.

It is difficult to state how bronchoscopy is helpful in these cases unless it is the result of removal from the bronchi of thick secretions that interfere mechanically with the exit of air during expiration. There can be no question that bronchoscopy is of value. If the symptoms are the result of simple mechanical obstruction of bronchi one would expect patients with extensive bronchiectasis to exhibit symptoms of bronchial asthma. The occurrence of obstructive emphysema and particularly a patchy obstructive atelectasis undoubtedly exerts an influence although this is difficult to prove. Lobal atelectasis as a complication of asthma has been described by Clarke and others. It was my privilege to observe Clarke's case bronchoscopically. The bronchoscopic observations made did not permit one to arrive at definite conclusions.

The coexistence of asthma with bronchiectasis is not frequent, although I believe that it is more common than medical literature indicates. It is probable that the asthma antedates the bronchiectasis. In spite of this, however, the asthmatic attacks are more frequent and severe when the bronchiectasis does not drain properly. The presence of bronchiectasis can be positively determined only by the introduction into the bronchial tree of iodized oil. Although this has been done in a number of cases without untoward results one death did follow its use. This patient, a woman, had frequent paroxysms of severe asthma for many years. There was evidence of bronchopulmonary disease. During the bronchoscopic aspiration of secretion she developed a paroxysm of asthma, about 9 cc of iodized oil were instilled into each of the lower lobe bronchi. Dyspnea increased and death ensued within 20 minutes. The cause could not be determined. No autopsy was permitted and it was not learned if bronchiectasis was present. Since bronchoscopy affords the best opportunity for the collection of material for the preparation of autogenous vaccines a word of comment on the use of such vaccines may be added at this point. The empiric use of autogenous vaccines in asthma may not be considered wholly scientific when there is doubt concerning the exciting factors. In spite of this, however, satisfactory results have been secured from such vaccines in a sufficiently large percentage of obscure cases of asthma to warrant their employment. In a previous communication I reported a case of asthma that secured complete relief of symptoms from the use of vaccine made from bronchoscopically removed secretions. This patient had been treated by several competent allergists without benefit. Two additional cases have now se-

cured complete relief following the use of autogenous vaccines. I believe therefore that they should be employed in selected cases.

SUMMARY

Bronchoscopy is of value in the study of certain clinical conditions described as bronchial asthma. No allergy or asthma clinic is complete without the services of a competent bronchoscopist.

Bronchoscopy should be given a trial in the treatment of cases of bronchial asthma that do not respond to commonly employed methods. The best results are secured in cases with tracheobronchitis, excessive secretions or bronchial obstruction.

Vaccines made from bronchoscopically removed secretions are of value in cases of so-called bacterial allergy.

PROGNOSIS IN ACUTE GLOMERULAR NEPHRITIS

By ARTHUR B. RICHTER, M.D., *Boston, Massachusetts*

THE outlook for adults who have acute glomerular nephritis has seldom been the subject of comment in the literature. Excepting war nephritis, the few studies on prognosis are mostly in children. The mortality during the acute stage of the disease is regarded as low in both groups, but both the immediate and the late prognosis are apparently more favorable in the earlier ages. However, the death rate during the acute stage in the cases of acute nephritis, chiefly adults, recently reported by Murphy, Grill and Moxon¹ was so high as to challenge the truth of these beliefs.

The present study was undertaken to determine what had been the experience at the Peter Bent Brigham Hospital in this regard. One hundred cases of typical, acute, diffuse glomerular nephritis were selected from 160 so diagnosed during the years 1913 to 1934 and the ultimate outcome determined by a follow-up study which was successful in disclosing the renal condition of all but 13 of the 90 individuals who survived their acute illness. The data are extraordinarily complete because of the constant interest in the disease shown by Dr. J. P. O'Hare and Dr. Henry A. Christian. Sixty cases were rejected because of one or more features which suggested that they were probably instances of chronic nephritis with acute exacerbation. All but one of the cases were observed in the hospital for an average of six weeks during their acute process, and the one exception was treated at home by Dr. O'Hare. It was, therefore, possible to observe almost all of the patients throughout the early stages of their disease.

Acute Stage. As can be seen in table 1, there were twice as many males as females. The age incidence varied from 12 to 59 years, the former being the lowest age limit for admission to the medical service of this hospital.

Acute nephritis is most common in children and young adults. This is the period of life when the causative acute infections of the upper respiratory tract are most frequent. Three-fourths of this series were between 12 and 30 years, only seven were above 40 years.

Ten patients died during the acute stage. In five, death was not attributed to the nephritis but to the causative infection, or to an incidental factor such as acute syphilitic meningitis, broncho-pneumonia, lobar pneumonia, hemorrhage from carcinoma of the cecum, and generalized peritonitis from perforation of a typhoid ulcer. Of the five patients whose death was due primarily to acute nephritis, four were in the third decade and one in the sixth. Three died of uremia, one of broncho-pneumonia and severe fatty degeneration of the liver, and one of erysipelas. The complicating

Rheumatic fever	1	0	0	1	0	0
Influenza and empyema	1	0	0	0	0	1
Unknown	15	0	0	8	4	3
Total	100	5	5	62	15	13

determined. The onset of acute nephritis followed scarlet fever in only four patients. The infrequency of postscarlatinal nephritis in this series is probably due to the fact that cases of scarlet fever are rarely admitted to this hospital. Three of the four cases of postscarlatinal nephritis occurred in brothers at about the same time, and could be classified as cases of so-called familial nephritis.³ These three are now cured, 16 years later. The remaining case did not return for follow-up study. Lobar pneumonia (in four cases), and broncho-pneumonia (in one) accounted for 5 per cent of the cases of acute nephritis. Rheumatic fever is rarely the cause of true glomerular nephritis,⁴ but it is the attributed cause in one of our cases. Another patient, following his second attack of rheumatic fever accompanied by an acute upper respiratory tract infection, developed acute nephritis which was believed due to the latter infection. The urine of this patient had not cleared at the end of three weeks, and he died of influenza a few months later. Mumps is not usually considered a cause of acute nephritis, however, one patient, aged 20, following an attack of epidemic parotitis, developed typical acute glomerular nephritis. Although the urine had not cleared during four months of observation, 14 years later there was no evidence of chronic nephritis.

Table 3 shows the frequency of the various symptoms and signs. Significant early symptoms and signs of acute nephritis may be absent, the

TABLE III
Symptoms and Signs in 100 Cases of Acute Nephritis

diagnosis being incidental to a routine urine examination. This was true in 14 of our cases. Edema, non-uremic convulsions, hypertension, neuro-retinopathies, myocardial failure, uremia, gross hematuria, and albuminuria were the only signs which seemed possibly related to the outcome of the nephritis.

Edema which occurred in two-thirds of both the cured and the chronic cases was usually confined to puffiness about the eyes and swelling of the ankles. There was no relationship between the degree or duration of edema and prognosis. As is usually true in acute nephritis, the amount of total protein, albumin and globulin of the blood was normal, or but slightly lowered, in the few cases in which these determinations were made.

Hypertensive encephalopathy manifested as convulsive seizures is not uncommon in acute nephritis, especially in children. Of the 100 cases, nine between the ages of 12 and 37 years had convulsions. All of them had hypertension and a normal or only slightly elevated blood urea nitrogen. In seven, the convulsions were due to hypertensive encephalopathy, while there was probably another cause in the other two. One of these died of acute syphilitic meningitis about two weeks after the onset of acute nephritis. The other patient is most interesting. The convulsions, first occurring at the onset of his acute nephritis, persisted periodically until death about eight years later. Although the nephritis became chronic, the blood pressure and kidney function remained normal. The true cause of the convulsions became evident with the development of more definite signs of brain tumor, which proved to be a glioma of the frontal lobe (no 8, chart 2). The seven cases of hypertensive encephalopathy recovered and are now without evidence of chronic nephritis five to 14 years later.

Hypertension was present in 53 of the 96 cases in which the blood pressure was recorded (table 4). Its occurrence was twice as frequent in the

TABLE IV
Range of Blood Pressure in 96 Cases of Acute Nephritis

* 16 cases had normal systolic and elevated diastolic pressures

patients who were seen within two weeks of their first symptoms of nephritis as in those admitted later. This suggests that hypertension tends to occur early in the disease, and that possibly the former group were brought to the hospital earlier because of a more severe form of nephritis. The presence of hypertension was unrelated to the outcome. The general rule that a gradually rising blood pressure, or hypertension, persisting longer than a few days is an unfavorable sign in acute nephritis was borne out in the two cases in which it was applicable. One died in the acute stage, the other developed chronic nephritis. Only one of the three patients who died of uremia had hypertension, and this was minor.

Slight neuro-retinopathy consisting of edema of the disc and retina, and constriction of the retinal arteries, was observed in three cases of the series all of which recovered.

Myocardial insufficiency, an important feature in a very small proportion of cases of acute nephritis, is at times precipitated during convulsive seizures. Cardiac failure did not, however, result from this cause in our series, although two patients had frequent severe convulsions for 24 hours before entry. Congestive failure, of moderate degree, occurred in only one case,

while dyspnea, which may have been due to left heart failure, was a symptom in three more. These four patients recovered.

All of the 100 cases had albuminuria as determined by the nitric acid test. The urinary sediments of 87 contained moderate to large numbers of red and white blood cells. In 13 there was only an occasional red blood cell during the period of observation, but more blood was probably present prior to entry to the hospital. In this clinic, the presence of red blood cell casts has been used as an important aid in distinguishing nephritis from other causes of hematuria. They were fairly constantly present in the early stage of the nephritis in the majority of the cases.

Neither the presence nor the severity of gross hematuria, which occurred in 42 per cent of the cases, was related to the outcome of the nephritis.

It is well known that renal function determined by the usual tests is of little significance in most cases of acute nephritis. This is partly due to the transient nature of the early injury in otherwise normal kidneys. During the period of anuria and oliguria the phenolsulphonephthalein excretion and urea clearance are diminished, and the blood urea nitrogen is elevated.^{5, 6} This was found to be true in our series. Azotemia, present in 49 of 90 cases, was slight in most of them, and it usually occurred early in the nephritis. The blood urea nitrogen ranged from 16 to 180 mg per 100 cc (table 5). The three patients who died of uremia had anuria and a urea

TABLE V

61-90	5
120-180	3

nitrogen of more than 120 mg per 100 cc. The phenolsulphonephthalein excretion was determined in most of the series. The urea clearance was determined less often than the dye test, but in the cases in which both were done, the information obtained was of as little prognostic value as from the dye test alone. This may be in part explained by too infrequent use of the tests, since it is well known that it is the trend of repeated tests over a period of time, and not the single test, regardless of the kind, which gives the most useful indication of kidney function.

Late Prognosis. Most of the patients returned to the renal clinic, under the direction of Dr. O'Hare. In a few the data necessary to determine the presence or absence of chronic nephritis were obtained from the patient's physician. The criteria for complete recovery from acute nephritis consisted of normal kidney function tests, negative urine examinations and normal blood pressure. However, two cured cases, who developed hypertension about 10 years after their acute nephritis 19 years ago, have shown no evi-

dence of chronic nephritis. The blood pressure of one of them has been normal since an attack of coronary thrombosis three years ago.

Eighty-one of the 90 who survived their attack of acute nephritis have been traced. The renal status of 77, or 85.5 per cent, has been determined at periods varying from 1 to 19 years after the onset of acute nephritis (table 1). The average follow-up period was 8.7 years. Of the 13 patients whose renal condition was undetermined, nine could not be found, two had died of influenza a few months following the onset of acute nephritis, and one had died of pulmonary tuberculosis 15 years later, the renal condition being unknown. The last, who is still living after 17 years, did not respond to our inquiries. Of the 77 patients whose renal condition is known, 62, or 80.5 per cent, are cured, while 15, or 19.5 per cent, have developed chronic nephritis.

Albuminuria is the most delicate evidence of the presence of nephritis.⁵ We have, therefore, as presented in charts 1 and 2, given special attention to the duration of albuminuria as a possible aid in prognosis. Of the 62 cured cases, the urine was known to have become free of albumin within two months in 14, within six months in 13, within 10 months in 4, and within a year in nine cases. The urine became albumin-free after one year in four cases, 1.5 years in one, and two years in two. The approximate time when the urine cleared in 15 patients could not be determined because of infrequent visits to the clinic. In other words, the urine became albumin-free in about half of the 62 cured cases within six months, between six months and a year in one-fifth and later than a year in one-ninth. Two patients (nos 8 and 24, chart 1) demonstrate the significant fact that acute nephritis may heal after albuminuria has been present for two years. It is quite possible that three cases (nos 13, 14 and 15, chart 2), now considered as having chronic hemorrhagic nephritis at 19 months in one case, and two years in the other two, may be found without evidence of nephritis in a longer follow-up study.

Of the 15 patients who developed chronic nephritis, the first 12, as shown in chart 2, were followed from 3 to 19 years. In eight of these, albuminuria in constant or increasing amounts was present on all examinations during the first year, and thereafter. Five of the eight developed chronic, hemorrhagic nephritis, and four of them were followed regularly until death. Two died in uremia five and eight years, respectively, after the onset of acute nephritis (nos 9 and 10). The other two, whose blood pressure and kidney function tests remained normal, died of incidental causes three and four years later (nos 8 and 12). The fifth patient (no 1) was not seen between the first and third years after the onset of acute nephritis, but returned regularly thereafter, at 19 years albuminuria was present but the blood pressure and kidney function tests were normal. Three of the eight cases in which albuminuria was present during the first year were followed less regularly than the five discussed above. The first (no 3) did not return after the first year, at the end of 16 years death was caused by uremia or cerebral hemorrhage. The second (no 6) had hypertension at three years.

CHART 1 Showing urinary examinations of 62 patients who are cured of acute nephritis

CHART 2 Showing urinary examinations of 15 patients who developed chronic nephritis

During the next nine years he was not seen at all, on his return, 13 and 14 years after the acute nephritis, the hypertension had increased. Although albuminuria and cylindruria were still present, various kidney function tests were normal. The heart was not enlarged on roentgen examination. There was moderate generalized arteriosclerosis. The third (no 2) was not observed between the first and second years after acute nephritis. He did, however, report to us later. The urine was negative at two years, positive for albumin and casts 10 months later, negative at five and seven years, and again positive at 17 and 19 years. Kidney function tests and the blood pressure were normal at all examinations. Moderate generalized arteriosclerosis was present.

In only two of the 15 chronic cases did the urine become negative within a year, during the first month in one of them. The latter case (no 4) was not seen from the first to the tenth year. An acute exacerbation of the chronic nephritis occurred during an acute infection of the upper respiratory tract at 10 and 14 years after the initial attack of acute nephritis. This patient would have been considered cured had he not been seen during the acute exacerbation. The other patient (no 7) had negative urine examinations between the first and second years, but at two years albuminuria and hematuria recurred. He was treated for pulmonary tuberculosis 10 years later when there was still evidence of chronic nephritis. The tuberculosis became arrested and he is now reported to be well.

The urine studies of five cases with chronic nephritis were too infrequent to be of value in estimating the significance of albuminuria. Case 5 was observed for two months after the onset of acute nephritis, 15 years later he was reported to have albuminuria, hypertension, and cardiac enlargement. In case 11 the acute nephritis progressed into chronic, hemorrhagic nephritis, the blood pressure and kidney function tests were normal during the four years he was followed. Cases 13, 14 and 15 have chronic, hemorrhagic nephritis with normal blood pressure and kidney function tests, about two years following the initial stage.

A comparison of charts 1 and 2 shows that 80 per cent of the regularly followed cases, in which chronic nephritis developed, had albuminuria one year after the onset of acute nephritis, while only 14.8 per cent of the cured cases had albuminuria at the end of the first year or later. In other words, when albuminuria was still present at the end of a year or thereafter, the chances for progression of the nephritis into the chronic stage were approximately 6 to 1.

Significant features not given in the charts are the presence of hematuria and cylindruria, and the degree of albuminuria. Hematuria and cylindruria, often occurring in the absence of albuminuria, were important signs of renal activity, but because of their intermittent occurrence and quantitative variation, the degree and duration of albuminuria served as a more useful indication of the general trend of the course of the nephritis. In each of the 62 patients who became cured, there was either a gradual or intermittent de-

crease in the amount, or complete disappearance of the albuminuria over a period of a few weeks up to two years after the onset of acute nephritis. In the 10 chronic cases who were examined regularly during the first year, there was a slight, early decrease of the albuminuria while the patients were at bed rest, but by two months and thereafter the degree of albuminuria was constant or increasing.

In only one patient did the acute nephritis progress rapidly so that hypertension had developed by the end of one year.

The patients, in our clinic, with the nephrosis syndrome were not observed during the initial stage of their nephritis, therefore, this complication was not present in any of the cases followed in the present study.

Orthostatic albuminuria was present in only one patient, six years after the attack of acute nephritis.

co-workers, and of McPhee and Kaye⁷ have been classified into an age group corresponding to the 100 cases of the present study, shows the death rates during the acute stage of 31.7 per cent in Murphy's series, 7.5 per cent in that of McPhee and Kaye, and 5 per cent in our series. In the cases of acute glomerular nephritis in children, reported by Tallerman,⁸ Guild,⁹ Lytle and Rosenberg,¹⁰ Osman,¹¹ Hill,¹² and Blackfan,¹³ the death rates during the acute stage ranged from 3.3 to 12.5 per cent, with an average of 6.6 per cent. The mortality, in the acute stage of war or trench nephritis, was slightly lower than in the acute glomerular nephritis of childhood, or in civilian nephritis of adults. Reports of cases of war nephritis by various authors^{14 to 21} gave death rates during the acute stage ranging from 0.8 to 7.6 per cent, averaging 3.6. In the literature the greatest variation in death rates in acute nephritis was found in the reports of various small series of postscarlatinal nephritis, where the virulence of an epidemic appeared to be a factor. However, in a large series of postscarlatinal nephritis in children and young adults, reported by Hansborg,²² the death rate was 4 per cent, and 6 per cent in a similar series of Barasch.²³ This review of the literature and the study of our cases not only bears out the opinion that the immediate prognosis in acute glomerular nephritis is good, but also shows that there is no essential difference in the death rate in children and adults, except in trench nephritis where the mortality was lower than in either children or adults in times of peace. The mortality of 28.7 per cent in the series of Murphy, Grill and Moxon is the highest found in the literature. The deaths in their series did not seem attributable to the disease which caused the nephritis.

A comparison of the late prognosis in acute nephritis of adults is also shown in table 6, in which the cases of Murphy and of McPhee and Kaye have been classified into age groups, similar to that of our series. The percentage of cases in our group which developed chronic nephritis is a little lower than in the adult cases of the other authors. In acute glomerular nephritis in children, reported by various authors,^{5, 6, 7, 9, 24, 25, 26, 27} the percentage of cases which became chronic varied from 0 to 16, indicating a more favorable remote prognosis than in adults. The high incidence of 51.8 per cent in the series of Patterson and Wyllie,²⁸ and 35.7 per cent in Osman's¹¹ series of children and young adults, was unexplained. The various reports of postscarlatinal nephritis gave a definitely lower incidence of progression into chronic nephritis than in nephritis of mixed etiology. In the reports of acute war nephritis,^{15, 16, 18, 29, 30} the percentage of cured cases ranged from 45 to 85. The number of cases which developed chronic nephritis is difficult to evaluate because of their grouping by some authors into cases which developed chronic nephritis, cases with "residual albuminuria" without signs of nephritis, and "cases of contracted kidney with retinal and vascular degeneration." The various authors writing about war nephritis have, however, believed that a greater proportion of these cases

developed chronic glomerular nephritis than in civilian nephritis, for which a satisfactory explanation has not been given

The present group includes both severe and mild cases of acute, diffuse, glomerular nephritis caused by various acute infections

The only clinical observation frequently related to the ultimate outcome of the nephritis was the degree and duration of albuminuria. Similar observations described by others have rarely been expressed statistically. Brown and Evans³¹ stated that the disappearance of albuminuria within a month after the onset of acute nephritis is a hopeful prognostic sign, while Tidy³² believed that the development of chronic nephritis is usual if albuminuria persists longer than a month. Fishberg³³ makes the statement that the longer albuminuria persists the greater the chances of the nephritis becoming chronic. Murphy¹ believed that gradually diminishing albuminuria points toward a healing process. In the majority of her cured cases of acute glomerular nephritis in children, Guild found the urine cleared promptly, within two months in most cases, but that albuminuria persisted for many months in a few. Addis,³⁴ by use of his sediment counts, and quantitated proteinuria, has shown that in three-fourths of the cases of acute, hemorrhagic nephritis healing occurs during the first year, but complete recovery occurred as late as the fifth year.

The results in our cases suggest that when albuminuria had persisted for a year or longer after the onset of the acute nephritis, the chances of the process becoming chronic were six to one.

It should be emphasized that clinical cure of acute nephritis may not always represent cure of the underlying pathologic process. This is well illustrated by the rare case (case 4, chart 2) in which the nephritis is manifest only during exacerbations following acute infections, the urinary and kidney function studies being entirely normal in the interim. When the intervals between observations or the exacerbations are long, or if antecedent flare-ups are unknown, such a case might easily be considered cured of the initial nephritis, if not followed for a very long time. In a clinical study of this kind such a possibility cannot be eliminated.

For the purpose of this study we have considered a patient cured if there was no evidence of nephritis at the end of one year. The validity of this is borne out by the fact that of the 42 cases apparently cured at one year (average 8.7 years), only two have been found to have chronic nephritis at a later date.

SUMMARY

Of 100 adolescents and adults with acute diffuse glomerular nephritis, 10 died during the acute stage, five primarily of their nephritis, and five of the causative infection, or of incidental causes. Eighty-one of the surviving 90 have been traced and the renal status determined in 77. Sixty-two are cured, and 15 have developed chronic nephritis during the follow-up periods, which were from 1 to 19 years with an average of 8.7 years.

The relation of the various clinical features to prognosis is discussed. The one clinical observation of greatest prognostic value was the degree and the duration of albuminuria. In the majority of the cases, disappearance or gradual and intermittent decrease in the amount of albuminuria indicated healing of the nephritis, while persistent albuminuria of a constant or increasing amount suggested progression into chronic nephritis. The results also suggest that when albuminuria (orthostatic factor excluded) persists for a year or longer after the onset of acute nephritis, the chances of the renal process becoming chronic are six to one.

THE EFFECTIVENESS OF THE SIPPY REGIMEN IN NEUTRALIZING THE GASTRIC JUICE OF PA- TIENTS IF THE AMOUNT OF ALKALI IS NOT VARIED *

By PAUL H. WOSIKA, M.D.,[†] *Chicago, Illinois*, and EDWARD S. EMERY,
Jr., M.D., *Boston, Massachusetts*

THE method of ulcer treatment as suggested by Sippy is frequently used in the belief that placing the patient on the routine as outlined will effect complete neutralization of the gastric contents. Some may question the necessity of maintaining neutrality in the stomach, or may even doubt that neutrality provides optimum conditions for healing. Sippy himself, however, suggested that the absence of free acid should be used as a criterion for the effectiveness of treatment, and this conception appears to have been commonly adopted in theory. We have been unable to find in the literature any data giving hourly values for gastric acidity in patients on unmodified Sippy management. The present study has been undertaken to determine how often the unmodified regimen will bring about complete neutralization.

METHOD OF STUDY

A representative group of 55 patients with peptic ulcer has been studied. Forty-six were suffering from duodenal and nine from gastric ulcers. Their ages varied from 20 to 70 years, the average age for the entire group being 44 years. Forty-eight were males and seven females. All of the patients were having symptoms of peptic ulcer at the time of entrance into the hospital. All but one showed a typical deformity with the roentgen-ray, and in most instances, a crater was demonstrated fluoroscopically. The one exception had such a typical history that the diagnosis of peptic ulcer seemed definite in spite of the negative roentgenographic studies. Because the number of gastric ulcers is small, we did not include them in our data. However, the findings in these patients were similar to those obtained in cases of duodenal ulcers.

No postoperative cases were used because of the difficulty encountered in determining the site of the tube in the stomach. Furthermore, it was thought that the data obtained on postoperative stomachs might be misleading in so far as the purposes of this study are concerned.

Patients were placed on the routine treatment as outlined by Sippy. They were started on 90 c.c. of equal parts of whole milk and 20 per cent cream on the hour, from 7 a.m. to 7 p.m. They were given a powder consisting of calcium carbonate (0.6 gm.) and sodium bicarbonate (2.0 gm.)

on the half hour. This procedure will be referred to in the remainder of the paper as the "first day Sippy." Increasing amounts of food were given in the succeeding days so that by the seventh day, patients were also receiving six small feedings of soft eggs, cereals, toast, crackers, butter, and jellies at two hour intervals. Studies were made on the first or second day after the patient was taking all six feedings. This period of study will be later referred to as the "seventh day Sippy." Two weeks later the diet was changed to the so-called "fourth week Sippy." Three small meals were substituted for the six feedings. Milk and cream and powders were continued as before. These meals included a wide variety of foods, although all vegetables and fruits were either strained or pureed. Relishes and highly seasoned food were forbidden. The patients were allowed out of bed and were encouraged to engage in as much activity as ward life would permit.

The patients were studied on the "first day," "seventh day," and "fourth week" periods. Because many physicians have disapproved of giving the amounts of alkali required by the Sippy regimen on the grounds that it tends to increase the production of hydrochloric acid and, therefore, defeats the purpose of the treatment, as well as producing alkalosis on occasion, we have also determined the effect of taking milk and cream without powders. Unless the patients were extremely ill, this procedure was carried out before the Sippy regimen was begun. This was done to avoid the possible cumulative effect of previous alkalis on the gastric response.

The routine on the days of study was as follows: a Levine tube was passed at 7 a.m. and the total fasting secretion was removed. Five c.c. specimens were withdrawn at intervals of 30 minutes throughout the day, just prior to the administration of milk or powders. The specimens were examined promptly after removal. It was found that the presence of bile could be traced in most instances to one of two causes. Either the tip of the tube had slipped into the duodenum, or bile had been regurgitated as a result of nausea and retching. We, therefore, discarded all those specimens which contained bile, although in some instances this may have been the result of normal regurgitation from the duodenum. However, it seemed that this rule would result in more accurate data.

All specimens were analyzed in the usual manner for free and total acidity, using Topffer's reagent and 1 per cent alcoholic phenolphthalein respectively. One observer (P. H. W.) performed all the titrations with tenth normal sodium hydroxide, and the results are expressed in the number of c.c. of a decinormal solution of sodium hydroxide required to neutralize 100 c.c. of gastric juice. (Clinical units.)

DATA AND DISCUSSION

Chart 1 shows the results of 30 determinations made when the patients were taking milk and cream, and 46 determinations on patients taking the "first day Sippy." The free acidity was somewhat higher with only

milk and cream (an average of two clinical units) than if the alkaline powders were added. A comparison of the curves obtained on patients taking only milk and cream with those obtained when patients were taking the "seventh day" and "fourth week" management (charts 2 and 3) shows

CHART 1 Free and total acidity curves on 30 patients who were given hourly feedings of milk and cream (A and A') and on 46 patients who, in addition to the milk and cream, were given calcium carbonate 0.6 gm and sodium bicarbonate 2.0 gm and on the half-hour, the first day Sippy regimen (B and B')

that, at no time, did the giving of alkali increase the amount of free acid present

Chart 2 compares the results of the "first" and the "seventh day" diets. The free acidity in the latter was distinctly lower. It was zero part

of the time and only on a few occasions rose above four. This drop in the free acidity was probably due to the longer period of rest (often two weeks), the combining power of the food for acid, and the ease with which these soft

CHART 2 Free and total acidity curves of 46 patients who were given the first day Sippy regimen (B and B') and 14 patients taking the seventh day Sippy regimen (A and A')

foods passed from the stomach. That an increase in the amount of acid was present may be seen by the total acid curve.

Chart 3 shows that the average free acidity was distinctly higher in the "fourth week" than on the "seventh day," and was somewhat higher than on the "first day Sippy." This increase in the free acidity accompanies greater activity on the part of the patient as well as the wider variety of

foods Because Sippy recognized this fact, he included the "fourth week" in his regimen, thus enabling him to overcome any higher values of acidity by changing the size of the powders The curve for the total acidity was much the same as on the "seventh day"

CHART 3 Free and total acidity curves on 14 patients on the seventh day Sippy regimen (A and A') and 14 patients on the fourth week Sippy regimen (B and B')

Although control of the free acidity is presumably the important factor of the Sippy treatment, the values for the total acidity have been given on the charts. It is seen that the total acidity was the same in all instances except on the first day that alkaline powders were instituted, where the readings average 14 points lower. This may be seen on chart 1. Because of the relatively large amount of data accumulated, we thought it might be

interesting to calculate the effectiveness of the alkalis, using the total acid determination as a basis without considering the free acid. Thus, if we assume that the stomach secretes approximately 1500 c c of juice daily, or about 50 c c per hour, with a total acid value of 150 clinical units, the hourly secretion of hydrochloric acid will be 7.5 milli-equivalents (274 mg). The amount of sodium bicarbonate required to neutralize this amount of acid can be calculated as 630 mg. Actually the average value for total acid was lower by only 14 clinical units on the days of alkali administration than on control days with only milk and cream (Chart 1). This is a difference of 0.7 meq of acid hourly, while the alkali given amounted to 35.0 meq hourly. In other words, on the average, 50 times more alkali was given than was actually used for purposes of neutralization. However, it may be maintained that the hourly secretion rate is higher where ulcers are found. Assuming, then, a secreting rate of 100 c c per hour, we still find that 25 times more alkali was used than should have been necessary in the neutralization process. These average values, however, are perhaps misleading since a wide variation in effectiveness was encountered as may be noted from table 1. But it seems clear that the majority of patients require amounts of alkali greatly in excess of that which is needed to neutralize the maximum amount of acid, which we believe the stomach to be capable of secreting.

There are two explanations for the fact that the amount of alkali required is much larger than the theoretical value calculated from the estimated rate of gastric secretion. The alkali may induce a more rapid emptying of the stomach, or may stimulate gastric secretion. Both possibilities should be considered. It seems probable, however, that rapid emptying is the more important.

Since these charts did not show the effect of the treatment on individual cases, table 1 has been included. The patients were divided into four groups as follows. Group 1 shows the percentage of cases which were completely controlled, i.e., those exhibiting no free acid during the day of the test, Group 2 includes those patients whose acidity never went above 10, Group 3 includes those patients whose acidity occasionally went above 10, but never

TABLE I

Showing the Relative Percentages of Effectiveness of Milk and Cream and Various Stages of the Sippy Treatment on the Gastric Acidity

Group	Gastric Acidity in Terms of 0.1N NaOH	Per cent of Cases			
		Milk and Cream	First Day Sippy	Seventh Day Sippy	Fourth Week Sippy
1	No free acidity	7%	10%	14%	71%
2	No reading over 10	10%	13%	7%	71%
3	No reading over 20	16.6%	13%	35.7%	28.5%
4	One or more readings over 20	66.6%	63%	42.8%	57%

over 20, and, Group 4, those patients whose acidity was above 20 on at least one occasion. The table shows again that the best results were obtained on the "seventh day" and that in general, the results on the "fourth week" were similar to the "first day."

We have classified as adequately controlled (1) those showing no free acid, (2) those showing free acid (below 20 clinical units) on not more than three occasions, provided the acidity did not occur in consecutive specimens, and (3) those having readings above 20 on one occasion but completely controlled the rest of the time. On this basis, 54 per cent were adequately controlled on the "first day," 71 per cent on the "seventh day," and 57 per cent on the "fourth week Sippy." These figures indicate that only a little more than one-half of the patients were controlled without any attempt being made to vary the size of the powders. Sippy recognized the importance of individual variations, for he states, "Control of the free hydrochloric acid should be maintained from the beginning," and he adds later, "It should be understood, however, that the presence of free hydrochloric acid now and then for a few minutes each day may not seriously interfere with the healing of the ulcer."

Since it would be of value to know before treatment is instituted in which patients adequate control can be expected, we tried to correlate the results of treatment with the fractional gastric analyses that were performed in all cases before the patient was placed on treatment. Fifty cc of 8 per cent alcohol were used as a test meal. The number of patients that were adequately controlled was then compared with the results of the gastric analyses, using the highest reading of the free acidity as the index. Adequate control occurred in all patients whose free acidity did not go above 20 at the time of the analysis. For those patients in whom the acid went above 20, the number of those adequately controlled fell markedly. It seemed to make little difference how far above 20 the acidity went. Fifty per cent of those patients whose acidity fell between 20 to 40 were controlled, 64 per cent of those between 40 to 60, and 65 per cent of those above 60. Since the number of cases in which the acidity remains below 20 is small, gastric analyses are of little aid in determining which patients will be controlled by the regimen. An attempt to use the average for all determinations of the gastric analysis as an index was found to be even less satisfactory.

We are unable to say what effect the continuous presence of the tube in the stomach may have had on these values. It is probable that the annoyance and discomfort, which the presence of the tube entails, would decrease the gastric response.

The treatment, as used, abolished all symptoms in all patients, usually by the second day and without exception by the fourth day. There appeared to be little difference in the clinical response of those patients in whom the acid was satisfactorily controlled as compared with those in whom adequate neutralization was not obtained. The present series is too small to permit an accurate estimate of the relationship between symptomatic relief

and effectiveness of acid neutralization, and we do not wish to enter upon that controversy at present. We can only say that in the present series no such relationship was apparent. The slight difference between the acid values on milk and cream alone and those when alkalis were added is significant in this connection, our data indicate that the addition of alkali to hourly milk and cream feedings produces but little decrease in free acid. This phase of the problem should be studied further.

We feel that the results here presented are helpful in understanding what is accomplished by alkali therapy in ulcer. Because the control was not absolute in all cases, we should not question the large amount of clinical experience which has demonstrated the effectiveness of alkali therapy in peptic ulcer.³ It does suggest that a more efficient regimen might be developed, and emphasizes that each patient should be considered individually.

SUMMARY

1 Forty-six patients with duodenal ulcer received the routine Sippy treatment. Specimens of gastric contents were removed every half hour from 7 a m to 7 p m and the free and total acid determined when only milk and cream were given and on days corresponding to the "first day," "seventh day," and "fourth week" procedures of Sippy.

2 The treatment given abolished symptoms in all cases.

3 The free acidity was adequately controlled in more than one-half of the patients, even though no variations were made in the amount of alkali given.

4 The data show that if the free acidity does not rise above 20 after an alcohol test meal, the patient will obtain adequate control by this treatment. There seem to be no criteria to determine which patients will be controlled in the larger group whose free acidity goes above 20 following an alcohol test meal.

5 Calculations suggest that 25 to 50 times more alkali was given than should be necessary theoretically.

6 If a routine treatment is used, one can be assured of complete neutralization only if frequent aspirations are performed.

THE VALUE OF A MIXTURE OF POWDERED MILK AND ALKALI FOR NEUTRALIZING THE GASTRIC ACIDITY OF PATIENTS WITH PEPTIC ULCER *

By PAUL H WOSIKA, M D , *Chicago, Illinois*, and EDWARD S EMERY, JR , M D , *Boston, Massachusetts*

SINCE Sippy introduced his method of treating patients affected with peptic ulcer, there has been no unanimity of opinion among the medical profession concerning its therapeutic value. Those who oppose the treatment do so largely on the ground that large amounts of alkali are contraindicated, and that the results do not justify the time and trouble which the treatment entails. Its enthusiastic advocates maintain that complete neutralization of the gastric contents can be obtained if the treatment is carried out properly and that better results will follow this therapy. They argue that the poor results claimed for the therapy by others follow a failure to administer the treatment properly.

Recent studies of the disease teach us that the important essentials of treatment consist of control of the gastric acidity and of debilitating influences such as fatigue, emotion and infection. The best form of treatment will control these factors, and the Sippy therapy is suited best for neutralization of the gastric contents. Unfortunately the frequent feedings, which are the only sure way to obtain neutralization, constitute in the opinion of all a serious objection to this mode of treatment. Patients dislike the bother of taking something every half hour and in many instances will not follow the regimen carefully or thoroughly enough to accomplish its purpose. To meet this objection many physicians are prone to introduce so-called modifications which so alter the efficacy of the treatment as to do away with whatever advantages it may possess over other therapeutic procedures. These modifications appear justified because frequently they will relieve symptoms as quickly and completely as Sippy's published regimen. But early relief from pain is a disadvantage, if it misleads the patient and physician into a false idea that healing is taking place with the result that other important aspects of treatment are ignored. Hence one must condemn modifications whose sole object is to provide relief. But a modification that will retain the value of the Sippy treatment and at the same time eliminate many feedings will be a distinct advantage. We are therefore suggesting a modification which seems to fulfill these requirements.

In the spring of 1933 one of our patients inquired about the justification of adding the prescribed Sippy powders to his milk. He believed that this procedure gave him a longer period of relief and that he did not require

From the Medical Clinic of the Peter Bent Brigham Hospital. The expenses of this study were defrayed by the Upjohn Company.

medication every half hour. Therefore, we decided to investigate the effect of powdered milk on the gastric juice, for, if this could be substituted for whole milk and cream, it would be a simple way for a patient to take an alkalinized milk product. This paper compares the effect on the gastric acidity of an alkalinized powdered milk with the effect of a routine Sippy regimen.

METHOD OF STUDY AND DATA

We have already prepared a detailed account of the method of investigation¹. To summarize it, we studied 46 patients with duodenal ulcer. A stomach tube was passed in the morning and allowed to remain in the stomach for 12 hours while 5 c c of gastric contents were withdrawn every half hour. One observer (P H W) performed all titrations for the free and total acidity in the usual manner, using Topffer's and 1 per cent phenolphthalein solutions as indicators. The patients were studied at various stages of the routine Sippy regimen—namely, the first day, seventh day, and fourth week. We also investigated the effect of milk and cream without powders. Next we determined the effect on the same patients of a commercial preparation of powdered milk. For this purpose we used 12.5 gm of "Klim" or "Parlac" mixed with 90 c c of water. According to the formula given for these products, patients received from 12.5 gm of the product approximately 4.75 gm of carbohydrate, 3.33 gm of protein, 3.5 gm of fat, with a total caloric value of 64. Ninety c c of the mixture of milk and cream ordinarily used in the Sippy treatment contain 4.27 gm of carbohydrate, 2.6 gm of protein and 10.12 gm of fat, with a total caloric value of 118.56. The commercial preparation afforded 22.1 per cent more protein, 65.5 per cent less fat, and about half as many calories.

The effect on the gastric acidity of using 90 c c of whole milk and cream is compared in chart 1 with the effect of 12.5 gm of powdered milk. The chart shows that the results are quite similar with both preparations, although with the powdered milk, the free acidity drops toward the end of the day to a level slightly below that obtained with whole milk and cream. The total acidity was much the same in both instances. These figures convinced us that 12.5 gm of powdered milk controlled the gastric acidity as successfully as 90 c c of milk and cream.

The next step was to compare the effect of an alkalinized powdered milk with the usual Sippy treatment. Therefore, we mixed 0.6 gm of calcium carbonate and 2 gm of sodium bicarbonate (the dose with which Sippy initiated treatment) with the 12.5 gm of powdered milk, and the entire mixture was given to the patient in 90 c c of water. This was repeated every hour. This method, if successful, would decrease the number of medications from approximately 29 to 14.

The results of this procedure, as compared to those with the routine Sippy, are shown in charts 2, 3, and 4. Chart 2 shows the average of 46 determinations on the first day Sippy. Water was allowed in small quanti-

CHART 1 Shows the average free and total acid curves of plain powdered milk (12.5 gm) (solid line) on 28 patients, compared with milk and cream (90 cc) (broken line) on 30 patients

CHART 2 Shows the average free and total acid curves of alkalinized powdered milk (125 gm plus one Sippy powder) (solid line) on 45 patients compared with the routine first day Sippy (broken line) on 46 patients

CHART 3 Shows the average free and total acid curves on the routine seventh day Sippy (broken line) on 14 patients, compared to hourly alkalized powdered milk and 6 small feedings (solid line) on 17 patients

CHART 4 Shows the average free and total acid curves on the routine fourth week Sippy (broken line) on 14 patients, compared with the same feedings but using alkalinized powdered milk (solid line) on 17 patients

ties, usually in the form of cracked ice in addition to the milk and alkalis. The free acidity remained low under both methods. The curve for total acidity was the same whether whole milk and cream or powdered milk was used. It is interesting to note that the total acidity was less when no alkali was given (compare with chart 1)

CHART 5 Shows the percentage of patients who had no free acid using powdered milk (solid line) on 28 patients and milk and cream (broken line) on 30 patients for half hour periods in 12 hours

Chart 3 shows the effect of both treatments on the seventh day, at which time the patients were receiving six small feedings in addition to the milk and alkalis. Observations were made on 14 patients who were receiving whole milk and cream with powders on the half hour, and 17 patients who were taking the alkalinized milk powder. The curves for both free and total acidity are virtually identical. The total acidity has again risen to the same level that existed before alkalis were started.

The results obtained on patients in the fourth week of treatment are shown in chart 4. The patients were receiving the same kind of treatment as on the seventh day, with the exception that the six feedings had been changed to three meals. They were encouraged to be up and around the wards in order to approximate as closely as possible the conditions under which they would live after leaving the hospital. The chart shows that

CHART 6 Shows the percentage of patients who had no free acid when alkalinized powdered milk (solid line) was used on 45 cases and the routine first day Sippy (broken line) was used on 46 patients

hourly feedings of alkalinized milk powder controlled the gastric acidity about as well as whole milk and cream with powders given on the half hour.

Although these charts show the average effect on all the patients by the milk and powders and alkalinized powdered milk, they give no clue as to the effect on the individual patient. Therefore, charts 5, 6, 7, and 8 are included to show the percentage of patients who showed no free acid for each half hour throughout the day. It is seen that the alkalinized powdered milk reduced the gastric acidity to zero in a much higher percentage of instances than the routine Sippy treatment.

In our previous report we discussed the efficacy of the routine Sippy procedure in producing adequate control of the gastric acidity. Included as being adequately controlled were (1) Patients whose gastric contents never showed free acid during the 12 hours of observation (2) Patients in whom the gastric contents showed free acidity of not more than 20 and was not found on more than three occasions provided this finding did not occur in consecutive specimens (3) Patients in whom the gastric contents

CHART 7 Shows the percentage of patients who had no free acid using alkalized powdered milk plus 6 additional feedings (solid line) on 17 patients and the routine seventh Sippy (broken line) on 14 patients

showed a reading above 20 on one occasion, but were completely controlled the rest of the time

This classification gives us a means of comparing the efficacy of the routine Sippy treatment with the alkalized powdered milk. Table 1 shows that 90 c c of milk and cream and powdered milk without alkali were equally efficacious. Milk and cream adequately controlled 47 per cent of the patients, compared to 50 per cent on powdered milk. However, when alkalies were added, the alkalized powdered milk gave much more satisfactory results. On the first day, 75 per cent were adequately controlled with

alkalinized powdered milk to 54 per cent by the routine Sippy. On the seventh day, the figures were 94.1 per cent by alkalinized powdered milk to 71 per cent by the routine Sippy, and on the fourth week, 94.1 per cent to 57 per cent.

CHART 8 Shows the percentage of patients who had no free acid using alkalinized powdered milk and three meals (solid line) on 17 patients and the routine fourth week Sippy (broken line) on 14 patients

DISCUSSION

These results were more satisfactory than we had expected. The most we had hoped for was a method which would simplify the treatment of the patient without sacrificing its efficiency. According to the present observations, the method is even more efficient as a means of neutralization than the usual procedure.

We have no data that explain the greater efficiency which the alkalinized powdered milk seems to possess. A greater dilution would lower the titratable acidity, but even less fluid was given by this method than the ordinary Sippy. It is hard to estimate what effect a difference in flavor might have. Most of the patients enjoyed the whole milk and cream better than the powdered milk. This became more pronounced when the patients

TABLE I

Showing the comparative results of milk and cream and routine Sippy procedures with powdered milk with similar feedings expressed in per cent Although the number of medications is one-half when powdered milk is used, the percentage of adequately controlled patients is seen to be higher

Group	Classification of Patients by Amounts of Free Acid Present	Procedure with Milk and Cream	Procedure with Powdered Milk
		Percentage control of 30 patients using milk and cream without alkalis	Percentage control of 28 patients using powdered milk without alkalis

1	No free acid	7 1	47
2	No reading over 10	7 1	23 5
3	No reading over 20	28 5	5 9
4	One reading over 20	57	23 5
	Adequate control	57	94 1

knew that it was powdered milk. However, it does have a flatter taste. A smaller "appetite secretion" might, therefore, result. On the other hand, the addition of three meals a day, which the patient received on the "fourth week" diet, not only failed to increase the amount of free acidity, but the patients were controlled more completely. The failure of the usual foods

to stimulate a greater secretion of acid argues somewhat against the idea that the "appetite secretion" made much difference. The greater amount of protein in the powdered milk should decrease the amount of free acid by increasing the amount of neutralization. As already pointed out, the powdered milk provided about one-fifth more protein than the milk and cream. It was also noted that the milk curds obtained in the samples were smaller with the powdered milk than with the whole milk. This suggests, of course, that the protein in the powdered milk could neutralize the acid more effectively.

Another observation makes us feel that the increased amount of protein is an important factor in the greater degree of neutralization. If we increased the amount of milk powder to patients whose acidity was not entirely neutralized by the 12.5 gm. dose, there resulted an increased degree of neutralization comparable to the greater effectiveness which seemed to exist with the alkalinized powdered milk over the ordinary Sippy. This difference could not be explained by the difference in "appetite secretion." Therefore, we feel that even though a difference in flavor may play some rôle, the alkalinized milk powder is more effective as a neutralizing agent.

This method of treatment has certain practical advantages. Mixing the dried milk with the alkaline powders overcomes the necessity of a patient carrying both fresh milk and powders. It also decreases the number of medications by one half, which is a distinct advantage to the patient who works. Finally, it costs somewhat less than if equal parts of whole milk and 20 per cent cream are taken, provided a non-advertised brand of powdered milk is purchased.

Among its disadvantages may be listed the taste, which is not pleasant to one unaccustomed to it. However, the taste is largely a matter of habit, and patients will overcome this objection in a short time. Moreover, a failure to stimulate secretion by the absence of flavor really is an advantage. The fewer number of calories which the powdered milk supplies can be taken care of easily by increasing the other simple foods allowed in the diet. Its greatest disadvantage is the difficulty of mixing the powder with the water. It tends to adhere to the glass and requires much stirring to obtain a smooth mixture. But we hope to circumvent this disadvantage by having the mixture made into tablets.

We do not wish to suggest this treatment as a substitute for the Sippy regimen, the object of which is to neutralize adequately the gastric acidity of every patient with ulcer. A physician can be sure of adequate neutralization only if he performs frequent aspirations and increases the amount of alkali to those patients who require it. No method of therapy which utilizes a fixed amount of milk and cream and alkali can be expected to neutralize completely the gastric juice of all patients. We feel that this method is a distinct advantage for those physicians who utilize the routine Sippy treatment, but for one reason or another do not attempt to secure complete neutralization.

More recent studies demonstrate that complete neutralization is not an essential requirement for healing. Many ulcers heal spontaneously in the normal course of events without any treatment. Those experiments which incriminate the acid as a cause of ulcers depend upon the prevention of all neutralization by duodenal regurgitation, which suggests that the development of an ulcer may follow from an interference with this normal means for regulating the acidity. The use of an alkalized milk powder at hourly intervals should neutralize the gastric acidity as effectively as duodenal regurgitation. Continued use of such a regimen should, therefore, regulate the stomach contents in such a way as to prevent the development of unusual degrees of acidity. The change in the incidence of feeding from half hourly to hourly intervals will permit a much larger group of individuals to carry out this simplified regimen.

SUMMARY

It has been found that 12.5 gm. of a preparation of powdered milk mixed with the usual Sippy powder containing 0.6 gm. of calcium carbonate and 2.0 gm. of sodium bicarbonate, and given at intervals of one hour, are somewhat more effective in neutralizing the gastric acidity than 90 cc. of milk and cream and the same powder given in the usual way advised by Sippy.

STUDIES IN HYPERTENSION; A PROPOSED CLASSIFICATION OF HYPERTENSION BASED UPON THE NITROGEN DISTRIBUTION OF THE SERUM PROTEINS *

By HENRY A RAISKY, F A C P, ADOLPH BERNHARD, and GEORGE L ROHDENBURG, *New York, N Y*

IN a previous publication¹ we reported that experimental hypertension in rabbits produced by the injection of a mono-amino acid (aspartic acid) is associated with definite alterations in the nitrogen distribution of the serum proteins. These changes are an increase in the mono-amino nitrogen and a decrease in the basic amino nitrogen with a resultant change in the ratio between these two fractions (referred to as the M/B ratio). We have noted in further studies similar changes in the nitrogen distribution of the serum proteins in hypertension in man. Since these changes offer a basis for the classification of hypertension, the results of this investigation are reported in this paper.

Methods The blood pressure readings were obtained either with the sphygmotonomograph or a mercury manometer. The procedure for taking the blood specimens, the separation of the serum proteins and the technical methods for the analysis of the blood protein fractions have been described in detail elsewhere². The amide and humin nitrogen were both removed before the other fractions were determined, consequently, they are of no significance in the present discussion.

EXPERIMENTAL RESULTS

Normal Values Table 1 shows the nitrogen distribution of the serum proteins in a group of 20 normal adults, most of whom were hospital interns between 21 and 30 years of age, the average being 26 years. The systolic blood pressure varied between 104 and 135, the average pressure being 117. The diastolic pressure ranged between 50 and 95, with an average of 76. The pulse pressure varied between 28 and 56, with an average of 41. All of the group were free from renal, cardiac, and metabolic disturbances.

In this group the total nitrogen varied between 420 and 700, with an average of 532 mg per 100 c c blood. The basic amino nitrogen varied between 100 and 190, with an average of 140 mg. In only one instance was it as low as 100 mg, while in 15 cases it ranged between 110 and 150 mg. This fraction represents 23 to 40 per cent of the total nitrogen after hydrolysis, with an average of 28 per cent. The lowest mono-amino nitrogen value was 190 mg, the highest 330 mg, and the average 269 mg. It

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono-amino nitrogen to the basic amino nitrogen

was between 200 and 300 mg in 13 cases (65 per cent) and in 6 cases (30 per cent) between 300 and 330. The mono-amino nitrogen expressed as percentage of the total nitrogen after hydrolysis varied between 40 and 69, with an average of 54. The M/B ratio varied between 1.0 and 2.3, with an average of 1.9. The ratio in one case was 1.0, in 6 cases (30 per cent) between 1.1 and 1.9, and in 13 cases (65 per cent) between 2.0 and 2.3.

Control Cases without Hypertension Table 2 records the nitrogen distribution in 11 individuals who, while not normal, suffered from conditions in which hypertension was not a factor, four were cases of cardiac disease, three of diabetes and one each of tetany, carcinoma of the rectum, and hemiplegia. The ages of this group varied between 29 and 81 years and the blood pressure between 105 systolic and 70 diastolic and 140 systolic and 70 diastolic. The basic amino nitrogen was slightly lower, while the mono-amino nitrogen values approximated those of the normal group. The

TABLE II

Nitrogen Distribution of Serum Proteins in Miscellaneous Disease Conditions without Hypertension

Case	Age	Blood Pressure	Total Nitrogen	Total Nitrogen* after Hydrolysis	Basic Amino Nitrogen	Percentage of Total Nitrogen after Hydrolysis	Total Nitrogen of the Phosphotungstic Acid Filtrate	Mono-Amino Nitrogen	Percentage of Total Nitrogen after Hydrolysis	M/B Ratio

Pulse Pressure High 70, Low 35, Average 50

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono-amino nitrogen to the basic amino nitrogen

M/B ratio was slightly higher than normal, being in 10 cases (91 per cent) between 1.0 and 2.9

NITROGEN DISTRIBUTION IN HYPERTENSION

In experimental hypertension, as previously stated, the changes in the nitrogen distribution of the serum proteins are in (a) the basic amino nitrogen, (b) the mono-amino nitrogen, or (c) in both. In hypertension in man similar changes have been found and the cases grouped accordingly.

Group A Hypertension with a lowered basic amino nitrogen, an increased mono-amino nitrogen, and an increased M/B ratio.

The data in a series of 18 cases showing a change in both nitrogen fractions are given in table 3. The ages of the individuals varied between 24 and 77 years, with an average of 56. The range of the systolic blood pressure varied between 165 and 286, with an average of 208, and the diastolic pressure varied from 70 to 142, with an average of 101. The pulse pressure varied between 65 and 200, with an average of 106.

The basic amino nitrogen varied between 60 and 90 mg with an average of 75 mg and formed between 10 and 21 per cent with an average of 15 per cent of the total nitrogen after hydrolysis. The mono-amino nitrogen ranged between 330 and 590 mg with an average of 462 mg. This fraction forms between 73 and 100 per cent with an average of 83 per cent of the total nitrogen after hydrolysis. The M/B ratio was the highest obtained of all the cases of hypertension studied, varying between 3.6 and 9.8 with an

average of 57. A comparison of the data obtained in this group with that of the normals shows a definite alteration in the nitrogen distribution.

One exception was encountered. Case 55, a male aged 42 years, with blood pressure of 128 systolic and 60 diastolic, whose nitrogen distribution was similar to that observed in the cases of hypertension. This individual had a neurosis and was considerably overweight. The urine was negative and there was no evidence of nitrogen retention in the blood. The blood

Pulse Pressure for hypertensive cases: High 200, Low 65, Average 106

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono amino nitrogen to the basic amino nitrogen

serum cholesterol was 145 mg per 100 c c and the basal metabolic rate was plus 14 per cent. There was no previous history of hypertension.

Group B Hypertension with a decrease in the basic amino nitrogen and no changes in the mono-amino nitrogen.

The data of the examinations in the 14 cases comprising this group are given in table 4. The age of the patients varied between 22 and 83 with an average of 62 years. The systolic blood pressure varied between 150 and 230 with an average of 180, while the diastolic pressure varied between 80 and 120 with an average of 100. The pulse pressure range was between 50

and 120 with an average of 81. The basic amino nitrogen values varied between 70 and 90, with an average of 84 mg, thus, this fraction varied between 13 per cent and 25 per cent with an average of 19 per cent of the total nitrogen after hydrolysis. The values for the basic amino nitrogen and the percentage of the total nitrogen after hydrolysis were slightly higher than those in group A.

While the mono-amino nitrogen values were within normal limits, the per cent this fraction formed of the total nitrogen after hydrolysis is lower

Pulse Pressure High 120, Low 50, Average 81

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono-amino nitrogen to the basic amino nitrogen

than those of group A, but higher than the normal group. The actual values varied between 220 and 310 mg with an average of 281 mg. The M/B ratio varied between 2.4 and 4.4 with an average of 3.4. These values, while not as high as those in group A, are increased over the normal.

Group C Hypertension in which there is an increase in the mono-amino nitrogen fraction only.

The largest number of our hypertensive cases are those in which there was a rise in the mono-amino nitrogen only. The data of these cases are

given in table 5 The group comprises 32 cases, the ages ranging between 26 and 87 with an average of 56 years The systolic blood pressure varied

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono-amino nitrogen to the basic amino nitrogen

between 152 and 250 with an average of 193, and the diastolic pressure varied between 50 and 160 with an average of 103 The pulse pressure ranged between 56 and 120 with an average of 89 The basic amino nitro-

gen varied between 100 and 190 with an average of 123 mg and formed from 13 per cent to 32 per cent with an average of 22 per cent of the total nitrogen after hydrolysis. The mono-amino nitrogen fraction varied between 330 and 750 mg with an average of 428 mg, as compared with an average of 269 mg for the normal group. This fraction represents between 64 per cent and 88 per cent of the total nitrogen after hydrolysis with an average of 75 per cent as compared with an average of 54 per cent obtained for the normal group. The M/B ratio varied between 2.0 and 6.8 with an average of 3.5 as compared with an average of 1.9 for the normal group.

Exceptions. There were seven individuals with normal blood pressure whose nitrogen distribution showed an increase in the mono-amino nitrogen fraction. Among these were three cases from which the spleen had been removed, and one each of pernicious anemia, abscess of the liver complicated with acute uremia, hypertrophied prostate, and Hodgkin's disease. The mono-amino nitrogen values of these nonhypertensive cases varied between 360 and 510 mg with an average of 354 mg. The M/B ratio varied between 2.1 and 4.2 with an average of 3.1.

Group D. Hypertension with normal nitrogen distribution.

In table 6 are given the data on 12 cases of hypertension in which there were no significant changes from the normal in the nitrogen distribution of

Pulse Pressure High 135, Low 35, Average 96

* After the removal of humin and amide nitrogen

The M/B ratio means the ratio of the mono amino nitrogen to the basic amino nitrogen

the serum proteins. The systolic blood pressure of this group varied between 117 and 252 with an average of 191, the diastolic pressure between 70 and 190 the average being 94, while the pulse pressure varied between 35 and 135 with an average of 96.

DISCUSSION

In 84 per cent of the cases of hypertension which we have studied there were definite changes in the nitrogen distribution of the serum proteins. When either the basic amino or mono-amino nitrogen fractions were altered, the degree of hypertension was about the same as determined by the averaged systolic and pulse pressures. These averaged pressures, however, were higher when both nitrogen fractions were involved in the change. This suggests some correlation between the degree of hypertension and the nitrogen distribution, although the exact relationship cannot be stated at the present time. From the results of animal experimentation,¹ hypertension seems to precede changes in the M/B ratio.

Although the majority of the cases of hypertension showed a change in the nitrogen distribution, there were 12 cases in which no change was demonstrable. In most of these exceptions the dominant clinical complaint was that of atherosclerosis rather than hypertension. In other hypertensive individuals in whom alterations in the M/B ratio was observed, atherosclerosis was not the dominant clinical complaint.

In previous work¹ an extensive fibrosis of the spleen was noted in animals suffering from aspartic acid induced hypertension, and it was pointed out that fibrotic changes also occurred in the spleen of human cases suffering during life with hypertension. It is interesting to note in the light of these observations that in five of the seven nonhypertensive cases exhibiting an altered nitrogen distribution, disturbances in the reticulo-endothelial system were evident. In three of these cases the capacity of the reticulo-endothelial system was greatly reduced by removal of the spleen, another suffered from pernicious anemia, a condition in which the spleen shows marked fibrotic changes, and the fifth from Hodgkin's disease which broadly considered is a lesion of the reticulo-endothelial system. These changes which occurred in (a) the spleens of hypertensive animals, (b) the spleens of human cases dying of hypertension and (c) in the reticulo-endothelial system of non-hypertensive cases suggests that the reticulo-endothelial system or the spleen plays a rôle in maintaining the M/B ratio at a normal level.

In the cases of hypertension with a low basic amino nitrogen, there was little or no evidence of nephritis. A review of the clinical aspects of the cases of hypertension having increased mono-amino nitrogen showed in the greater majority of the patients a mild degree of nephritis without retention of the non-protein nitrogenous constituents. Four of the cases, however, showed slight nitrogen retention. In the group of hypertensive cases in which both nitrogenous fractions deviated from the normal, there was us-

ually evidence of a marked nephritis with nitrogen retention in the blood to a varying degree

On the basis of the chemical and clinical studies in the group of hypertensive cases reported in this paper, the following classifications appear possible

Class 1 Hypertensive individuals whose blood serum proteins showed a decreased basic amino nitrogen and an increased mono-amino nitrogen. This group showed evidence of a severe nephritis with moderate non-protein nitrogen retention in the blood which occasionally was severe

Class 2 Cases of hypertension in which the blood serum proteins showed a low basic amino nitrogen, no change in the mono-amino nitrogen fraction and little or no evidence of nephritis

Class 3 Cases of hypertension in which only the mono-amino nitrogen fraction of the blood serum proteins was increased. This group showed a moderate nephritis, occasional nitrogen retention, with little or no evidence of arteriosclerosis

Class 4 Cases of hypertension in which the basic amino and mono-amino nitrogen fractions were within normal limits. These cases showed arteriosclerotic changes and symptoms. This group did or did not have evidence of kidney impairment

On the basis of the classifications outlined above, one might readily speculate both as to the etiology of hypertension and as to therapeutic possibilities. It might be that the changes noted in the nitrogen distribution are due to a functional disturbance of the reticulo-endothelial system. Organotherapy of the reticulo-endothelial system might prove to be of therapeutic benefit alone, or in combination with dietary changes. It is possible that the hypertension might disappear if the ratio between these two nitrogen fractions could be restored to normal by raising the basic amino nitrogen. In the animal experiments as reported elsewhere,¹ the mono-amino nitrogen values dropped when the injections of aspartic acid were discontinued and the blood pressure returned to normal. It is within the realm of possibility to raise the basic amino nitrogen values by suitable changes in the diet

CONCLUSIONS

1 Changes from the normal were observed in 84 per cent of 76 cases of hypertension in either the basic amino or mono-amino nitrogen fractions of the blood serum proteins or in both these fractions, the change in 23 per cent was in both fractions, in 18 per cent only the basic amino nitrogen was altered, in 42 per cent the mono-amino nitrogen alone was changed and in 15 per cent no change in either fraction was demonstrable

2 Based upon these chemical changes, a classification of cases of hypertension is proposed. The more exact details of the various groups are given in the body of the paper

SEDIMENTATION TIME IN ACUTE CARDIAC INFARCTION *

By CHARLES SHOOKHOFF, M D , ALBERT H DOUGLAS, M D , and MEYER A RABINOWITZ, M D , *Brooklyn, N Y*

IN 1931 the authors reported 10 cases of acute cardiac infarction secondary to coronary artery thrombosis in which the red blood cell sedimentation time was studied¹ Burak² subsequently reported a similar study, but the literature on the subject has, in general, been scant Singer³ and Wollheim⁴ have both mentioned the increased rapidity of red cell sedimentation rate as a diagnostic factor in coronary thrombosis Because the sedimentation time has frequently been of great help to us in the diagnosis and treatment of acute coronary thrombosis, we are reporting an additional series of cases studied during the past three years

METHOD

The sedimentation times were done according to the method of Linzenmeier⁵ Sixty minutes has been taken as the lower limit of normal, i e sedimentation more rapid than 60 minutes to the 18 mm mark is regarded as abnormal No corrections were made for variations in the red blood cell count, but this did not appear to make a serious difference in this series

Twenty-nine cases of acute coronary thrombosis were studied In all cases included in this series, the clinical diagnosis was confirmed by electrocardiography Of nine patients who died, five were autopsied, and an acute coronary thrombosis found Cases which had complicating disease which might influence the sedimentation rate were excluded

RESULTS

In *all* the cases studied the sedimentation time was abnormally rapid at some time during the course of the disease In all the cases but one, the rate was abnormally rapid by the fifth day In the one exception the figure did not go below 60 minutes until the second week, but even in this case a drop was apparent toward the end of the first week (Chart 1) In several cases the sedimentation time became abnormal as early as the second day (Chart 2) The earliest in this series at which the sedimentation time returned to normal was the thirteenth day, and the latest, the thirty-ninth day At times it was kept rapid over a rather long period by repeated thromboses (Charts 2 and 3)

In two cases the temperature and leukocyte count were normal throughout while the sedimentation time was definitely abnormal In most of the

DISCUSSION

Patients not infrequently present themselves with a history of an attack of angina pectoris occurring several days or even several weeks previously which arouses suspicion of a recent coronary artery thrombosis. The temperature and blood count are usually normal at this time, and the electrocardiogram may frequently be indefinite. It is in these cases that we have found the sedimentation time to be of great help, and where an electrocardiograph is not available, the increased sedimentation rate may be the only definite evidence of active cardiac muscle involvement.

Even where the diagnosis is clear, we believe it is of definite value to follow the sedimentation time. We have found it to be a sensitive indicator of subsequent thrombosis in the heart or elsewhere, or of embolus or infection. (Chart 5) It enables one, too, to estimate the rapidity of healing. At the present time there is no definite evidence that the rapidity of the sedimentation time is proportionate to the extent of the damage in the heart, but it seems justifiable to assume that while the determination is abnormal, active changes are taking place in the heart muscle. We believe that the sedimentation time makes less arbitrary the duration of bed rest for a particular case and that a patient with an acute coronary closure should be kept in bed at least until this determination has returned to normal. We wish to emphasize the importance of a careful search for infection or infarction outside the heart before a cardiac significance is attached to a rapid sedimentation rate.

CONCLUSIONS

1 The red blood cell sedimentation time was studied in 29 cases of acute cardiac infarction. It was abnormally rapid in all.

2 It became rapid between the second and fifth days and returned to normal between the thirteenth and thirty-ninth days.

3 An abnormal sedimentation rate may outlast the return of temperature and leukocyte count to normal by as much as four weeks. It may be abnormal when the temperature and leukocyte count have been normal throughout.

4 It is of great help in cases seen first several days or weeks after the occurrence of a cardiac infarction.

5 It helps in the recognition of subsequent thrombosis or infection.

6 It makes less arbitrary the duration of bed rest.

COMBINED MEDICAL AND SURGICAL MANAGEMENT OF PEPTIC ULCER, WITH EMPHASIS ON THE TREATMENT OF HEMORRHAGE *

By J W THOMPSON, M D , F A C S , and H W SOPER, M D , F A C P ,
St Louis, Missouri

THE first pre-requisite for an intelligent approach to the treatment of peptic ulcer by any method is an accurate conception of the pathologic changes in the gastroduodenal mucous membrane which are designated as "peptic ulcer" This term has been applied to all variations of pathologic changes from a simple erosion of the mucosa to a deep penetrating lesion with attachments to the neighboring viscera The confusion that exists in the general medical mind relative to peptic ulcer can be directly attributed to the fact that frequently the disputants have entirely different lesions in mind Then strangely enough the disease seems to vary in different races both in incidence and severity The Hebrew evidently is more prone to peptic ulcer and its complications than is the Aryan Walters and Snell,¹ who are quite familiar with the clinical and surgical manifestations of ulcer in the United States, observed that the central European nations present a different anatomico-pathologic picture from that seen in this country The Austrian peoples are more prone to multiple ulcerations combined with a severe chronic gastritis, whereas the lesion most often seen in America is a single localized area of inflammatory change with the remainder of the mucosa in an approximately normal state The important point then in any discussion of peptic ulcer is to so focus the attention that everyone has the identical pathologic process in mind

The experience of the authors has been chiefly comprised of patients from the middle western United States, most of whom have been of northern European origin but including a liberal number of Semitic descent Peptic ulcer in these peoples is usually confined in number to a single lesion and is more frequently situated in the duodenum than in the stomach It has been our observation that multiple ulceration when it occurs is more common in the duodenum

Therefore, for the purposes of this paper we will define peptic ulcer as solution in the continuity of the gastroduodenal mucosa, varying between lesions of minute size and confined superficially to the mucosa, and the larger, punched out, characteristic ulceration with a definite crater and a base that is comprised of scar tissue of variable extent These lesions may be multiple, especially in the duodenum, and have a distinct tendency to heal and recur periodically with an increasing deposit of cicatrix after each episode As the process advances, perforation through the walls of the stomach

* Read at Regional Meeting of the American College of Physicians, Springfield, Illinois, September 24, 1935 Received for publication October 7, 1935
From the Soper-Mills Clinic

or duodenum may take place, at times quite rapidly and in other instances over prolonged periods of time. During this process attachment to neighboring viscera or even perforation into them may occur.

The etiology of peptic ulcer still remains unproved. The experimental surgeons have presented evidence that ulcer is due to acid gastric secretions acting on the mucous membrane that lacks some neutralizing factor to adjust the fine physiologic balance between the secretions and enzymes of the digestive juices of the stomach, duodenum, pancreas and liver. Mann and Williamson² have produced experimentally so-called surgical duodenal diaphragm peptic ulcers in dogs that are indistinguishable histologically from those found in humans. Quite recently Bollman and Mann,³ corroborating the experiments of Von Wagoner and Churchill,⁴ have described ulcers produced in dogs by prolonged ingestion of the drug cinchophen. These ulcerations are likewise quite similar to those seen clinically.

The healing process in ulcer of the stomach and duodenum is an exact counterpart of that observed in varicose ulcer of the leg. The crater of the ulcer is gradually filled in with fibrin, and the epithelial edges proliferate toward the center, gradually closing the defect. Just as the varicose ulcer of the lower leg needs to be protected from traumatization of the delicate, tender, fragile, advancing margin of newly forming epithelium, so does the ulcer of the gastroduodenal mucosa need to be guarded. The slightest trauma will dislodge the plug of fibrin in the base of the crater, disrupting the newly forming glandular epithelium and leaving the base vulnerable to the acid gastric secretions. These points were admirably demonstrated in the experimental work of Mann⁵ presented at a recent Hodgen lecture. The practical clinical application is obvious.

Malignant degeneration of peptic ulcer of the gastric mucosa is a distinct possibility. It practically never happens in the duodenal lesion. McCarty⁶ long ago advanced the theory of metaplasia from peptic ulcer to gastric cancer. Therefore, ulcer of the stomach must be classified as benign or malignant. Alvarez⁷ has stated that any gastric ulcer larger than a dime is potentially malignant, and gastric resection should be seriously considered in such patients no matter what the age may be.

The association of gastric and duodenal ulcer in the same patient is of frequent occurrence, and the possibility of a carcinoma of the stomach should always be kept seriously in mind in any case of duodenal ulcer presenting a persistent occult blood reaction in the feces. It is quite possible that there may be roentgen-ray evidence of deformity in the duodenal cap or in the region of the pylorus, and that a severe hemorrhage from a gastric cancer may be mistakenly attributed to the old ulcer in the duodenum. The following case history strikingly illustrates this point.

Mrs. Ursula M., aged 45, a married woman, presented herself at the clinic complaining of dyspepsia and belching accompanied by a burning sensation in the epigastric region. General physical examination revealed that she was of the asthenic type with visceroptosis. Examination of the feces by the guaiac test showed occult

blood present persistently despite adequate medical treatment. The patient was advised to have surgical exploration because of this but refused to consider it. In addition there was a filling defect of a seemingly benign nature at the pyloric ring. No evidence of filling defect in the stomach was observed. While under observa-

FIG 1 Roentgenogram demonstrating atonic stomach with duodenal ulcer (Note smoothness of outline of both greater and lesser curvature)

tion, and having refused elective operation, she was taken with a severe series of hemorrhages which depleted her circulation of blood until her erythrocyte count was approximately 1,200,000 and her hemoglobin 25 per cent (Dare). She was im-

mediately hospitalized and given three blood transfusions, while under the trans-nasal suction siphonage method of treatment for hematemesis. As soon as her condition permitted she was operated upon and the source of the bleeding was found to be not in the pyloric region as suspected (figure 1) but arising from the base of a shallow

FIG 2 Postoperative roentgenogram of same patient as in figure 1 following partial gastrectomy with removal of segment of stomach containing grade III carcinoma

gastric cancer situated on the greater curvature of the stomach. A partial gastrectomy was done removing approximately two-thirds of the stomach well above the growth. The patient made a good recovery and examination of the stools has been

negative Roentgen-ray films show the remaining portion of the stomach smooth in outline with no evidence of recurrence (figure 2)

This case is presented to demonstrate the association of gastric cancer with duodenal and prepyloric benign lesions. The roentgen-ray here did not disclose the lesion situated on the greater curvature of a large visceroprotic stomach. It is well to reiterate that a persistent occult blood reaction (guaiac) in the feces when the patient is on a meatless dietary regimen should always excite the suspicion of malignancy. Surgical exploration should be advised even in the absence of a lesion demonstrable by means of the roentgen-ray.

In complicated gastroduodenal ulcer the combination of a medically minded surgeon with a clinician who fully appreciates the advantages of surgery offers the patient the greatest chance of permanent relief. In the type of individual who has what we may term "ulcer diathesis" neither medical nor surgical treatment offers very promising results. These are the patients who have recurrent ulcerations after any and all types of surgery, gastric resection not excluded. The simple benign uncomplicated peptic ulcer of the gastroduodenal mucosa is the type amenable to successful treatment by a medical regimen of which there are innumerable variations.

Medical management of duodenal ulcer has been greatly simplified in recent years and placed on a more rational basis. There has been some tendency to make it difficult again by employing various hypodermic injections of organic compounds of histidine. Most of these methods are accompanied by careful dietetic instructions and it is of extreme uncertainty where to attribute the credit for any relief obtained. All tissues, more especially epithelial structures throughout the body, have an inherent biologic tendency to proliferate and heal over any break in their continuity. Hargis and Robertson⁸ demonstrated by postmortem studies on patients who succumbed to unrelated constitutional diseases that evidences of old healed scars of peptic ulcers were present when no mention had been made of gastric symptoms in the patients' chief complaints. Upon interrogation of the near relatives of these deceased patients it was learned that they did have "stomach trouble" (symptoms of peptic ulcer) for which they quite frequently never consulted a physician. Consequently, it is quite justifiable to conclude that there are many individuals who have mild peptic ulcers which undergo several periods of recurrence without causing severe symptoms.

The smooth diet, judiciously increased according to the progress of the patient's symptoms and combined with sedative drugs and alkalies to diminish hyperacidity, forms the orthodox rationalized basis of treatment founded on an accurate understanding of the fundamental pathologic processes involved and the physiologic resources of the patient required to promote healing of the lesions. In the acute stages a diet consisting chiefly of milk and cream, junket, thin cooked cereals, with cream and sugar added, forms the standard measure employed. The feedings are given in quanti-

ties of six to ten ounces every two hours. Diluted egg albumin alone often allays the severe symptoms. The frequent feedings serve to lower acidity and provide a smooth texture to the gastric contents and prevent trauma to the healing ulcer that might occur when foods of coarse fibrous nature are ingested. The coarse foods damage the growing epithelial coating of the healing ulcer and promote recurrence or delay complete recovery. The modern dietary, consisting of various combinations of raw vegetable and fruit fibers made up in so-called "salads" comprising tomatoes, celery, apples and carrots among other things, is a common cause of persistent gastric symptoms in ulcer patients. The eating of these things by an ulcer patient is comparable to a varicose vein patient treating his varicosities and concomitant ulcers by daily rubs with coarse sandpaper.

Since Marriott⁹ in 1929 advocated the use of evaporated milks in the feeding of young children, the senior author, H. W. S., began to employ them in the treatment of gastric and duodenal ulcer and ulcerative colitis. Milk as a source of bacterial infection in human beings, particularly in streptococcus sore throats and other infectious diseases, has been repeatedly emphasized. The work of Rosenow^{10,11} in this regard is highly significant. The splendid experimental work of Saunders¹² in demonstrating that milk is a possible etiologic factor in gastric and duodenal ulcer lends credibility to the belief that milk may possibly be a source of infection to individuals who are susceptible to a combination of factors leading to the development of peptic ulcer. Ross¹³ has reported a series of cases of peptic ulcer treated with the evaporated milks. The clinical observations of the author (H. W. S.) suggest that evaporated milks are a helpful adjunct in the dietary management of ulcer patients. Our diet lists have in recent years been modified to contain many raw fresh eggs which supply all the needed vitamins. A preliminary report of these observations has been published by Soper,¹⁴ and a more complete report of clinical observations with evaporated milk will be made later.

The administration of alkalis to ulcer patients has long been a matter of controversy. We no longer employ them extensively. The smooth diet, frequently fed, seems to be the secret of successful management. After two to three weeks on strictly soft foods the patient is permitted coddled eggs, increased amounts of cooked cereals, together with cottage cheese, toast with the crusts removed, creamed vegetable soups, ice cream, jello, baked or mashed potatoes, stewed fruits, white meat of chicken and tender broiled steaks or lamb chops.

A favorite sedative employed for many years with great satisfaction is a small dose of barbital (one gram) combined with atropine sulphate (one five-hundredth gram) together in a capsule with sugar or milk. The atropine is sufficient when taken three or four times daily to relieve pylorospasm, and the barbital is a very mild sedative. This prescription can be taken over protracted periods without harm or oversedation.

The more severe forms of benign gastric ulcer will occasionally require

hospitalization We have used with great satisfaction trans-gastric feedings by means of the indwelling Levin nasal catheter The tube is permitted to find its way into the jejunum, and a high caloric mixture is given through the tube, placing the stomach completely at rest This is the same principle as employed by Balfour¹⁵ in surgical jejunostomy minus the attendant surgical risk The nasal catheter is usually quite well tolerated by these cases after the first few hours of discomfort

The above outlined principles constitute the measures which we have employed in the medical management of peptic gastroduodenal ulceration Fortunately we have been consistently successful and see no reason for changing our methods Practically all patients can remain ambulant and employed Bleeding or hemorrhagic ulcer demands more detailed consideration

Soper¹⁶ in 1931 presented a method of treating hematemesis by means of the retention catheter Severe hemorrhage from a gastric or duodenal lesion benign or malignant is quite alarming, and often accompanied by shock Recovery frequently is prolonged Balfour,¹⁷ Bevan¹⁸ and Lahey¹⁹ all advise against immediate operation but reserve intervention for recurrent bleeding Practically all writers agree that blood transfusion is immediately indicated in all severe hemorrhages and that morphine hypodermically, blood coagulants, and complete bed rest are all essentials

The principle of keeping the stomach at absolute rest in order to allay bleeding from it or into it (as in the case of duodenal ulcer or esophageal varices) is physiologically sound, and borne out by practical experience in other comparable hollow viscera such as the urinary bladder Any quantity of liquid material in the stomach will incite peristalsis and provoke additional bleeding or prevent it from stopping The gastric wall and neighboring contractile viscera containing bleeding vessels must be absolutely quiet in order to promote clot formation and cessation of the hemorrhage Nature creates a vicious circle by virtue of the fact that the blood in large quantities escapes into the stomach, excites peristalsis and thereby accentuates the bleeding This process is comparable to a hemorrhage into the urinary bladder from any source The bladder fills up with clots and in the attempt by the hollow contractile organ to expell its contents tenesmus, spasm, overactive contraction and congestion are produced and the bleeding is aggravated The quickest method of relief here is to empty the bladder with a large catheter or an evacuator and place it at rest by an indwelling catheter and keep it at rest The analogy to hemorrhage into the stomach is entirely logical In spite of this one hears and reads of the so-called "expectant treatment of hematemesis" which consists of the administration of morphia and of letting the stomach do the best it can to get relief by vomiting or by expelling its contents into the intestinal tract It is to encourage the wider use of our method of gastric siphonage in the treatment of hematemesis that we wish to present in detail its employment and to reaffirm our satisfaction in its further use

By this method one has absolute control of the situation in gastric hemorrhage. The introduction of the tube is not uncomfortable to the patient if careful technic is used. The stomach is readily emptied of all clots and placed immediately at rest. Retching and vomiting such as are caused by lavage with a large tube are avoided, to the great satisfaction of the patient. A thromboplastic substance can be given hypodermically to promote coagulation in the bleeding vessel, and the same substance is of great advantage in the stomach itself, for seemingly it not only aids in stopping the bleeding but apparently causes the larger clots to be broken up into fine black particles so that they may be readily withdrawn through the nasal tube. Recurrent bleeding is readily detected by observing the washings, and the presence of acidity may be noted by testing with congo paper. The stomach can then be gently lavaged with a mild alkaline solution of soda bicarbonate to neutralize the acid secretion.

The following detailed points in the employment of this method are worthy of reiteration.

- 1 The technic of passing the tube is important. The nasal mucous membrane should be shrunk with a 2 per cent solution of cocaine hydrochloride. The Levin nasal catheter with several perforations in the distal six inches should be slowly passed down the esophagus and the patient allowed to take a swallow of water with each short advance of the tube. The glass pistoned syringe should be used often to keep the tube free of small clots. The tube may be permitted to drain by siphonage alone or may be attached to an apparatus to provide continuous suction, such as described by Ward,²⁰ Wangenstein,²¹ Orr²² and others. The character of the secretion passing through the tube should be observed frequently and tested for acid with fresh congo red paper. Liquid petrolatum is dropped along side of the tube through the nostril three times daily, and if the patient complains of sore throat a spoonful of liquid petrolatum may be given every one or two hours.

- 2 The use of a local hemostatic is important. We employ thromboplastic solution, injecting it undiluted directly into the stomach after the clots have been removed. The fine black clots that result are characteristic of this hemostatic.

- 3 The patient is usually thirsty, and we find that fresh egg albumin, water and gelatin water rarely excite acid secretion and can be safely permitted by mouth. Proctoclysis with a physiologic solution of saline and the intravenous injection of 2000 to 3000 c.c. of normal saline containing glucose in 5 to 10 per cent solution are continued for a period of three days. After that time the tube is permitted to find its way into the jejunum. This can be demonstrated by a roentgen-ray film. The patient is then fed a high caloric mixture and the stomach is still maintained at rest for a period of a week or 10 days according to the condition of the patient and the amount of discomfort caused by the nasal tube.

The obvious advantages of the method are its simplicity, and its value

in the removal of clots from the stomach and placing it at rest, the control of acidity, the easy detection of further bleeding, the elimination of nausea and vomiting and the maintenance of the patient's comfort. In addition the tube may be employed to give jejunal feedings and so maintain the stomach at rest for any desired period of time in accordance with the requirements of the individual patient.

Just which cases of peptic ulcer of the stomach and duodenum should be selected for surgical treatment has long been controversial. It is only through intelligent cooperation between the clinician and surgeon that the best interests of the patient are served. It is generally conceded that all uncomplicated cases of simple duodenal ulcer should be treated by a medical regimen, reserving surgical procedures for those cases which do not respond to the more conservative methods. In borderline cases the choice of method is frequently a matter for weighty decision. It is likewise conceded to be justifiable to use a medical regimen in the treatment of benign gastric ulcer. Emphasis must be placed on the dictum that any gastric ulcer which does not show an immediate response to diet and rest with a definite tendency to heal quickly, as shown by competent roentgenography, should be considered potentially malignant and recommended for surgery.

The successful surgical treatment of duodenal ulcer has been a great achievement. Relief of the patient's symptoms with minimal risk should be the goal rather than to subject him to a pre-determined type of operative procedure. It would seem obvious that extensive operations, such as gastrectomy and gastroduodenal resection, will carry a higher mortality in any surgical clinic than the more conservative procedure of gastro-enterostomy. We believe that the acid factor is the most important one in causation of ulcer. The reduction of acidity by a well functioning gastro-enterostomy certainly seems to be the more reasonable and conservative choice of procedure, especially since it is admitted that achlorhydria is secured in but 56 per cent of patients subjected to total or partial gastrectomy. These points were emphasized recently by Klein, Aschner and Crohn²³.

The choice of operative procedure, then, in duodenal ulcer should be made from a conservative point of view. The selection of procedure should be suited to the individual case and will vary according to the anatomic and pathologic characteristics of the ulcer and of the patient. The position of the stomach in the abdomen and its accessibility at the operating table will also influence the surgeon in his choice. In a series of 129 cases the author (J W T) found it justifiable to perform gastro-enterostomy on 87 patients whereas it was deemed advisable to choose pyloroplasty in but 17 of this series, pyloroplasty of Bilioth I type being employed in five cases. Partial gastrectomy was done in 18 instances for gastric ulcer. In 50 per cent of these the lesion proved to be malignant. The author (J W T) has never deemed it justifiable to perform extensive partial gastrectomy for duodenal ulcer but has conservatively employed the more physiological complete pylorotomy of Bilioth I type in five cases with uniformly satisfactory re-

sults Walters²⁴ recently stated that "the case for subtotal gastrectomy with removal of the duodenal ulcer remains one for further study, during which time gastro-enterostomy should continue to hold a position of high regard, for it will give good results at low operative risk in properly selected cases in which the response to a properly carried out medical regimen has been inadequate"

Proper selection of surgical cases requires experience and clinical judgment, and as an aid the following classification has been suggested

- 1 Acute perforated
- 2 Recurrent hemorrhagic
- 3 Chronic recurrent (with duodenitis—multiple serpiginous ulceration)
- 4 Obstructive
- 5 Multiple ulcerative (severe symptoms, short duration, no relief by medical regimen)

6 Chronic perforative (with attachment to pancreas or gall-bladder)
Case reports illustrative of those several types have been made previously by Thompson²⁵

The perforated duodenal or gastric ulcer is of course always a surgical emergency. Shelley²⁶ reviewed 82 cases in which there was an immediate mortality of 18.3 per cent due to peritonitis and pulmonary complications. His follow-up records of cases were excellent and his statistics confirm the conservative opinion that a single incision of a perforated ulcer with drainage of the abdomen will save more patients than any other procedure. Adding posterior gastro-enterostomy to the load the patient already carries will in not a few instances be a factor in causing his death. It is only in rare combinations of circumstances favorable to the patient, such as a very recent perforation with actual or impending pyloric obstruction, that gastro-enterostomy should be done simultaneously with incision. Should obstruction occur later, gastro-enterostomy can be done with minimal risk. Many patients after perforation are strikingly free from symptoms following single incision. This fact alone condemns the routine performance of gastro-enterostomy in the presence of acute perforation.

The question of closure of such perforated cases without drainage again is a matter of very careful individual judgment and opinion. Closure without a drain in any wound such as a thyroidectomy, radical or simple mastectomy, or cholecystectomy is an ideal which should not be too strenuously pursued. In most cases of perforated duodenal ulcer, or of any other hollow viscus, it would seem advisable to follow the practical old masters who almost invariably drained such cases.

There is no one who will disagree with the statement that obstructing duodenal or pyloric ulcer patients should be treated by appropriate surgical procedure such as gastro-enterostomy, pylorotomy or gastro-duodenostomy. The results obtained by gastro-enterostomy in this type of case have been uniformly satisfactory. It is the duodenal ulcer patient without obstruction who has long been a subject of controversy between internist and surgeon.

It is a very serious mistake and an absolutely unjustifiable policy to deny surgical relief and cure to those unobstructed patients who have chronic or severe acute symptoms unrelieved by an adequate medical regimen. Such patients suffer intensely and should demand surgical treatment if and when they fail to get relief of their symptoms by medical measures such as diet, sedation, alkalies and rest in bed.

TABLE I
Results Following Various Surgical Procedures for Peptic Ulcer

Operation	No of cases	Symptom free	Incomplete relief	Hospital deaths following operation	Per cent operative mortality	Remarks
Gastro enterostomy	87	80	Persistent mild dyspepsia 7	2	2.3	Deaths due to vicious circle and intestinal obstruction
Pyloro-plasty	17	16	Recurrent bleeding 1	0	0	Patient with poor result (bleeding) refused re-operation
Bilroth I pyloroplasty	5	5	0	0	0	All patients entirely free of symptoms
Closure of perforation and drainage	20	12	3	2	10	Deaths from peritonitis due to delayed operation
Excision of jejunal ulcer	1	1				Followed gastro-enterostomy done elsewhere in presence of acute perforation
Gastric resection	18	16	Complain of peristaltic rushes 2	1	9.2	Eight patients proved to have malignant ulcer
Total cases	148	Approximately 90% complete symptomatic relief 130	Approximately 10% incomplete relief or poor results 13	5	3.1	Average per cent operative mortality

The severe burning pain which is unrelieved may be a precursor to perforation which will demand emergency surgery under adverse circumstances at great risk. Many duodenal ulcer patients will present themselves with hyper-motility, hyper-peristalsis, severe pain and pylorospasm. These persistent symptoms will frequently require surgical relief after medical failure.

The choice of operative procedure in such patients is of great importance. Some type of pyloroplasty can frequently be used to advantage. This operation is more physiological in that it empties the acid gastric contents into an area of high alkalinity which is biologically designed to receive them. The fearful complications of gastro-jejunal ulcer are avoided. It is, however, not always technically possible to perform pyloroplasty or pylorotomy with minimal risk. Gastro-enterostomy when properly performed will give symptomatic relief to the majority of such patients who suffer from chronic (non-obstructive) single or multiple ulceration of the duodenal mucosa.

The term "complicated duodenal ulcer" has been frequently used to designate those cases which do not obtain relief by medical regimen. This terminology is acceptable, but one cannot accept the viewpoint that a patient without organic obstruction or gastric motor insufficiency is to be advised against surgical treatment. Such advice is bad and can only be accounted for by a misconception of the pathologic changes in the duodenum which accompany peptic ulceration.

Peptic ulcer of the gastric mucosa should always be considered potentially malignant. The majority of benign gastric ulcers quickly heal under a careful dietetic and sedative regimen. Occasionally a stubborn case will require hospitalization and jejunal feedings by the Levin trans-nasal duodeno-jejunal catheter. In the event that an immediate response to treatment does not result, then all gastric ulcers no matter what their size or location should receive the benefit of surgical exploration. Total gastrectomy, while a formidable procedure carrying a relatively very high mortality rate, has been successfully performed many times by competent gastric surgeons. Gastric cancer even when viewed through rose colored glasses is still a very grim spectacle. While extensive resections are possible, recurrences are frequent and permanent cures are few. These facts should not deter one from advising surgical exploration of all suspicious gastric ulcers.

The postoperative management of gastro-duodenal surgical patients is made much easier by the routine use of the Levin nasal catheter with continuous suction siphonage. This method is far superior to the intermittent gastric lavage by means of the large caliber tube. One can determine just when the gastrointestinal tract begins to function. The patient's stomach is never allowed to fill with secretions or liquids, and gastric dilatation is prevented. Nausea and vomiting are almost entirely eliminated by intelligent use of this method which we have employed since 1928. Routine administration of carbon-dioxide inhalations aids in preventing postoperative pulmonary atelectasis. The diet is increased gradually about in accord with the methods employed in the treatment of acute medical cases. Following surgical dismissal all patients are carefully followed up by the clinician who strongly warns them against dietary indiscretion.

These patients can eat a liberal variety of foods but must not be permitted utterly to disregard the knowledge that their gastro-duodenal physiology is not perfect or they would not have developed peptic ulcer, therefore, they

must use caution in their gastronomic behavior following surgical procedures

The teeth, tonsils, paranasal sinuses, cervix, prostate gland are all to be considered possible sources of focal infection and such infections should be eliminated by appropriate methods if found to be present. These patients should always be considered as possessors of physiologically abnormal gastrointestinal tracts and warned to temper their habits with discretion

SUMMARY AND CONCLUSIONS

1 The best interests of the peptic ulcer patient are served by combined medical and surgical judgment

2 The superiority of the trans-nasal suction siphonage in the treatment of gastro-duodenal hemorrhage is emphasized

3 A series of surgically treated peptic ulcer cases is reported in tabular form

4 A very careful postoperative dietary and hygienic regimen is essential in securing permanently good results

OBSERVATIONS ON THE EFFECT OF SUDDEN CHANGES IN ARTERIAL TENSION IN ANGINA PECTORIS *

By E W BITZER, M D , F A C P , *Tampa, Florida*

ANGINA pectoris is generally considered to be a manifestation of diseased coronary arteries. Coronary sclerosis is present in most cases but not in all, and marked coronary sclerosis may be found in cases which have not shown the anginal syndrome. To account for the cases with little or no pathological findings the theory of coronary spasm has been advanced^{1, 2, 3}. This is also a possible explanation of the angina of rest. The finding of changes in the R-T segment of electrocardiograms taken during spontaneous or induced attacks^{4, 5, 6} has been considered confirmatory evidence of the occurrence of coronary spasms. It is known, however, that changes in the R-T segment may occur in coronary thrombosis without pain. Similar changes have been produced by exercise in patients with angina pectoris, without precipitating an attack of pain⁶. Such changes have also been reported in rupture of the right auricle⁷ and have been produced experimentally by injecting various substances into the pericardium⁸.

It has been found that the coronary constrictor mechanism is poorly developed in animals,^{9, 10} and the suggestion has been made that a failure of the dilator mechanism may account for some cases of angina pectoris. Wenckebach¹¹ believes a failure of the depressor mechanism is responsible for a sudden increase in aortic pressure and that this is the mechanism of attacks in certain cases which he designates true angina pectoris, as distinguished from coronary sclerosis.

The nerve control of the coronary circulation has not been definitely worked out. The vagus is probably the coronary constrictor and the sympathetic the coronary dilator¹². The reverse is true in the peripheral vascular system. Drugs that constrict the peripheral vascular system frequently precipitate attacks of angina pectoris, and dilator drugs usually relieve the pain. These drugs may act through a local effect on the blood vessels rather than through the nerve mechanism.

The purpose of this study was to demonstrate a possible change in the coronary circulation by a physical stimulus to the vascular system that did not entail any physical effort and that was free from any local effect on the coronary vessels. The "Cold Pressor Test" of Hines and Brown¹³ admirably fulfills these requirements. It produces in most instances a marked vaso-constriction demonstrable by an elevation in blood pressure. This is usually accompanied by a slight increase in the pulse rate, which suggests a widespread effect on the sympathetic system. If coronary spasm is a factor in producing attacks of angina pectoris, it is an abnormal reaction due to an

* Received for publication May 22, 1935

irritability of the vascular system in the heart. Consequently it seemed reasonable to suppose that in some cases attacks would follow the application of this test.

METHOD

A modification of the cold pressor test was used. The left hand was immersed in a large basin of water at a temperature of 6° C and was kept in the water until the test was completed. The blood pressure was taken on the right arm at least 14 times. A cardiogram was taken immediately before and at the height of the blood pressure reaction. Only one lead was taken during the test and in most instances this was a chest lead with one electrode on the anterior chest, just inside the apex, and the other on the left leg. The subject was questioned before and after the test in reference to pain in the chest.

MATERIAL

Sixty-four patients with angina pectoris were subjected to this test. There were 46 males and 18 females. Thirty-two cases had normal blood pressure, 27 were hypertensives and five were hypotensives. All 64 cases had angina of effort. Ten had both angina of effort and rest. Five conformed to Wenckebach's description of true angina. Seventeen cases had definite histories of coronary thrombosis. The following table gives the age of the patients and the duration of the disease.

TABLE I
Angina Pectoris Duration of the Disease, and Age of the Patients

DURATION	1 yr or less	1 to 3 yrs	3 to 5 yrs	5 to 8 yrs	10 yrs or over
No of Cases	28	14	10	9	3
AGE	30 to 39 yrs	40 to 49 yrs	50 to 59 yrs	60 to 69 yrs	70 to 79 yrs
No of Cases	1	6	24	26	7

RESULTS

Figures 1, 2 and 3 show maximal systolic and diastolic blood pressure reactions to the cold pressor test of the entire group. There was comparatively little difference between the reactions of the anginal patients with normal blood pressure and the hypertensives. The maximal reaction in the hypertensive group was 82 mm systolic and 45 mm diastolic. The maximal reaction in the anginal cases with normal blood pressure was 74 mm systolic and 40 mm diastolic. Fifty-three per cent of the angina pectoris cases with normal blood pressure had a "ceiling" or maximal rise in systolic pressure of 150 mm or more. The average rise in this group was 29.84 mm systolic and 16.53 mm diastolic. A group of 41 cases with normal blood pressure were subjected to the same test. This group was composed of normal in-

FIG 1 The maximal systolic and diastolic changes in blood pressure during the cold pressor test in 32 angina pectoris cases with normal blood pressure (Heavy lines denote diastolic pressure)

FIG 2 The maximal systolic and diastolic changes in arterial tension during the cold pressor test in 27 hypertensive angina pectoris cases (Heavy lines denote diastolic pressure)

dividuals, cases with cardiac neuroses and cardiac diseases, other than angina pectoris. Fifty-three per cent showed a "ceiling" of 150 mm or above. The average rise in pressure was 32.63 mm systolic and 18.29 mm diastolic. It is possible that some cases in both groups have had hypertension in the

FIG 3 The first four lines (slanting) represent the drop in pressure in two cases of angina pectoris that had a reverse reaction. The other 10 lines (straight) represent the increase in pressure in five hypotensive angina pectoris cases. (Heavy lines denote diastolic pressure.)

past, but it was impossible to prove it. There were two cases shown in figure 3 that had a reverse reaction, a precipitate drop in blood pressure, with a slowing of the pulse rate, pallor and sweating about the face and head.

ELECTROCARDIOGRAPHIC FINDINGS

Sixty-two cases that did not have anginal symptoms were used as controls. There were 10 hypertensive cases. Nine averaged a rise of 39.2 mm systolic and 14 mm diastolic. One hypertensive case showed a reverse reaction, with a drop in pressure from 170 mm systolic and 110 mm diastolic to 118 mm systolic and 85 mm diastolic. The average rise in 41 cases with normal blood pressure was 32.63 mm systolic and 18.29 mm diastolic. Eleven cases with low blood pressure averaged a rise of 24.81 mm systolic and 13.81 mm diastolic.

In this group the changes in the Q, R and T were slight, one mm or less. There were no changes in the R-T segment. In the 64 angina pectoris cases only 12 showed more than 1 mm change in the Q, R, S and T deflections during the cold pressor test. One of these cases showed a reverse reaction, with a drop in blood pressure of 38 mm systolic and 20 mm

diastolic The remaining 11 averaged an increase of 39.3 mm systolic and 15.4 diastolic

There is nothing characteristic in the changes in the Q, R, S and T's in these cardiograms. Such well-marked changes, however, did not occur in any of the other angina pectoris cases or controls. The changes in the R-T

FIG. 4. The first cardiogram in each group is a chest lead (anterior chest, just inside the apex, and the left leg) taken immediately before immersion of the left hand in ice-water. The second is the same lead taken at the high point in the blood pressure. (A) Shows an S which is decreased during the ice-water test. The increase in blood pressure was 4 mm systolic and 5 mm diastolic. (B) Shows an increase in the Q and a decrease in the R during the test. This is a case with normal blood pressure. The increase in pressure was 33 mm systolic and 25 mm diastolic. (C) Shows a decrease in the Q. There is an increase in the notching and in the negativity of the R-T segment. The T is increased. This is a case of malignant hypertension with an angina pectoris syndrome. The increase in blood pressure was 66 mm systolic and 20 mm diastolic.

segment in figure 5 (a) and (b) are of the type suggestive of coronary obstruction. In figure 5 (c) the R-T segment changes from negative to isoelectric during the cold pressor test. Only four cases showed changes in the R-T segment. It seems probable that these changes are significant of a

damaged myocardium It is not possible to assume that they are the result of coronary spasm

PAIN

Only 11 cases failed to complain of pain in the hand immersed Two stated that the pain radiated up the left arm as far as the shoulder Two developed slight shortness of breath and the feeling of oppression in the chest Three cases that had slight anginal pain in the substernal region before the test were relieved when the hand was immersed in the ice water

FIG 5 (A) During the ice-water test the R-T interval becomes positive This individual is a diabetic with angina pectoris and a normal blood pressure The increase was 48 mm systolic and 30 mm diastolic (B) A female with hypertension showed an increase in the systolic pressure of 30 mm and 10 mm in the diastolic (C) A hypertensive case The R is increased, the Q and T are decreased and the R-T segment becomes isoelectric The blood pressure increase was 50 mm systolic and 25 mm diastolic

Two developed a pulsus alternans during the test. Four cases showed frequent premature beats that were not present before the test. One case developed a typical attack that gradually subsided when the hand was removed from the water. The pain was in the substernal region and radiated to the back and both arms. The increase in blood pressure during the cold pressor test in this case was 35 mm systolic and 25 mm diastolic. The cardiogram which was taken during the attack failed to show any change in the complexes or in the R-T segment. At a later date the carbon dioxide test was used on this case with an increase in blood pressure from 204 mm systolic and 120 mm diastolic to 240 mm systolic and 150 mm diastolic. This failed to induce an attack.

CASE REPORT

A married woman, 57 years of age, of normal appearance, had lived in Florida for the past 20 years. The family history was negative. There were no known hypertensive cases in the family. She had pleurisy two years ago and malaria one year ago. She stated that her blood pressure was elevated two years ago but did not know how long it had been elevated.

Her chief complaint was pain in the substernal region, radiating to both arms and to the back, precipitated by exercise, excitement or contact with anything cold, relieved by immersing the hands in hot water and by nitroglycerine. She first noticed these symptoms five years ago. Handling ice, eating ice cream, drinking ice water, even standing in front of the open door of an electric refrigerator will precipitate the pain. She discovered a year ago, while washing dishes, that hot water relieved the pain and since then has been immersing the hands in hot water for immediate relief. For the past year walking one-half to two blocks has produced pain in the calves of both legs, which is relieved by standing still for a few minutes.

Examination She was five feet tall and weighed 130 pounds. The teeth, throat, neck, thyroid and sinuses were negative. The reflexes were normal. The skin was normal. The temperature, pulse rate and respirations were normal. The blood pressure was 225 mm systolic and 135 mm diastolic, sitting, 230 mm systolic and 140 mm diastolic, lying, 192 mm systolic and 125 mm diastolic, standing, and 208 mm systolic and 130 mm diastolic, after 50 steps. The radial arteries were palpable, grade one. The retinal arteries showed the early changes of hypertension. Pulsation was not felt in the dorsalis pedis and posterior tibial arteries of either foot. The urine was negative. The abdomen and chest were normal. The heart was slightly enlarged to the left and the substernal dullness of the second space was increased. No abnormal sounds were heard, except an accentuation of the aortic second.

Frequent observations over a period of eight months showed a variable blood pressure ranging from 170 mm systolic and 110 mm diastolic to 225 mm systolic and 135 mm diastolic. On restricted activities and theobromine she has passed a whole month without pain in the chest. During the cold weather this winter, however, she had anginal pain at frequent intervals. Two electrocardiograms, made six months apart, failed to show any abnormalities or change in the complexes.

COMMENT

In the 64 cases studied it is apparent that sudden changes in blood pressure, either a rise or a drop, of short duration and without muscular effort, failed to precipitate attacks of pain. The three cases that had pain in the

chest which was relieved by the cold water suggest an improved coronary circulation, either through the increased blood pressure, or, possibly dilation of the coronaries. However, the pain in the hand while in the cold water may have over-shadowed the mild substernal distress.

The explanation of the cardiographic changes is not so apparent. The Q, R, S and T changes probably have no specific bearing on this problem, though they were not found in other types of heart disease. Of the four cases showing changes in the R-T segment two were suggestive of coronary occlusion. In one of these a similar change was not produced at a second examination. It seems unlikely, however, that this change was the result of coronary spasm since there was no pain, though the criterion of pain is not decisive. The most plausible explanation is the effect of the increased pressure on a diseased myocardium.

In the case that developed an attack during the test, it is apparent that the elevation in blood pressure was not the precipitating factor. Total absence of electrocardiographic changes suggests that coronary spasm did not occur but is not definite proof. In a vasomotor system acutely reactive to cold, it is conceivable that this might reflexly initiate a coronary spasm that failed to show in the cardiogram. The only other possible explanation is that the pain is due to some abnormal condition in the nervous system and is entirely independent of the cardiovascular system.

SUMMARY

1 Sixty-four angina pectoris cases were subjected to the cold pressor test. In one case a typical anginal attack was precipitated by the test.

2 A chest lead was done as nearly as possible at the height of the blood pressure reaction in all 64 cases. Only 12 cases showed well-marked changes in the cardiogram.

3 The failure of extensive peripheral vasoconstriction to initiate attacks of angina pectoris suggests that the cause of such attacks lies in a failure of the vasodilator mechanism rather than in a coronary spasm or in the nervous system.

4 An unusual case is reported in which attacks are precipitated by contact with cold in the absence of physical effort and are not dependent upon changes in arterial tension.

THE PRACTICAL USE OF HOBBIES IN THE PRACTICE OF MEDICINE¹

By JOHN R. HAMILTON, M.D., F.A.C.P., *Nassawadox, Virginia*

It is my purpose in the following pages to discuss those conditions in which hobbies are a rational and necessary method of correction, and to point out that the discovery or development of hobbies for patients suffering from certain types of diseases should be more fully recognized as a definite and distinct type of treatment. Hobbies should be studied in regard to the form used, the type administered, the indications and contraindications, harmful effects, and other points of interest so that the results may be observed and controlled as in any other type of treatment.

First let us establish a definition for the term because it is necessary to have a clear conception of a tool before it becomes usable. The medical dictionary and three encyclopedias to which I had access did not even list the term. In Webster's dictionary it is defined as "a subject or plan to which one is constantly reverting, a favorite and ever recurring subject of discourse, thought, or effort, a topic, theme or the like (considered as) unduly occupying one's attention or interest." Evidently, when that definition was composed, a hobby was ascribed very little worth or even desirability. Since that time the need for some recreation or play in the life of everyone has become more generally recognized. Recently the "Leisure League of America" was organized in order to spread the doctrine of play and assist in the choice of workable hobbies. They have already published three excellent booklets and have outlined a very promising series to follow. The first, "The Care and Feeding of Hobby Horses" by Ernest Elmo Calkins, with an excellent bibliography compiled by Hugh Brotherton, is most informative. With this newer, broader view in mind and with especial regard to its application in medicine, I have with a great deal of temerity constructed the following definition paraphrasing Gaskell's description of the action of the heart muscle. "A hobby is the activity in one's life, either physical, mental or both, which possesses the power of rhythmically creating a stimulus to equalize and balance life and to divert it from the overutilization of its powers towards the securing of food, clothing and protection and the accumulation of worldly goods, it enables the possessor to receive all stimuli with a broader and less fatigued outlook, to respond to these stimuli with more poise and judgment, to convey these stimuli throughout life from activity to activity, and maintains throughout one's life a certain ill-defined condition called tone." This, I hope, pictures more nearly the practical, usable therapeutic agent.

In the practice of medicine there has been a general increasing emphasis

* Received for publication December 26, 1934 (Presented before the Seaboard Medical Association of Virginia and North Carolina, Kinston, N. C., December 5, 1934.)

on the value of preventive medicine. This has brought about a closer contact with those not already stricken with disease. In the endeavor to maintain uninterrupted, happy, healthful living and promote longevity, the beneficial effect of a well regulated life, without unnecessary worry or undue mental tension and with the proper exercise, rest and fresh air, is worthy of consideration. The accomplishment of such a state could be aided by the development of a suitable hobby and would, I believe, greatly reduce the future number of some diseases such as certain types of psychoneuroses, gastrointestinal tract disorders, and cardiac diseases. And with the public's growing regard for a periodic check-up by a physician, more and more opportunity will be furnished the medical profession for preventive measures. To the knowing eye of the physician many a person is climbing the ladder of success so intently that he sees only the rungs underfoot and will crash to the ground before he realizes that the angle of inclination is too steep for him ever to reach the top. On the other hand the physician also sees the type of patient who has never attempted to climb, bound by the monotony of existence, his life so dull and tedious that he has never even seen the ladder. Both types of patients, the over ambitious and those lacking in ambition, need a hobby as definitely as others need relief from constipation.

Rest, either absolute or at intervals, is an important factor in the successful treatment of many diseases. First there must be rest in the physical sense. In the case of an irrational patient, cessation of motion may be forced by a sufficient number of attendants and a restraining sheet. Except in such cases few would feel the rest obtained was beneficial. Obviously, mental acquiescence is necessary to physical repose. If, passing beyond this stage of mental acquiescence, real mental relaxation can be reached, with the physical being rested because it is dissociated (so to speak), and the mind happily and peacefully occupied, then we have achieved the state of real rest. Here again a hobby is a vital factor in securing desired results.

In diseases such as typhoid fever, streptococcic septicemia, influenza, scarlet fever, acute tonsillitis, acute bronchitis, and acute nephritis, the patient is acutely ill and adequate rest is indispensable. A hobby, at first probably entirely mental, then during convalescence involving both mental and physical activities, is a real therapeutic agent. Pulmonary tuberculosis (post-sanatorium care), chronic cardiac insufficiency, angina pectoris (interval treatment), arthritis, and hysteria may be cited as a panorama of the chronic diseases demanding more prolonged treatment. Securing necessary rest in this group is often a difficult task. The physician's advice should not be filled with "don'ts" which may lead to mental anxiety and physical restlessness. Here, then, skillful guidance is essential. Hobbies to divert mental tension or to replace mental idleness, to increase or decrease activity, can be used as a definite therapeutic measure.

As in any other types of treatment certain fundamental principles can be laid down for guidance in prescribing hobbies.

Above all the choice of a hobby must come from some deep-seated in-

terest within the patient himself. A school teacher, with an interesting and colorful exhibit at the end of the term in mind, was greatly disappointed in the following choices of her pupils: cigar bands, movie stars' pictures, marbles, match boxes, and hat bands with slang expressions. But, since they were, for some obscure but real reason in each case, that pupil's genuine choice, substitution would have been an error. This illustration from the schoolroom, showing children's natural selection of hobbies in the purest form, also brings out clearly that hobbies are personal interests and not mere fads, not things done to be keeping up with the Joneses, not necessarily beneficial in a commercial sense, and things that cannot stand unskillful handling or too much analyzing.

It is most pertinent that this discussion be illustrated by the hobbies of childhood and adolescence because many of the hobbies of mature men and women are a continuation of, or a resumption of, some interest acquired in youth. Guidance and helpful aid will help many a person uncover innate desires or fancies and lead to the discovery of "an instinctive something that needs but an inner consciousness of its existence to be fanned into a flame of glowing warmth that will sustain him against the cold realities of life" ¹. Then it will transport the patient out of his tedious routine and be his mitigating shock absorber.

When helping in the choice of a hobby, or when attempting to uncover those deep-seated but long-suppressed interests, it is necessary to study the inherent nature of the person in question. At one stage of our development collecting is a major interest often establishing habits and interests which are retained throughout life. For those there are many and varied choices, from paintings to canning recipes and back through butterflies, Victrola records, autographs, stamps, pieced quilts, post cards, pipes, embroidery stitches, early American bottles, guns, clocks, old maps, stuffed animals, and etchings.

There is a large group of people engaged in some business or profession who yearn to work with tools and their hands. Too often the unfortunate regard of parents for "white collar" jobs has forced a boy with the making of a first class mechanic or cabinet-maker to end his days as an unhappy, third rate bank clerk or insurance collector. On the other hand, others happily and successfully engaged in the bond business or practice of law have a mechanical turn. People of these types may find relaxation in a basement work shop making ship models or doll furniture or reconditioning old furniture. These hobbies would come under the general classification of "making things" ² which includes the arts and crafts, wood-carving, painting with water colors, making marionettes, landscape gardening, carving soap models, crocheting, photography, weaving, making models of airplanes, hooked rugs, building boats, taxidermy, and the like.

Another group of persons is interested in more active pleasures: golf, baseball, polo, racing, walking, coasting, bowling, foxhunting, fruit raising,

bee culture, training dogs, cruising, raising carrier pigeons These would come under the general head of "doing things" ²

At the other extreme are those who like to retire from action and are happiest surrounded by books, engaged in research or some intellectual feat such as translating Dante from the original or following Einstein through the theory of relativity The hobbies for these could come under the general classification of "learning things," ² which would include history of railroads, astronomy, study of birds, chemical experiments, tracing one's ancestors, study of ferns, and following Byrd's expedition to the South Pole

The flexibility of hobbies or the group of allied hobbies centering around most subjects of interest must be kept constantly in mind For example in the case of a patient who is interested in boats there is a wide range of activities enabling one to choose that phase best suited to the case The patient who is confined to his bed or room or who enjoys quieter pursuits may follow stories of the sea, either reading to himself or listening to someone else, or he may collect pictures of various types of boats or ships The man financially unable to buy the materials for a real boat or to take time off from work for long trips may enjoy making ship models The man of means who is interested in boats but unable (either in fact or imagination) to leave his business over long enough periods for sea voyages may find relaxation in a collection of paintings or etchings of ships Another patient may spend long and happy hours tinkering with an antiquated engine in a battered motor boat and never envy his richer neighbor with the perfectly appointed yacht

Fishing, in itself, brings activity of mind and body, fresh air, and change of surroundings When moderate exercise is indicated, the patient can be limited to fishing from the bank of a stream or from a power boat Trout fishing or deep-sea fishing provide more strenuous activity For those for whom actual fishing must be prohibited or who are not within easy reach of a stream or sea-port, there are the collecting of rods and flies, mounting specimens, painting or kodaking fish, making flies, reading books on fishing, and the study of fishing grounds These various phases allow great range in activity, time spent, and financial outlay

It is usually best that a hobby not be too closely related to one's vocation When a bank cashier leaves his work after a day spent indoors with ledgers and figures, a ten-mile drive in search of an antique comb-back, Windsor chair reported seen in a Negro hut, provides fresh air and physical exercise as well as relaxation and stimulation Recently, many of us were startled by the announcement that the King of England knits and crochets scarves and mufflers, but what could be a more restful diversion for one who spends such a large part of each day hurrying from corner stone laying to opening of a hospital speech and constantly in, or rather before a crowd

A hobby should be chosen with regard to the age of the patient and should allow modification as age increases A man who spends his vaca-

tions climbing mountains at the age of thirty in later years will have to content himself with arranging his snap shots in scrap books or following the ventures of others. This may often be provided for by choosing a series of allied hobbies, the more active ones leading into the less strenuous as time passes. On the other hand as age increases leisure time usually increases, and a man or woman who starts a stamp collection early in life may allow more and more time to it as years pass. Thus both the collection and the interest may grow apace until the classification and arrangement of the collection, attending auctions, reading pamphlets, books and catalogs, and comparing notes with other enthusiasts fill with delight what for many is a wretched void.

Of course, one consideration behind every choice is the patient's financial condition. But here again alteration is usually possible. The man with limited means naturally cannot collect old masters. But he can find excellent reproductions well within his means. The woman who is a garden enthusiast may not be able to buy imported bulbs but she can still create a bit of satisfying loveliness with tamed donations from nature.

The physician must not be surprised or discouraged if his patient suddenly loses interest in a hobby he has been following either from choice or at the physician's suggestion. Neither should it be pushed, but dropped, and new interests found in the same way as one would not prescribe quinine for a patient with a known idiosyncrasy to the drug. As in any other procedure which the physician adopts, his interest and skill will increase with continued use.

It has been said that "The knowledge which a man can use is the only knowledge which has life and growth in it and converts itself into practical power. The rest hangs like dust about the brain or drops like rain drops off the stones" (Froude). How often in medicine recurs the advice "Help the patient develop a hobby," or "The patient should find a hobby," but because of the vague conception of the term in the minds of both patient and physician and the lack of practical suggestions this excellent therapeutic measure often fails to "convert itself into practical power." It is hoped that this paper has shown that helping develop a hobby is both practical and simple with only a few general rules and underlying principles to be considered.

CASE REPORTS

PROLIFERATIVE INTIMITIS OF SMALL ARTERIES AND VEINS ASSOCIATED WITH PERIPHERAL NEURITIS, LIVEDO RETICULARIS, AND RECURRING NECROTIC ULCERS OF THE SKIN

By NELSON W BARKER, M D , F A C P , and THOMAS W BAKER, M D ,
Rochester, Minnesota

THE various types of occlusive vascular disease produce clinical pictures which may vary greatly with the extent and situation of the lesions and the rapidity with which they develop. However, certain clinical and pathologic entities have been established and although their exact etiology still remains obscure the diagnosis usually is not difficult. This case is presented because of its unusual clinical and pathologic features which do not conform to any of the more common syndromes.

One of the outstanding features of the case was the marked degree of livedo reticularis. This is a descriptive term which has been given to a permanent bluish-red, retiform mottling of the skin of the extremities and frequently the trunk also. According to Williams and Goodman, the basis for livedo reticularis, also called livedo racemosa and generalized telangiectasis, is a capillary dilatation or atony which may be primarily functional or may be associated with congenital vascular anomalies or organic disease of small arteries and veins. In 1893, Unna reported a case in which there were multiple ulcers and "chronic phlebitis." Endarteritis of small arteries and endophlebitis of small veins have been found in the skin at biopsy in cases of livedo reticularis, by Stokes, Urbach, Becker, and Ebert. Periarteritis and periphlebitis also have been noted occasionally. No extensive pathologic studies of larger vessels and nerves have been described.

The etiology of the vascular lesions in various cases, which have been reported, has been ascribed to syphilis (Ehrmann), arteriosclerosis (Giosz and Kerl), and tuberculosis of the erythema induratum type (Williams and Goodman). Stokes, Becker, and Ebert have reported cases in which no etiologic factor was apparent. Associated ulceration of the skin was noted also in Ebert's case. The combination of livedo reticularis, recurrent indolent ulcers, severe intractable pain, and acute arterial occlusion of the toes has not been described.

CASE REPORT

History A man, aged 34 years, formerly a machinist, first came to The Mayo Clinic in October 1932. Eight years before, a diffuse reticulated purplish mottling had gradually developed over all the extremities and to a lesser degree over the trunk.

* Submitted for publication May 13, 1935.

From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

This condition had been more noticeable over the lower extremities than it had been elsewhere, and had been markedly aggravated by cold. A short time after the onset, a series of painful sloughing ulcers had developed on both legs, the usual site had been the lateral aspect of the ankles. The patient said that these ulcers had developed without preceding nodules but always in one of the blue patches. New ulcers never

FIG 1 Photograph of patient at the time of the first observation, prior to lumbar sympathetic ganglionectomy. Note the reticulated mottling of the extremities, and ulceration and scarring of both legs.

had appeared simultaneously on both legs. Healing usually had occurred within 14 to 60 days, regardless of the therapy which had been employed, and had left an atrophic pigmented scar. The Wassermann reactions of the blood and spinal fluid had been negative. In 1928, four years after the onset, while he had been working with white lead as a lubricant, a left peroneal palsy had developed. At this time, lead had been found in the stools and urine, and basophilic stippling had been found in the erythrocytes. The foot drop had disappeared spontaneously when contact with lead had been discontinued, and there had not been any recurrence nor had this episode seemed to influence the mottling of the skin or development of ulcers of the legs.

The patient had also been the victim of two severe attacks of influenza, in 1918 and 1927, and in the latter attack he had observed a disappearance of the livedo during the acute febrile course of the disease. Tonsillectomy had been performed in 1928, without benefit. No familial history of vascular or nervous disease was elicited. There was no previous history of thrombophlebitis or varicose veins.

Two weeks prior to his admission to the clinic, the patient had suffered a sudden acute pain in the right great toe which had become pale and cold and had remained so.

Physical Examination and Laboratory Data Physical examination revealed a well nourished, rather mentally depressed man. Aside from the cutaneous manifestations, the general examination did not reveal anything abnormal. There was a marked livedo reticularis of arms, legs, and lower part of the trunk (figure 1), without definite purpura or telangiectasis. A moderately deep ulcer, measuring 3 by 4 cm, with a dirty sloughing base and slightly indurated borders, was present over the lower third of the anterior aspect of the right leg, and there were several depressed pigmented scars of the skin of both ankles and legs. The entire right great toe was pale and cold and showed a few small patches of subcutaneous hemorrhage. Pulsations in both radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial arteries were present and of normal volume. There were no postural color changes in the feet, with the exception of the right first toe, which became very white on elevation and excessively red on dependency. There were no varicosities. Repeated estimations of the blood pressure were normal. The Kolmer modification of the Wassermann reaction of the blood and the Kline, Kahn, and Hinton tests were all negative. The Mantoux test was negative. No changes in the bones or thorax were revealed by roentgenologic examination, and the routine studies of the blood and urine did not disclose any abnormality. No lead was found in the urine. Special studies of blood smears did not demonstrate anything significant. A small specimen was taken from the margin of the ulcer for biopsy, but it showed only moderate fibrosis and a slight degree of nonspecific, inflammatory reaction. A special tissue stain for tubercle bacilli did not reveal the presence of these organisms.

Therapy and Subsequent Course Since there were definite signs of a recent occlusion of the digital arteries of the right first toe, several intravenous injections of typhoid vaccine were administered. These relieved the pain and caused a return of color. There was also some reason for believing that obliterative and vasospastic changes in the arterioles were the basis for both the livedo reticularis and the ulcers. Therefore, with the idea of increasing the blood supply of both toes and ulcer-bearing regions, a bilateral lumbar sympathetic ganglionectomy was performed by Dr. Craig, on October 25, 1932. The ulcer was entirely healed within 15 days after operation. The mottled blue areas became red below the knees and the toes and feet remained warm and dry. No ulcers appeared for four months, the longest remission that the patient had noted since the onset of the disease. However, at the end of that time they did recur, and an acute arterial occlusion of the left great toe developed. This was similar to that previously experienced in the right great toe, although it recovered more rapidly. Cyanosis, mottling, and sensitivity to environmental cold, of the upper extremities increased so that the patient feared that similar ulcers might develop on the hands.

He returned to the Clinic in August 1933, complaining of new ulcers and of pains in the calves of his legs. The peripheral arterial pulsations again were found to be entirely normal. The feet were warm (34°C). The livedo reticularis was the same in the legs as it had been before, but it was more marked in the arms, and the hands were cold and slightly cyanotic. An arteriogram (Allen and Camp technic) of the right arm did not reveal any evidence of arterial occlusion. Sufficient typhoid vaccine to give a systemic fever of 104°F produced an increase of the skin temperatures of the fingers from 28.2°C to 37.9°C .

Three applications of roentgenotherapy to the ulcerated areas of the legs and six subcutaneous injections of an autogenous vaccine, which was prepared from a culture of the ulcer, were administered. Partly at the patient's request, and as a prophylaxis against a possible ulceration of the hands and arms, bilateral cervicothoracic sympathetic ganglionectomy was performed by Dr. Craig on September 9, 1933, with almost complete relief of symptoms and signs in the upper extremities. During the postoperative convalescence, the ulcers of the legs healed but whether we are justified in ascribing this to therapy other than enforced rest in bed is doubtful.

The patient was discharged in October 1933, but returned for further observation in January of the following year. In the interval between visits, he had been free of ulcers for two months, only to have them return with increasingly severe pain which finally required morphine. On his admission to the hospital at this time, a deep sloughing ulcer, which was similar to the previous ones, but larger, was present over the external malleolus of the left ankle. There was also a small area of discoloration of the right calf, which appeared to be about to break down. A biopsy of this lesion revealed some fibrosis of the corium, but did not reveal any inflammatory reaction. In two arterioles in the cutis there was slight hypertrophy of the media. A roentgenologic examination of the bones of the leg showed only a slight osteoporosis. Seven daily intravenous injections of 20 cc of activated sulphur, and six injections of the autogenous vaccine (0.1 to 0.6 cc) were given without benefit. Potassium iodide and mercury were administered by mouth, but there was no change. Hot packs and pantocain ointment were applied locally but gave only slight relief from pain. Following this, five injections of 0.4 gm of neoarsphenamine were administered in three weeks, without noticeable benefit. Wet dressings of potassium permanganate and thioglycerol were employed but no healing followed. The patient was even suspected of producing the ulcers and keeping them from healing, and for this reason, an occlusive dressing, designed so that any tampering could be detected, was applied for two weeks, but the ulcers became larger. A dressing of balsam of Peru and an elastoplast bandage were applied, with a rubber sponge to exert pressure over the ulcer, as advocated by McPheeters and Merkert for the treatment of ulcers, caused by venous stasis, but no appreciable healing resulted, and the pain increased until opiates were again required. The patient became very nervous and mentally depressed, and finally insisted that the left leg be amputated, although he was fully aware that this was no insurance against recurrence of ulcers in the remaining leg. An amputation below the knee was finally performed by Dr. Ghormley, June 28, 1934. Convalescence was uneventful, and the stump healed promptly. The patient returned home in August. He recently has reported that ulceration has recurred in the remaining leg. There has not been any noticeable progression or improvement in the livedo reticularis.

Pathologic Studies. Dissection of the anterior and posterior tibial arteries of the left leg, and their vena comites, did not reveal any evidence of occlusion or gross pathologic changes. However, the walls of both the long and short saphenous veins were extremely thick, and the lumina of these veins were very small. Histologic sections of the base and the margins of the ulcer showed

considerable fibrosis of the subcuticular tissue and a mild degree of inflammatory reaction. There was no evidence of any specific type of granulomatous lesion, but there was chronic ischemia with low grade secondary infection of the tissues. Sections of the toes, particularly the first toe, revealed increase in the fibrous

FIG 2 Photomicrograph of section of small artery from base of ulcer, showing active intimal proliferation. Hematoxylin and eosin stain ($\times 215$)

tissue, and decrease in the fat, with atrophy of the cutaneous glands. The essential histologic lesions were found in the blood vessels and nerves. Sections of the large arteries, such as the posterior tibial, showed slight proliferation of the intima only. However, more extensive proliferation of the intima and definite perivascular fibrosis were found in many small arteries and veins (figures 2 and 3). This was particularly true in vessels which were 200 to 1,000 microns in diameter and situated in the tissue in the base and margins of both the active and healed ulcers. These vessels were situated farther below the cutis than were the vessels in the tissue which was removed at biopsy. In some of the arteries of the first toe, the lumen was occluded by a fibrous mass and there was marked periarterial fibrosis, these apparently represented a late stage of the lesion (figure 4). There was little or no inflammatory reaction in either the media or adventitia of the small arteries and veins. The thickening of the walls of the long and short saphenous veins was almost entirely the result of proliferation of the intima and there was little inflammatory reaction in the wall of the

vein itself (figure 5). Many arterioles (25 to 100 microns) had abnormally thick walls and small lumina, in some, there seemed to be hypertrophy of the muscle and slight proliferation of the intima. In many places, these were surrounded by solid fibrous tissue.

FIG 3 Photomicrograph of section of small vein near base of ulcer, showing well advanced intimal proliferation and almost total occlusion of lumen, stained with elastin H stain ($\times 95$)

The peripheral nerves all showed perineural and intraneural fibrosis and patchy loss of the myelin sheaths. These changes were only of slight degree in the anterior and posterior tibial nerves and their branches, but were very marked in the long saphenous and sural nerves, in which only a very few myelin sheaths in each nerve bundle took the Weigert stain (figure 6). The vasa nervorum showed the same changes noted in other small arterioles and veins.

COMMENT

In summing up the essential clinical features of this case, we have a young man, aged 36 years, who, for 10 years, had had a permanent livedo reticularis of the legs, arms, and lower part of the trunk, and a series of ulcers of the lower legs which gradually had become more and more difficult to heal and gradually had become more and more painful in spite of a wide variety of therapeutic pro-

cedures designed to increase circulation and promote healing. Finally, amputation of the leg was necessary because of pain in a large ulcer which could not be healed. There were two episodes of acute arterial occlusion of toes, without definite gangrene or ulceration. There was no evidence of tuberculosis or syphilis. A lumbar sympathetic ganglionectomy seemed to inhibit the formation of the ulcers for a short time only.

FIG 4 Photomicrograph of section of long saphenous vein, stained with hematoxylin and eosin. There is marked proliferation and fibrosis of intima, but no inflammatory reaction in media ($\times 25$)

The essential pathologic changes appeared to be a proliferative, occlusive intinitis of small blood vessels, both arteries and veins, and of larger superficial veins. The term proliferative intinitis is used because both arteries and veins were affected and endarteritis and endophlebitis are loosely used in medical literature to denote a variety of vascular lesions. The arterial occlusions produced varying degrees of chronic ischemia of skin and toes and a rather marked degree of ischemic neuritis. There was also a definite thickening of the walls of the arterioles, which possibly was secondary. There was some evidence in favor of an additional factor of venous stasis in the production of the ulcers, because of the fact that veins were obstructed as well as arteries. The pathologic picture of the vascular lesions suggests that they were slow in development and dis-

tinctly different from the lesions of thromboangitis obliterans, arteriosclerosis, and periarteritis nodosa

There is no definite clue as to etiology. One would suspect that the proliferative intimitis was a reaction of the vascular endothelium to some chronic toxemia, endogenous or exogenous. There was not any evidence of syphilis, tuberculosis, or other systemic or focal infection. It is noteworthy that the pa-

FIG 5 Photomicrograph of section of small artery of first toe, showing complete occlusion by intimal proliferation with secondary hyaline fibrous degeneration, and periarterial fibrosis. Hematoxylin and eosin stain ($\times 155$)

tient had had an episode of clinical lead poisoning four years after the onset of the disease, and it is possible that this contributed to the pathologic changes in both blood vessels and nerves. Whether or not he had had atypical or mild chronic lead poisoning since the onset of the disease is problematical as he had had no known exposure to lead. Subsequently, the condition had been progressive for a long period when he had no contact with lead, none of the typical symptoms of lead poisoning, and had not excreted any lead in the urine. A specific type of vascular lesion produced by lead poisoning has never been adequately described, and possibly does not exist. Certainly, some individuals can have definite clinical lead poisoning without ever having clinical or pathologic evidence of any vascular disease. However, isolated cases of several types of vascular disease have been described in association with definite clinical lead

poisoning, this may be coincidental. The case, described by one of us (Barker) and Brown, as disseminated arteritis of unknown etiology, showed proliferative intimitis of small arteries as well as arteritis and periaarteritis of arterioles. There was some, though inconclusive, evidence for chronic lead poisoning in this case, because lead was found in the urine before death, and in certain tissues at necropsy.

FIG 6 Photomicrograph of section of portion of long saphenous nerve stained with Weigert's myelin sheath stain. Note disorganization of nerve bundles and only a very few myelin sheaths remaining ($\times 150$)

One remarkable aspect of the case herein reported was its slow but definite progression and refractoriness to therapy. On this basis, the prognosis, both as to loss of other limbs and of life, is uncertain.

THE BENEFICIAL EFFECT OF THE DEVELOPMENT OF AN ABNORMAL RHYTHM WITH SLOW VENTRICULAR RATE IN CIRCULATORY FAILURE *

By WILLIAM C COOKE, M D, *San Diego, California*

THAT digitalis medication is often of little value in the treatment of circulatory failure in the presence of persistent sinus tachycardia is well recognized. Digitalis frequently does not slow a regularly beating heart. It has been known since Withering's introduction of the use of the drug that patients with auricular fibrillation respond particularly well to digitalis therapy, and it has been stated frequently ^{1, 2, 3, 4, 5} that auricular fibrillation in itself is often well tolerated and compatible with satisfactory cardiac function. That patients with circulatory failure may show marked clinical improvement following the development of auricular fibrillation or other abnormal rhythm with a slow ventricular rate has been seldom emphasized or even mentioned in textbooks or articles on cardiac therapy. An exception to this statement is Meakins' recent observation ⁶ that improvement "is often seen when a rapid regular rhythm which cannot be controlled gives place to auricular fibrillation which can be controlled by digitalis, or when complete heart block develops in a failing heart reducing the rate to around forty. In both of these instances great improvement in cardiac function may be seen."

The following case history is an example of the apparently beneficial effect on the circulation of the replacement of a rapid regular sinus rhythm by auriculo-ventricular dissociation upon one occasion and by auricular fibrillation later.

CASE REPORT

The patient, a retired merchant, 63 years of age, entered the hospital on February 25, 1933, complaining of shortness of breath upon exertion and at night, at times accompanied by substernal oppression and asthmatic breathing. These symptoms and considerable gaseous indigestion had been present with gradually increasing severity for the preceding six months although the patient had been confined to his home and was taking adequate doses of digitalis. Previous to the development of his present illness he had been well, although he had known for at least eight years that his blood

* Received for publication April 22, 1935

pressure was elevated. He had had a gonorrheal infection at 28 years of age but denied syphilis, he had had an appendectomy at the age of 25. His family history was negative except that his mother died of uremia at 73 years of age.

Physical examination revealed a well nourished man, apprehensive, dyspneic and moderately cyanotic. Orthopnea was marked and at times periods of Cheyne-Stokes breathing were noted. There were some distention and pulsation of the veins of the neck, and a heaving diffuse precordial pulsation. The left border of cardiac dullness was 12 cm from the midsternal line, 3 cm to the left of the midclavicular line. The heart sounds were of poor intensity with a proto-diastolic gallop rhythm at the apex. The heart and pulse rates were 108. The blood pressure was 170 mm of mercury systolic and 110 diastolic in both arms. Moist râles were present at the bases of both lungs. The liver edge extended 3 cm below the costal margin. There was no edema. Other physical findings were normal. The Kahn reaction of the blood was negative. Urinalysis showed a specific gravity of 1.012, a trace of albumin and numerous granular casts. The blood count was normal. The urea content of the blood was 36 mg per 100 c.c. of blood. The electrocardiogram (figure 1) showed a regular

FIG 1 Electrocardiogram taken on February 25, 1933, during first attack of circulatory failure. Regular rhythm, rate 110, P-R interval slightly prolonged (0.22 sec), QRS interval 0.1 sec. Marked left axis deviation. Depression of S-T₁ and elevation of S-T₃, probably due to the marked left axis deviation.

sinus rhythm with a rate of 110, a prolonged auriculo-ventricular conduction time (0.22 sec) and a QRS interval of 0.10 sec. There was marked left axis deviation with depressions of S-T₁, inversion of T₁ and elevation of S-T₃. A diagnosis of hypertensive and coronary heart disease with left ventricular failure was made.

For about one month prior to admission to the hospital the patient had been taking powdered digitalis leaves. He had taken three grains for the first five days and then 1 1/2 grains daily. In view of the prolongation of the auriculo-ventricular conduction time it was felt that he was well digitalized and the maintenance dose of 1 1/2 grains daily was continued. Caffein citrate was given every four hours by mouth and was replaced later by caffein sodium benzoate, grains 3 3/4 hypodermically, be-

cause of nausea Dilaudid, grains 1/32, or morphine sulphate, grains 1/6, was given as necessary to control nocturnal dyspnea and cardiac asthma

During the first nine days of his hospital stay there was little change in his condition except that he became less dyspneic and the Cheyne-Stokes breathing disappeared while under the influence of caffeine The heart rate continued to be rapid, varying from 90 to 130 There was no significant change in the blood pressure readings On March 4, because of the development of nausea and vomiting, digitalis was discontinued It was started again 10 days later with the same dosage of 1 1/2 grains of the leaves daily, but after six days it was discontinued again because of nausea, although the pulse rate was not slowed He still had severe dyspnea and cardiac asthma at night Three days later the administration of digalen, 1 c c three times daily, was started, after six days the dose was decreased to 1 c c twice daily

Three days later, on April 3, the pulse rate became very slow and irregular The electrocardiogram (figure 2 A) showed a shift in the auricular pacemaker and dissociation of the auricles and ventricles with a slower auricular rate The auricular rate was 48 and the ventricular rate 66 Occasionally there was a ventricular re-

FIG 2 Lead II only of electrocardiograms showing A-V dissociation and return to normal rhythm

A Taken April 3, 1933 Auricular rate 48, ventricular rate 66 P-R interval 0.28 sec The auricles and ventricles are dissociated except periodically when an impulse from the more slowly beating auricle reaches the ventricle during a non-refractory period and causes a ventricular contraction The P-waves are inverted showing a shift in the auricular pacemaker away from the sino-auricular node

B Taken April 5, 1933, one-half hour after the hypodermic administration of atropine sulphate grs 1/100 Shows the same phenomena as (A) except that the ventricular rate is more rapid (80 per min) and the P-R interval less prolonged (0.24 sec)

C Taken April 14, 1933 Regular rhythm, rate 60, P upright, P-R interval 0.28 sec

sponse to the auricular impulse. This occurred when the impulse reached the ventricle during a phase in the cycle in which the muscle was not refractory from a previous contraction. The following day another electrocardiogram (figure 2 B), taken one-half hour after the hypodermic administration of atropine sulphate, grains 1/100, showed the same abnormal rhythm but with less prolongation of the P-R interval (0.24 sec) and a more rapid ventricular rate (72 min). The abnormal rhythm shown in these electrocardiograms is an example of the rare condition of auriculo-ventricular dissociation with unidirectional block and a more rapid ventricular rate such as has been reported by White⁷ and Hewlett⁸ in cases of digitalis poisoning. The drug was discontinued.

In spite of the development of this abnormal rhythm there was very marked clinical improvement. The symptoms of dyspnea, cardiac asthma and Cheyne-Stokes breathing were relieved. The pulse continued to be slow and usually irregular until April 6 when it became regular with a rate of from 60 to 80 per minute. The electrocardiogram taken on April 14 (figure 2 C) showed a return to normal rhythm with auricular and ventricular rates of 60, a P-R interval of 0.28 sec, and no change in the deflection of the various complexes.

The patient was discharged from the hospital on April 17 with no symptoms of circulatory failure. He was advised to remain in bed at home and to take digitalis leaves, gr 1 twice daily. For the next two weeks he continued to feel well. At the end of that time his heart rate gradually began to increase. Coincident with this increase in heart rate the symptoms of nocturnal dyspnea, Cheyne-Stokes breathing and cardiac asthma returned.

FIG 3 Electrocardiogram taken July 15, 1933, showing auricular fibrillation with a ventricular rate of 40 to 50 per min

He was readmitted to the hospital on May 9 with symptoms of advanced circulatory failure. Distention of the jugular veins, moderate cyanosis and very evident dyspnea were present. The heart rate was 110. Pulsus alternans was present with a systolic blood pressure of from 170 to 180 and a diastolic pressure of 110. Many moist râles were heard at the bases of the lungs. In addition to his previous symptoms he now presented the picture of a failing right ventricle with enlargement of the

liver and subcutaneous edema over the sacrum. Urinalysis showed a moderate cloud of albumin and many hyaline and granular casts.

The administration of powdered digitalis leaves, gr 1 twice daily, was continued and a diuretic regimen instituted consisting of a low fluid intake, ammonium nitrate, grains 90 daily, and the intravenous injection of salyrgan, 1 c.c. at two- to three-day intervals. Under this regimen evidences of congestive failure disappeared in about two weeks' time. However, the subjective symptoms of dyspnea, especially at night, apprehension and occasional attacks of substernal oppression were relieved only partially.

During a period of two weeks his condition remained stationary except for slight recurrences of the congestive symptoms of liver enlargement and dependent edema which cleared up promptly following the administration of ammonium nitrate and salyrgan. The pulse rate remained slightly elevated, varying from 80 to 100 while at rest in bed. There was no significant change in the blood pressure readings.

On July 15, the pulse rate dropped to from 50 to 60 per minute and became irregular. An electrocardiogram (figure 3) showed that the irregularity was now due, not to A-V dissociation, but to auricular fibrillation with a very slow ventricular rate. Coincident with the development of the slow heart rate he began to improve rapidly and in a few days the dyspnea, Cheyne-Stokes breathing and cardiac asthma had disappeared. The administration of digitalis, which was discontinued with the drop in pulse rate, was resumed on July 22 with a dose of 1 1/2 grains daily, and the dose increased to two grains daily about 10 days later. Auricular fibrillation continued with a ventricular rate of from 60 to 70. The patient was allowed to be up for gradually increasing intervals and was discharged from the hospital on August 4 feeling quite well except for weakness and slight dyspnea upon exertion.

It has now been 21 months since he left the hospital. During this time his heart has continued to fibrillate. The ventricular rate has been maintained at from 50 to 60 per minute by the administration of 1 1/2 to 3 grains of powdered digitalis leaves daily. He has felt very well and has had no subjective symptoms of circulatory failure although his activities have been restricted only to a moderate degree.

DISCUSSION

In the case reported, as often happens in the presence of a decompensating heart with a rapid regular sinus rhythm, digitalis administration resulted in very little if any slowing of the heart rate or improvement in the patient's general condition until the development of auriculo-ventricular dissociation with a slow ventricular rate. It was felt that digitalization had been pushed to the limit of tolerance and even intoxication prior to this as nausea and vomiting, necessitating withdrawal of the drug, had developed on two occasions.

The development of an abnormal rhythm was at first considered another unwelcome incident of digitalis intoxication. To our surprise, however, the patient became much more comfortable and began to show rapid improvement as soon as the slow rate developed. Within a period of two weeks his condition was satisfactory for dismissal from the hospital. After the abnormal rhythm had been present for three days the cardiac mechanism again became normal but with a slow rate, and his condition remained satisfactory for a period of two weeks. The rate then increased gradually to from 100 to 110 per minute in spite of continued bed rest and the administration of two grains of digitalis leaves daily. Coincident with the increase in the heart rate, symptoms of circulatory failure again appeared.

When he was admitted to the hospital the second time, moderately severe congestive failure had developed in addition to the marked symptoms of left ventricular failure. The congestive symptoms cleared up promptly following the administration of salyrgan and ammonium nitrate but recurred several times. His improvement was again unsatisfactory until the development of a very slow ventricular rate, this time due to auricular fibrillation with a high degree of auriculo-ventricular block.

Auricular fibrillation has continued for 21 months. The rate has been maintained at from 50 to 60 per minute by digitalis, and there has been no recurrence of circulatory failure although he has been engaging in moderate activity.

The improvement which followed the development of an abnormal rhythm with a slow ventricular rate upon the first occasion was considered a coincidence. A repetition of the experience upon the second occasion convinced us that the abnormal mechanism was really the means by which improvement was effected. The ventricular rate could then be slowed by digitalis and more efficient cardiac function obtained by the increased coronary blood flow and diastolic rest of the myocardium made possible by the longer period of diastole.

CONCLUSION

A case of circulatory failure in which improvement was twice dependent upon the development of an abnormal cardiac rhythm is reported.

Our experience in this case demonstrates the improvement in cardiac function which may result when an abnormal rhythm with a slow rate replaces a regular rhythm with a rapid rate. This improvement may be explained by the more effective depression of auriculo-ventricular conduction by digitalis in the presence of an abnormal mechanism such as auricular fibrillation.

A REPORT OF IDENTICAL ALBINO TWINS OF NEGRO PARENTS¹

By ELMER G WAKEFIELD, M D, *Rochester, Minnesota*, and
SAMUEL C DELLINGER,† *Fayetteville, Arkansas*

THE object of this report is to record identical twins and total albinism occurring in the Negro race. Although such an anomaly in identical twins is exceedingly rare in all races, we believe that the biologic phenomena involved in the production and accidental association of identical twins and albinism have been satisfactorily, if not correctly, explained in the literature on twins, twinning, and albinism. These children were neither pupils nor patients of ours, therefore, the only tests or examinations which could be made were those which are reported here.

The twins were girls, aged about eight and a half years (figure 1). Each weighed 20.9 kg, and was 131 cm in height. They were well developed, well nourished, and appeared healthy. Their hair was abundant, snowy white, and coarse, when combed out, the hair of each child was equal in length. The degree of kinkiness of the hair, the distance between kinks, the hair line on the foreheads, about the ears, along the sides of the temples, and down the back of the necks were identical for each child. The skin, also, was totally devoid of pigment, and there were no freckles, moles, or blotches. The skin was fine and soft in texture, it was moist and delicate. It became sunburned from very short exposure, and required a great deal of protection during the summer months. (One of the children had a large, blistered sunburn on her back at the time of the examination.) The ears were small. The noses were flat, and the nares were wide apart. The lips were moderately thick, and the features were characteristically Negroid. The eyes were squinty, red and nystagmic. When the four eyes rolled from right to left, or vice versa, in order to follow the examining finger, all the nystagmic motions were synchronous. Examination of the ocular fundi revealed that the choroids were devoid of pigment. Examination of the ears, nose, throat, tonsils, thyroid gland, heart, lungs, abdomen, reflexes, and extremities of each child did not reveal anything unusual. After the children had reclined quietly on a bed for 20 minutes, the heart rate of each child was found to be 100 beats per minute. The value for the blood pressure of each child was 130 mm of mercury for the systolic and 70 mm of mercury for the diastolic. Their respirations were abdominal in type, and the respiratory rate was 20 per minute. The following measurements were obtained for each child: circumference of thorax, 55 cm, circumference of neck, 28 cm, circumference of waist, 55 cm, circumference of middle third of thighs, 24 cm, circumference of calves of legs, 20 cm, circumference of middle third of arms, 16 cm, circumference of wrists, 12 cm, length from the fourth thoracic vertebrae to tips of fingers when arms were extended laterally, 70 cm, length of legs from anterior-superior spine of ilium to soles of heels, 65 cm, and length of the middle fingers from wrists, 14 cm.

* From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota, and the Department of Zoology, University of Arkansas, Fayetteville, Arkansas.

† Research Series, number 411.

These children had been born at term, after a short labor which had lasted four or five hours. The second child had been born about 10 or 15 minutes after the first. The mother was certain that there had been only one "after-

FIG 1 The twins at the time they were examined

birth" From birth, the children had been fed on the breast until they had been "two or three" years of age. The mother thought that one of the children always had been a little larger than the other. They had enjoyed good health. Their only illnesses had been measles and chickenpox, which had occurred simul-

taneously and had been of the same severity in each. It had been very noticeable that when one of the children had had a cold or any sort of illness, the other had been affected similarly and to the same degree. Their likes and dislikes of food and clothes were identical. They may have quarrels and disagreements between themselves, however, it is impossible for one of the family to disagree with one of the twins without invoking the anger of the other.

Mental tests under our supervision probably would not have been of much value. These children were quiet, modest, polite and obedient. They had never had an opportunity to go to school. It is our opinion that they were mentally within normal limits.

FIG 2 The maternal grandmother, the mother, the twins, and two of their cousins (girls), two years prior to examination

In neither the father's family nor the mother's family (figure 2) were albinos or admixture of the white race known to be present. The father appeared to be full-blooded Negro. We saw the mother's parents, who, like the mother, were moderately black, and had the characteristic skin, features, and hair of Negroes. The possibility of admixture with the white race or any other race is admitted. This we believe to be irrelevant because albinism and identical twins occur in all races.

COMMENT

The essential feature of albinism is the total absence of pigments of the melanin group, which are the chief factor in the surface coloration among all animals. The absence of these pigments in the eye results in the primary incapacitation of this affliction. The ordinary causes of pigmentation, whatever they may be, are not operative in the albino. Short exposure of albinos to hot sunlight produces a hyperemia which very quickly is followed by the formation of blebs if the exposure is continued. The fat and blood pigments are normal and are excreted in normal quantities in the urine, whereas, the mechanisms for

metabolism and control of the pigments of the melanin group are nonoperative. The foregoing statements apply only to genuine albinism, which is not the most common form observed. In cases of incomplete albinism, the hair has various tints from yellow to red. The usual albinic Negro has yellow hair and pigmented freckles.

There is still a third type which is termed partial albinism. These individuals may have albinic eyes, or they may have albinic skin, normal eyes, white locks of hair. In the latter case, the skin may be flecked with white, and there may be piebald skin or the so-called mosaic inheritance. Clinically, partial albinism should be distinguished from such conditions as vitiligo.

In the majority of instances, albinism continues throughout life. However, it has been stated that an individual who had been born albinic occasionally has recovered. Apropos of this, mention should be made of the seasonal albinism in Arctic mammals and birds. As far south as Minnesota, during winters with much snow, the jackrabbits (subgenus *Macrotolagus*) become albinic.

By selective breeding, albinism can be reproduced indefinitely among lower animals. Thus, the mode of incidence of this inborn error would seem to have a ready explanation, if it is regarded as a rare recessive character in the mendelian sense. If two characters, one of which tends to be dominant, and the other, recessive, are observed in cross-bred individuals, the dominant character will tend to be manifested. This manifestation of the dominant character is explained by the supposition that the germinal cells or gametes of each generation are pure so far as the qualities in question are concerned. It is by such reasoning that Mendel's theory accounts for the numerical results observed by the production of dominant and recessive gametes in equal numbers in successive generations of inbred individuals in the less complicated gametes. The length of life of man, his limited reproductive capacity, his innate tendency to forget unpleasant details in the family history, and especially those matings and the resulting offspring which may be considered undesirable and, finally, his qualities of nomadism, and infidelity, render mendelian interpretation of his dominant and recessive characters practically impossible. Thus, the occurrence of such an inborn error as albinism among human beings is in reality an accidental fertilization of an ovum, which possesses recessive pigmentary characteristics, by a similar spermatozoon, except in consanguineous marriages. To illustrate the results of consanguineous marriages, in 24 families which contained 60 albinic members, five of these latter were the offspring of matings of first cousins. In only two instances was albinism directly transmitted from parent to child.

The reports of genuine identical albinic twins are scarce. According to Garrod,¹ there are 29 records of twins, one or more of whom were albinic. In 11 pairs, both were albinos and in 18 pairs, one twin was normal. In 20 cases the twins were of the same sex, and in seven cases they were of different sexes, the sex of two pairs was not stated. In 10 cases in which both twins were albinic, both of the twins were of the same sex. Since it usually has been argued that identical twins are always of the same sex, probably no more than 10 pairs of these twins were identical. Furthermore, the probabilities are that all of these 10 pairs were not identical twins.

The biology of twins² and the physiology of twinning³ among human beings has been considered in great detail by Newman and his associates. They ex-

pressed the opinion that a single ovum, or identical twins are the result of one of the following processes (1) fission of the blastoderm, (2) double gastrulation, or (3) fission of the bilateral halves of a single embryonic axis. In order for any one of these processes to take place, some retarding mechanism must be present, which prevents normal implantation of the fertilized ovum. One of the following possibilities probably is the retarding mechanism (1) a defective development in the stimulating mechanism of the spermatozoon, (2) a defective stimulating influence of the corpus luteum on the uterine mucosa, or (3) twinning, which is an hereditary character dependent on a recessive gene.

It is interesting that, in a consideration of identical twins who are also albinos, the possibility of both the occurrence of the twins and the albinism may have genetically similar origins. That is, both may be the result of opportunely placed recessive genes so that in the formation of the gamete the conditions are there for both anomalies.

SUMMARY

Identical albino Negro twins have been described. Some of the essential features of albinism and twinning have been discussed. Whatever the fundamental mechanisms are for the production of albinism and twinning, they are present in the original germ plasma. The scarcity of the combination of genuine albinism in identical twins, as indicated by the literature, has been pointed out.

EDITORIAL

FACTORS IN THE FALLING DEATH RATE FROM TUBERCULOSIS

FOR fifty years the tuberculosis death rate has shown a striking and fairly steady decrease, so that in the United States it is now about one-sixth of its height in the eighties. Moreover, this remarkable phenomenon has been observed to a greater or lesser extent in most of the European nations. On the other hand a world survey indicates that there are still countries, such as Puerto Rico and the Philippines, in which the mortality from tuberculosis not only stands at a very high level but appears to be actually rising.

The recent studies ^{1, 2, 3, 4} bearing on the causes of these variations have by no means completely clarified the problem, but they have at least broadened our conception of the epidemiology of the disease and incited the collection of more accurate data which will perhaps in time make it possible to substantiate what is at present to a considerable extent surmise.

Certain environmental factors, such as urban or rural residence, type of housing, food supplies, occupation, wages, etc., have long been known to show a correlation with the tuberculosis death rate in groups better or worse situated in these regards. That these are potent factors in increasing the incidence of infection with tuberculosis in a community and in activating latent infections is scarcely disputable. Indeed, under the strain of the extreme conditions of malnutrition, crowding, overwork and exposure engendered by the World War, the death rate from tuberculosis in the chief combatant nations rose abruptly during the war years. When, however, one considers the fifty years from 1883 to 1933 in this country, during which the fall in death rate from this disease from approximately 360 to 60 per 100,000 has occurred, it is apparent from the details available that no change in purely environmental factors is sufficient to explain what has occurred. The rate has fallen in urban as well as in rural communities during this period, it has fallen in spite of a tremendous influx of country dwellers into the cities, it has fallen even in the crowded slums, even in the more dangerous occupations, and it began its fall in a period of low wages and unemployment and has continued to fall through several panics and notably through the recent unexampled depression. It seems evident that some more fundamental cause exists for the regression of tuberculosis than variations in purely environmental factors.

⁴ WHITNEY, JESSAMINE S. New and supplementary facts and figures about tuberculosis, National Tuberculosis Association, New York, 1935.

It might be assumed that, following the discovery of the contagiousness of tuberculosis in 1865 and the isolation of the tubercle bacillus in 1882, the consequent gradual development of a great international campaign against this disease was the potent factor leading to its increasing control. The history of this movement, however, shows that it was merely in its infancy during the first twenty-five years of the falling tuberculosis death rate. Even today when there are estimated to be 73,000 beds for tuberculous patients in the United States and over 8,000 public health nurses devoting some of their efforts to the campaign against this disease, it is probably true that anti-tuberculosis measures are not the underlying cause of the continuing subsidence of the disease, though they undoubtedly constitute our most effective method of hastening its decrease in our communities. The difficulties of control measures are better realized when it is stated that there are probably between four and five hundred thousand cases of clinically active tuberculosis in the United States and that the relatively scant data available as to the incidence of infection in the total population would suggest that over 50 per cent have been attacked.

In recent times there is a growing tendency among students of this disease to pay more heed than formerly to the development of racial resistance as possibly the chief factor in its diminution as a cause of death. According to this conception the last fifty years in this country constitute a waning phase of a long drawn out epidemic of tuberculosis.

The word epidemic used in this connection may sound a little strangely and yet there exist a number of reported instances which illustrate clearly the possibility of relatively brief and acute epidemics of tuberculosis. Among the Canadian Indians placed in the Qu' Appelle reservation about 1880 the disease became epidemic about 1884. By 1890 the mortality rate had reached a height of 9,000 per 100,000. It then began to fall relatively rapidly and reached 1,000 per 100,000 in 1907. It remained at close to this level until 1926 and then fell rapidly to 273 per 100,000 in 1931. During the height of the epidemic an acute generalized form of the disease predominated, as the epidemic subsided the dominant type was a chronic one. The incidence of glandular involvement in the population was estimated at 33 per cent in the '90's, whereas in 1932 less than 1 per cent of the school children were found to have this malady. This outbreak as recorded by Ferguson⁵ is a classical example of the epidemic characteristics of tuberculosis in a susceptible race. There are excellent records also of the wave-like spread of tuberculosis in the Scandinavian countries from the cities in the south where it raged in the last century to the sparsely settled northern regions where the highest rates are now observed.

In support also of the influence of human resistance in altering the epidemic characteristics of tuberculosis may be cited the known differences in racial and national resistance to tuberculosis as observed in some of the

⁵ FERGUSON, R. G. The Indian tuberculosis problem and some preventive measures, Trans 29th Annual Meeting Nat Tuberc Assoc, 1933

larger cities of this country Throughout the country the tuberculosis mortality among Negroes is very much higher than among whites, in 1931 in the registration area the rate for whites was 49.7 and for colored was 171.9 That this higher rate cannot be due merely to greater opportunity for infection is indicated by the fact that tuberculin testing in childhood in New York does not show any higher incidence of infection among the colored than among the white children, the difference in mortality rates in these races in this city (white, 52, colored, 260) must depend, therefore, on the difference in ability to combat the infection after it has been acquired This is borne out by the suggestive studies of Asserson⁶ who found in testing babies of different national origins that all were infected at practically the same rate, but that when the positive reactors were later followed up 10 per cent of the Irish babies had died, 5 per cent of the Italian, 3.5 per cent of the American and 1.2 per cent of the Jewish

The importance of this factor of racial resistance is again indicated by the repeated observations which show that in races with low resistance and high mortality rates there is a preponderance of deaths in infancy and the preadult years, a high occurrence of rapidly generalizing forms, of massive exudative lesions and of lymph gland involvement, whereas in nationalities in which the tuberculosis mortality has fallen to a low level there is a great decrease in mortality from the disease in infancy, the peak of the death rate occurs in those over 40 years of age and the characteristic pathological changes of the disease are chronic localized fibrotic lesions in the lungs It seems that by a study of the age incidence of the deaths, the frequency of the various clinical forms and the distribution and character of the pathological lesions one might assess the progress made by any racial strain toward effective resistance to the disease

It is too early to do more than speculate about the character of this resistance to the extension of tuberculous infection There are two factors, however, which seem self evident At the stage of a tuberculosis epidemic where the greatest number of deaths occurs in infancy and childhood, the nation involved is being subjected to a drastic process of selection whereby only the more resistant survive long enough to propagate the race In the second place no degree of resistance has yet been developed which in the face of exposure to the disease will keep down to very low levels the incidence of infection

Analysis of the statistics of tuberculosis in the United States suggests that national resistance to the disease is growing steadily higher If the death rate continues to fall the number of active cases will eventually shrink to manageable proportions In this phase control measures may deal the decisive blow

It would not do to close upon this optimistic note without in fairness pointing to the reverse of the shield There is every reason to believe that a population in which there is very little tuberculosis becomes in time a

⁶ ASSERSON, M. A. Tuberculosis in infants, *Am Rev Tuberc*, 1927, xvi

population highly susceptible to rapidly fatal forms of the disease. It has already been noted that there is an increasingly high proportion of tuberculin negative young adults in the entering classes of our schools. These must be looked upon as a large group of persons who have escaped exposure to infection. The interesting observation has been made in certain training schools for nurses that it is in this tuberculin negative group that the majority of the active clinical cases of tuberculosis develop. This may indicate that we are already beginning to develop a group of people in this country who survive not by virtue of resistance to tuberculous infection, but by grace of fortuitous lack of exposure.

We may conclude that unless it prove feasible to completely exterminate tuberculosis we shall be saved from recurring epidemics due to loss of racial resistance only by the discovery of some immunizing agent.

REVIEWS

Behavior Development in Infants, a Survey of the Literature on Pre-Natal and Post-Natal Activity, 1920-1934 By EVELYN DEWEY, New York, published for the Josiah Macy, Jr., Foundation, by Columbia University Press

This book deals primarily with literature which has accrued since 1920 covering the fetal period and the first two years of life. The references are confined to the theories drawn from psychology and biology on the fundamental processes underlying growth and development of behavior, and to objective studies of fetal and infant behavior.

The material is organized as follows: Part I, growth processes—theories of behavior development, evidence from biology and neurology, correlation of structure and function from animal studies, Part II, behavior of the human fetus, Part III, neonatal behavior, Part IV, behavior during infancy, Part V, summary and conclusions. A bibliography of 216 titles is included.

The writer has avoided mere citations and direct quotations from the various authors and has instead attempted to assimilate and interpret the mass of ideas which has gathered around the development of certain types of infant behavior. The individual abstracts are extremely well written and the entire book is so organized as to provide continuity of thought, which makes for sustained interest and readability.

The literature surveyed covers a period during which there has been great progress in technic of research in infant behavior. The book is an invaluable reference handbook for those who are interested in the problems covered, including not only physicians, but psychologists and biologists as well.

A J R

Practical Neurological Diagnosis, with Special Reference to the Problems of Neurosurgery By R. GLEN SPURLING xi+233 pages, with 99 illustrations. Charles C. Thomas, Springfield, Illinois. 1935. Price, \$4.00.

Anyone who has had the task of presenting clinical neurology to undergraduate students will appreciate the motive which led the author to compile "a simple account of the principles of neurological diagnosis." The method of presentation of the subject in teaching, as well as in such a treatise, is always a matter of concern. What shall be stressed and what shall be omitted? Is it better to "cover the field" and leave the average student with a hodge-podge memory of neurology, or present the kernel of elementary neurology so that he at least can recognize the common disorders of the nervous system?

The author has chosen to present the basic facts which he feels will give the student a working knowledge. The book is divided into three parts: neurological examination, cerebrospinal fluid, and x-ray diagnosis. The first part consists of seven chapters in which the chief subdivisions of the nervous system are covered. The opening chapter deals with the patient's history and gives several important points in history-taking. A little more detail here would have been advantageous. A well-taken neurological history will often tell the practitioner that something is wrong with the nervous system when an examination alone might fail. The cranial nerves are taken up in order. There is a brief anatomical review for each with the clinical application and the technic of examination. This section is very well done. The cerebrum and cerebellum are similarly presented in Chapters 3 and 4. A text written by a neurosurgeon would naturally devote considerable space to these subdivisions because of the great importance of cerebral localization in neurosurgery. However,

it seems that 14 pages devoted to the frontal lobe is a little out of proportion to the brevity used elsewhere, especially when one realizes that the physiology of this lobe still presents many unanswered questions. Only proved clinical facts would seem to have a place in an outline of this type. The examination of the motor and sensory systems is discussed in the chapter on the spinal cord. The presentation here seems a bit disjointed and lacking in perspective. The chapter dealing with reflexes is very well done.

The section on the cerebrospinal fluid is clear and concise. The technic of lumbar puncture, the examination of the fluid, and cerebrospinal fluid dynamics are discussed.

The final chapter deals with roentgen-ray diagnosis, including routine skull examinations, air injections, and lipiodol technic.

The book is up to the usual quality of this publisher. It is well illustrated with 99 well-chosen diagrams and photographs. The bibliography contains 18 titles. Students will find this book of interest.

J G A, JR

Around a World on Fire By KARL E. KASSOWITZ. 198 pages, 14 × 19.5 cm. Gutenberg Publishing Company. 1935. Price, \$2.00.

The World-War gave rise to many strange and thrilling journeys, only a few of which have been printed. The story of Dr. Kassowitz's experiences as an Austrian army surgeon attached to combatant troops, his capture by the Russians and removal to Siberia, his escape with a comrade and flight in Chinese disguise across the frozen wilderness of North China to the relative safety of the Austrian Legation in Peking and his eventual return to Austria after imprisonment by the British in Gibraltar,—all this high adventure is told vividly and modestly and almost too briefly in this attractive little volume.

M C P

Diagnosis and Treatment of Disorders of Metabolism By JAMES S. McLESTER, M.D. 328 pages, 24 × 15.5 cm. Oxford University Press, New York. 1935.

This book reflects the conventional viewpoint concerning metabolic disorders as understood and written about a decade or two ago. The subjects treated include gout, obesity, diabetes, and disorders of the intermediary metabolism, which embrace uraturia, oxaluria, phosphaturia, cystinuria, alkaptonuria, hemochromatosis and pentosuria. Aside from diabetes there is no mention of other endocrine diseases or any hint that these also are important disorders of metabolism. There is nothing about disturbances of calcium metabolism, or of thyroid dysfunction, although basal metabolism is mentioned. If obesity is discussed, it would seem necessary to treat of undernutrition also. The chapter on disturbances of the water balance is highly inadequate. That on acidosis contains directions for various chemical determinations for which the reader might better be referred to one of the standard laboratory manuals. Some of the directions for determination of the plasma carbon dioxide capacity, for the determination of its hydrogen-ion concentration and for estimation of the alveolar carbon dioxide tension, are obsolescent, and indicate lack of recent familiarity with the procedures.

Altogether this is not a very adequate book and cannot be conscientiously recommended.

G A H

The Diseases of the Endocrine Glands By HERMANN ZONDEK, M D (Berlin) 492 pages, 25 × 18 cm William Wood and Company, Baltimore 1935 Price, \$11 00

The author is one of the several eminent internists lost temporarily, at least, to Germany by reason of the political upheavals of the past few years. He is a member of a family prominent in medical science. His brother's name linked with that of Aschheim is widely known in connection with a test for pregnancy. The author's reception in England where he worked for some time in Manchester before going to Palestine doubtless led to this revision of the 1926 German edition of his work and to the excellent translation by Prausnitz.

"Primarily a book for the clinician," it is admirably adapted to this purpose. The first or general part occupies 105 pages of this nearly 500 page volume and contains eleven chapters including those on the relations between the different glands, the physiology and chemistry of the hormonal glands, hormones and vitamins, the vegetative nervous system and its relations to the hormonal system, methods for the examination of patients and general remarks on organotherapy.

It is in the second or special part comprising four-fifths of the volume that the unusual arrangement will appeal particularly to the clinician. Here are considered definite clinical pictures, e.g., Graves' disease, myxedema, tetany, obesity, diencephalopathy, acromegaly, dwarfism, osteomalacia, osteitis fibrosa, Addison's disease, diseases of the generative system and others. The subjects are presented as problems in internal medicine and the glandular and hormonal factors are fully discussed. Case reports and illustrations are taken from the author's own patients.

His points of view as a rule are logical and conservative. To quote a paragraph from the preface, "A number of fundamental hypotheses some of which were derived from the author's personal work on the hormone problem, run through the book and give it its special outlook. As instances the following may be cited: (1) Hormone effect is not an absolute but a variable quantity, depending not least upon the momentary condition of the organ on which it acts, more especially the physico-chemical conditions of its cells, (2) Functional and anatomical changes in endocrine glands should not always be regarded as the cause of disease, but in many cases as the reactions of the glands to morbid processes primarily located in certain other organs, (3) With phylogenetic evolution and progressive differentiation of cellular functions, the hormone appears on the scene as the intensifier of such functions, even in the most highly developed beings, however, not all of them are indispensable to life, (4) The endocrine system is but one link in the chain of vegetative functions of the organism. This should be emphasized in order to avoid the danger of overestimating the role of the hormonal factors."

The book may be highly recommended to the clinician for whom it was prepared

T P S

Practical Endocrinology Symptoms and Treatment By MAX A. GOLDZIEHER, M D 358 pages, 22 × 15.5 cm D Appleton-Century Company, New York City 1935 Price, \$5 00

The author is entitled Endocrinologist, Gouverneur Hospital, Chief of Endocrine Clinic, Gouverneur and Brooklyn Woman's Hospitals, former Professor of Pathology, Royal Hungarian University, Budapest. He has been an active worker in this field for many years and is the author of another book, "The Adrenals."

"Practical Endocrinology" is quite a readable book, it is divided into short chapters and is expressed in a simple and direct style. The arrangement of subject matter is pleasing to the reviewer but may quite possibly offend other readers. There are three short introductory chapters on morphology and physiology of the endocrine

glands and on the examination of the patient. Following sections relate to Disturbances of Development and Growth, Disturbances of Nutrition, Disturbances of Metabolism, etc., with, in closing, a brief and succinct section on treatment. The reader must use the index and turn many leaves to get the full picture of a definite disease, e.g. Graves' disease or myxedema.

The author seems a sufficiently ardent therapist, somewhat conservative toward surgery and x-ray treatments but leaning rather heavily on organotherapy. He recommends pituitary and adrenal tablets by mouth in addition to similar products parenterally. He also describes methods of physical therapy, diathermy and light treatment, adapted to the endocrine organs.

The book was written and arranged for the general practitioner. It expresses the ideas and opinions of the author without argument or discussion. There are no references to the work of others. It is not therefore a good work for students if their skepticism is to be stimulated by differences of opinion, but the book will doubtless be highly valued by those who know the author well and who have great confidence in his opinion.

T P S

COLLEGE NEWS NOTES

NEW LIFE MEMBERS

The total number of Life Members in the American College of Physicians has been increased to fifty-eight. The following Fellows have become Life Members since January 1, 1936, their listings being in the order of their accession:

Dr Casper H. Benson, Columbus, Ohio
Dr Donald Gregg, Wellesley, Mass
Dr James Ray Arneill, Denver, Colo
Dr Thomas Fitz-Hugh, Jr., Philadelphia, Pa
Dr C. Charles Burlingame, Hartford, Conn
Dr Noble Wiley Jones, Portland, Ore
Dr Cecil M. Jack, Decatur, Ill
Dr Roy M. Van Wart (formerly of New Orleans, La.), Descanso, Calif

The members of the Board of Regents of the College have joined in issuing a personal invitation to the Governors to a dinner to be held in Detroit on Sunday evening, March 1, prior to the opening of the Clinical Session.

STATE MEETING OF COLLEGE MEMBERS IN LOUISIANA

Under the Chairmanship of Dr Joseph E. Knighton, Governor of the College for Louisiana, a combined scientific and social meeting was held at Shreveport on January 30, 1936. The meeting was conducted particularly for those Fellows and Associates of the College residing in and about Shreveport, and was attended by some guests, one of whom was the President of the local organization representing the American College of Surgeons.

Dr T. P. Lloyd discussed subacute bacterial endocarditis, with a report of a case; Dr W. S. Kerlin discussed pernicious anemia and exhibited a patient showing the characteristic achylia and neurological changes, but only minor blood changes; Dr A. A. Herold discussed recent developments in the treatment of diabetes.

The scientific discussions were followed by a dinner and a delightful evening of good fellowship. Similar meetings are planned for the future.

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following gifts to the College Library of publications by members. Special emphasis is placed on gifts of books of which members are the authors, for the College is desirous of obtaining particularly all books written by its members.

Dr Sigmund S. Greenbaum (Fellow), Philadelphia, Pa.—one autographed book, "Diseases of the Mouth and Their Treatment."

Dr J. Arthur Myers (Fellow), Minneapolis, Minn.—two books, "Modern Aspects of Diagnosis, Classification and Treatment of Tuberculosis" and "The Child and the Tuberculosis Problem."

Dr Linn J. Boyd (Fellow), New York, N. Y.—one translation, August Bier's Study on Inflammation.

Dr Walter L Bierring (Fellow), Des Moines, Iowa—one reprint, "The Social Security Act"

Dr Herbert T Kelly (Fellow), Philadelphia Pa—one reprint

Dr Alfred J Scott, Jr (Fellow), Los Angeles, Calif—one reprint

Dr John W Torbett (Fellow), Marlin, Texas—two reprints

Dr Stephen H Curtis (Associate), Troy, N Y—six reprints

Dr William B Grayson (Associate), Little Rock, Ark—two reprints

Dr R R Hendershott (Associate), Tiffin, Ohio—one reprint

At the Fourth Annual Symposium on Heart Disease of the Los Angeles County Heart Association, during December, the following Fellows contributed as indicated

Dr John C Ruddock—"Coronary Occlusion"

Dr B O Raulston—"Circulatory Edema"

Dr E Richmond Ware—"Pulmonary Embolism"

Dr R Manning Clarke—"Paroxysmal Tachycardia"

Dr A M Hoffman—"Peripheral Vascular Failure"

Dr Donald J Frick—"The Use of Drugs in Cardiovascular Disease"

Dr A S Granger—"Diet in Heart Disease"

Dr Howard F West—"The Challenge of Arteriosclerosis"

The Guilford County Medical Society recently awarded to Dr Frederick R Taylor, High Point, N C (Fellow), a plaque for the most "outstanding contribution" to medical literature contributed by members of the society during the past year. Prominent among Dr Taylor's contributions was a chapter in Oxford Medicine on "Arachnidism—The Clinical Effects of Spider Bite"

Dr Mary O'Malley (Fellow), for many years Clinical Director of St Elizabeths Hospital, Washington, D C, has resigned that position and retired from active practice. She is now residing in Buffalo, N Y

Dr Salvatore Lojacono (Fellow) has resigned the Superintendency of Morgan Heights Sanatorium at Marquette, Mich, effective January 25, 1936, and is now located in Lansing

Dr Walter P Gardner (Fellow) has resigned from the Hastings State Asylum at Hastings, Minn, to accept the Medical Directorship of the Fergus Falls State Hospital at Fergus Falls, Minn. This is a two thousand bed hospital for psychiatric cases

Dr Edward Weiss (Fellow), a member of the Department of Medicine of the Temple University Medical School, has been made Professor of Clinical Medicine in that Institution

Dr Constantine P Faller (Associate), Harrisburg, Pa, has been awarded the biennial Seibert Prize of \$500.00 for study in Europe of the Harrisburg Academy of Medicine

Dr Joseph I Linde (Fellow), Clinical Professor of Pediatrics, Yale University School of Medicine, is the Health Officer of New Haven

Dr Edwin C Swift (Fellow), Jacksonville, Fla , is the President of the Florida East Coast Medical Association for the present year

Dr Arthur U Desjardins (Fellow), Rochester, Minn , and Dr Walter M Simpson (Fellow), Dayton, Ohio, are members of the American Committee for the International Conference on Fever Therapy to be held in New York City during September, 1936 Therapeutic, physiologic and pathologic phases of fever will be discussed All papers presented will be translated in abstract form into French, English and German

Dr Thomas F Sellers (Associate), Atlanta, Ga , is Secretary of the newly organized Georgia Association of Pathologists

Dr William Henry Walsh (Fellow), Chicago, has been appointed as a consultant to study the hospital needs of the Institute of Tropical Medicine at San Juan, Puerto Rico

Dr Robert A Black (Fellow), Chicago, has been appointed a member of the Chicago Board of Health

Dr Reginald Fitz (Fellow), Boston, Mass , for many years Associate Professor of Medicine at Harvard University Medical School, has been appointed Professor of Medicine in the Boston University School of Medicine and Director of the Robert Dawson Evans Memorial, the department of research and preventive medicine of the Massachusetts Memorial Hospitals

Dr Hyman I Goldstein (Associate), Camden, N J , delivered addresses during the past year before the Congress on Gout and Uric Acid at Vittel, France, the International Congress of the History of Medicine at Madrid, Spain, and before the Pazmany Peter Royal University of Budapest

Dr Lewis J Moorman (Fellow), Oklahoma City, was recently named to Oklahoma's Hall of Fame by the Oklahoma Memorial Association in recognition of his achievements in medicine Dr Moorman is a former Dean of the University of Oklahoma School of Medicine and ex-President of the Oklahoma State Medical Association and an ex-President of the Southern Medical Association

Dr Alvan L Barach (Fellow), Columbia University College of Physicians and Surgeons New York City, has received a grant from the National Research Council for research in the therapeutic use of helium

Dr Raymond G Taylor (Fellow), Los Angeles, was elected one of the Vice Presidents of the Radiological Society of North America at its last annual meeting

Dr Frank H Redwood (Fellow), Norfolk, Va , was elected a Vice President of the Seaboard Medical Association at its last annual meeting

Dr John G FitzGerald (Fellow), Dean of the Faculty of Medicine and Director of the School of Hygiene and Connaught Laboratories, University of Toronto, delivered the annual Morris Hertzstein lectures, March 2-4, under the auspices of the Medical Schools of Stanford University and the University of California

Dr Millard E Winchester (Fellow), Brunswick, Ga , has been reelected Secretary of the Georgia Public Health Association for 1936

Dr Herbert A Burns (Fellow), Superintendent of the Minnesota State Sanatorium for Consumptives at Ah-Gwah-Ching, has also been placed in charge of a new annex erected exclusively for treatment of Indians. The Indian annex will be under the direction of the State Board of Control, in cooperation with the Federal Office of Indian Affairs. It is said to be the first sanatorium in the United States for Indians, excepting a small inadequate one at Onigun on Leech Lake, which has now been destroyed by fire and the patients transferred to the new institution

Dr Anthony Bassler (Fellow), New York City, was elected President of the National Society for the Advancement of Gastro-Enterology at its annual meeting in New York during December

Dr Elliott P Joslin (Fellow), Boston, Mass , delivered the Eastman Memorial Lecture, January 10, on "Diabetes of Today and Tomorrow," in connection with the tenth anniversary of the opening of the University of Rochester School of Medicine and Dentistry, Strong Memorial Hospital and the School of Nursing

CHARLES GODWIN JENNINGS, M.D., F.A.C.P.

OBITUARIES

CHARLES GODWIN JENNINGS

Charles Godwin Jennings was born at Leroy, New York, February 4, 1857, of the union of Thomas A. Jennings and Matilda Godwin. He began his education in the public schools of Seneca Falls, New York, and graduated in 1875 from Mynderse Academy. In the same year he began the study of medicine in a preceptor's office, where he remained until October 1876, when he entered Detroit Medical College from which he graduated, with the degree of Doctor of Medicine, in 1879.

During his Senior year he served as undergraduate interne in St. Luke's Hospital and upon graduation received the appointment of Resident Physician. In May 1880 Dr. Jennings began the practice of medicine in Detroit as Assistant to Dr. E. L. Shurley. Thus it is that Dr. Jennings practiced his profession in the city of his adoption continuously for fifty-six years. No truer estimate of the quality and scope of that long period of beneficent service to the public and his profession can be noted than the erection in 1930 of the Charles Godwin Jennings Hospital on Jefferson Avenue, largely by devoted friends and patients as an enduring testimonial of the appreciation, admiration and affection in which he was held by those who knew him best.

At one time or another he had held commanding positions on the staffs of all the Hospitals of his city. At the time of his death, Dr. Jennings was Chairman of the Board of Trustees and of the Medical Board and attending physician of the Charles Godwin Jennings Hospital. He was consulting physician to the Harper Hospital, the Grosse Pointe Hospital, the Children's Free Hospital, the Detroit Tuberculosis Sanitarium, and to the U. S. Marine Hospital.

In the period between 1881 and 1920 Dr. Jennings was a member of the Faculties of the Detroit Medical College and the Detroit College of Medicine and Surgery. Beginning his teaching as Lecturer in Chemistry he successively occupied the chairs of Professor of Chemistry, Professor of Diseases of Children, Professor of Practice of Medicine and Diseases of Children and finally Professor of Medicine. Dr. Jennings was a member of many medical societies and associations, among which are the American Medical Association, American Climatological Association, American Therapeutic Society, American Pediatric Society, The Michigan State and Wayne County Medical Societies and the American College of Physicians, in which he took an active part during the twenty years of his membership, having been Vice-President, Regent and Chairman of the Board of Governors. At the time of his death Dr. Jennings was Chairman of the Committee on Arrangements for the Annual Meeting in Detroit this year.

Dr Jennings was 1st Lieut , Medical Reserve Corps, U S Army, 1911 to 1917, Captain, Medical Corps, U S Army, 1917-1919, on duty Camp Grant , member Central Examining Board at Detroit 1911-1918

He had been a member and President of the Detroit Board of Health, member of Gorgas Memorial Institute, etc

The University of Michigan conferred upon him the honorary degree of Master of Arts and from the College of the City of Detroit he received the honorary degree of Doctor of Science

Dr Jennings was a prolific reader. He was Associate Editor of the *Annals of Clinical Medicine* and of the *Archives of Pediatrics*, Editor of *The Microscope*, 1885-1890, contributor to Tice's Practice of Medicine, Therapeutics of Internal Diseases, and to the Cyclopedia of Diseases of Children

Dr Jennings was a member of the Yondotega, the Wilenagemota and the Grosse Pointe Clubs, as well as the Sons of the American Revolution

It is not for his professional, scientific, literary or civic attainments, however outstanding, that Dr Charles Godwin Jennings will be remembered by his colleagues far and near, but for the qualities of heart and mind, and the gift of true friendship possessed to the highest degree by this kindly gentleman. His charming personality, his keen sense of humor and his generous devotion to his friends, his colleagues and his students, won for him the confidence and affection of men and women throughout the United States and Canada. As evidence of the esteem in which he was held in his own State a testimonial dinner was given him on February 28, 1934, by the Wayne County Medical Society, on the fifty-fifth anniversary of his graduation in medicine. This dinner was attended not only by men prominent in medicine, dentistry and the civic leaders of the State, but also by colleagues from all parts of the country.

One of the underlying causes for Dr Jennings' continued physical fitness, his alertness of mind and his unquenchable enthusiasm for his profession and for life in general was his devotion to his hobbies, namely fly-fishing and hunting, in each of which he was an expert. Each year saw him off to the great open spaces for several weeks with rod and gun.

Fortunate indeed were those of his close friends who were able to accompany this ardent sportsman and nature lover.

Few men, who have gone on the long journey, from any walk in life, are missed so acutely by as large a circle of loyal and devoted friends as is this great physician.

WILLIAM GERRY MORGAN, F A C P

DR HENRY WALD BETTMANN

Dr Henry Wald Bettmann (Fellow), Cincinnati died December 5, 1935, aged, 67 years

Dr Bettmann was born in Cincinnati, attended public schools in that city, and graduated with highest honors at the University of Cincinnati. He was a charter member of the Cincinnati Chapter of Phi Beta Kappa. During his undergraduate days at the University he was a prominent member of the football team. In 1889 he graduated with high honors from the Medical College of Ohio (University of Cincinnati). After serving his internship at the Cincinnati Hospital, he spent two years in postgraduate work abroad, chiefly in Berlin, Vienna and Prague. On his return to Cincinnati in 1893, he began general practice but continued his scientific work at the Cincinnati Hospital. While serving as curator of the laboratory he originated the first city-wide service for the bacteriological diagnosis of diphtheria, and with a group of colleagues gave the first course on clinical microscopy in Cincinnati.

In 1894 Dr Bettmann was appointed pathologist to the Cincinnati Hospital. During the years that followed, he did much investigative work and published many papers and in 1905 he won the Alvarenga prize for his monograph on "The Shape and Position of the Stomach." He served as pathologist until 1907, when a serious autopsy infection forced his resignation.

Early in his practice, Dr Bettmann became interested in gastro-enterology. He was a charter member of the American Gastro-Enterological Society and was its President in 1920.

In 1921 he was appointed Director of the Medical Service of the Jewish Hospital of Cincinnati, and inaugurated the weekly clinical conferences at that institution, which he directed until his death.

In 1931 he was made Professor of Medicine in the University of Cincinnati College of Medicine, having held the rank of Associate Professor for a number of years previously. His course in gastroenterology was an outstanding one.

The claims of a large practice did not prevent his filling many other positions. He was President of the Academy of Medicine, Cincinnati, in 1927. He was one of the founders, and for many years a member of the governing body of the University School of Cincinnati. For over twenty-five years he was an active member of the board of the Public Library. He was intensely interested in belles lettres and had a profound knowledge of the masterpieces of English, French and German literature.

He was an amateur botanist of distinction, he was a world authority on chess problems To his patients he was indeed the beloved physician To his friends, his charm, his goodness and his loyalty were real sources of inspiration He was an honor to his profession and his life work will endure Of him it might well be said, " He loved truth and beauty and he never did an ignoble thing "

ALFRED FRIEDLANDER, M D , F A C P

ERRATUM

" Chemical Studies in Myasthenia Gravis," by M Adams, M H Power and W M Boothby The sentence which begins in the last line of page 825 of the January issue should have read If the five patients (cases 11, 3, 12, 13 and 14), who were all 65 years of age or more, and obese, are excluded from consideration, the coefficients of the remaining patients will be found to vary from 6.6 to 9.7

LONG-STANDING CASES OF AURICULAR FIBRILLATION WITH ORGANIC HEART DISEASE, SOME CLINICAL CONSIDERATIONS^{*}

By WILLIAM A. EVANS, M.D., F.A.C.P., *Boston, Massachusetts*

THE onset of auricular fibrillation is generally considered an unfavorable event in the course of organic heart disease. The reports in the literature indicate that the average duration of life after the onset of fibrillation is a matter of a few years comparable to that following the onset of malignant neoplastic disease. White¹ gives two to three years as the average duration. Of a group of 173 fatal cases Willius² found the average duration one year and three months. In 20 cases of auricular fibrillation associated with rheumatic heart disease Jones³ found an average duration of three years and six months. Clerc and Stieffel⁴ observed 54 per cent of their cases living a year or more and only 9 per cent over three years. Frick and Kennicott⁵ reported an average duration of five years and eight months in a group of cases observed to exitus, while Cookson's⁶ averages are five and one-fourth years for the rheumatic group and seven years in the non-rheumatic group. Thus in the more recent studies with perhaps longer periods of observation the outlook in auricular fibrillation appears to be more favorable. A few isolated instances of auricular fibrillation of unusually long duration have been reported. The longest is that of Heitz,⁷ a case of non-valvular heart disease with fibrillation observed over a period of 32 years. He also reports two cases of 10 and 12 years' duration. Vaquez⁸ observed a case for 12 years. Laslett's⁹ report is of a case of 15 years' duration, and he mentions a case of Cowan's surviving almost 12 years. In the group studied by Frick and Kennicott, instances of fibrillation observed for 20, 16, 15, 13 and 12 years are recorded.

The purpose of the present study was to analyze a group of cases of organic heart disease known to have persistent auricular fibrillation for a long period of time and to determine what features may have contributed to their longevity. Cases of transient auricular fibrillation were excluded. From the records of the Peter Bent Brigham Hospital and of the private

^{*} Received for publication September 5, 1935.

From the Medical Clinic of the Peter Bent Brigham Hospital, Boston, Massachusetts.

practice of S A Levine of Boston, 39 such cases were collected. The duration was regarded as being from the time at which auricular fibrillation was first recognized clinically until the time the patient was last seen. Inasmuch as in many instances the onset of auricular fibrillation must have antedated by years or months the time of clinical recognition and inasmuch as 26 or two-thirds of the cases are known to be still alive, the actual duration must be really much longer. Ten in the group are known to be dead and three are lost. At the time of onset the diagnosis was usually confirmed by the electrocardiogram, but in a few instances the diagnosis was considered to be established with certainty when made by a number of observers at different times clinically. In this group the duration of observed fibrillation was at least 8 years, the upper limit being three cases of 15, 17, and 18 years respectively, and the average duration for the whole group 10.3 years. The average duration in the rheumatic group was 10.0 years, as compared with 10.6 in the non-rheumatic group.

SEX

The sex incidence in the whole group was not remarkable, there being 22 males and 17 females, or 56 per cent and 44 per cent, respectively. In the rheumatic group there was a predominance of females (41 per cent versus 59 per cent), while in the non-rheumatic group there was a predominance of males (76 per cent versus 24 per cent). The slight predominance of males is quite similar to that found by Lewis,¹⁰ Willis,² Brachman¹¹ and Mohler and Lintgen¹² in unselected groups of cases with auricular fibrillation. Campbell¹³ and Levine¹⁴ observed an equal distribution, and White¹⁵ a slight predominance of females, while Cookson⁶ in a large group found twice as many females as males.

AGE

There have been many reports of the age incidence in auricular fibrillation and eight of these have been charted (figure 1). There is the same

FIG 1 Age incidence in auricular fibrillation of unselected groups of cases obtained from the literature compared with the age incidence in this series of long-standing fibrillation

general shape and character to these curves, and they offer a satisfactory standard for comparison with our group. Here the age taken was that at the time at which auricular fibrillation was first recognized. It is apparent that the cases of long duration may occur at about any age but that they are most common in the fifth and sixth decades as with unselected cases of auricular fibrillation. The close agreement of the curves indicates that the age of the patient at the time of onset has little to do with the prognosis. When the valvular and non-valvular cases are analyzed separately, slight differences are detected which may have significance, and this will be discussed below.

INCIDENCE OF ASSOCIATED HEART DISEASE

A number of reports on the incidence of associated heart disease are available, and these have been tabulated for comparison (Table 1). Here

TABLE I
Type of Heart Disease Associated with Auricular Fibrillation

Authors	Number of Cases	Rheumatic Heart Disease per cent	Non-Rheumatic Heart Disease per cent				
			Artero-sclerotic	Hyper-tensive	Thyroid	Syphilitic	Unclassified
Mohler, Lintgen ¹⁹	220	42	32		4.6	1.4	20
Levin ²²	33	64	15		9	3	9
Clerc, Stieffel ⁴	75	65					
Coffen ¹⁸	37	62					38
Campbell ¹³	100	53	36		11		
Brachman ¹¹	359	62	32		3	2	
Levine ¹⁴	128	36	31				34
Cookson ⁶	361	69	22		7	2	
Stroud, Laplace, Reisinger ²⁰	253	48	35		4	9	4
McEachern, Baker ¹⁶	575	34	31	17	8	3	7
Frick, Kennicott ⁵	51	49					51
Yater ²¹	145	20		8	44	1	27
Lewis ¹⁰	141	54					46
Willius ²	500	31		20	33		16

the agreement is not so satisfactory, partly because of different terminology and criteria for diagnosis, partly because of the variable incidence of such diseases as rheumatic fever and toxic goiter in different localities and possibly also because of a greater interest in certain types of disease in different institutions. However, certain general features are available for comparison.

Rheumatic heart disease occurred in 22, or 54 per cent, of our group, a figure one might reasonably expect to find in an unselected group. A diagnosis of mitral stenosis was made in all of the 22 cases. An additional

diagnosis of aortic insufficiency was made in six, two of which also had aortic stenosis. There is nothing peculiar about this distribution which would help in basing the prognosis on the kind of valve lesion. The average age of the patients at the time of onset of auricular fibrillation in this rheumatic group was 39.7 years. This compares with an average of 37 years found by Levine¹⁴ in a comparable group. This supports the view that in rheumatic heart disease auricular fibrillation is less serious if it occurs in older rather than in younger individuals.

Syphilitic heart disease is very rarely associated with auricular fibrillation, and it is not surprising that no instance of that type of heart disease appeared in our series. In the 31 cases in which the Wassermann test was carried out it was reported negative.

Hyperthyroidism was present at the time auricular fibrillation was recognized in two of the cases. However, the fact that fibrillation persisted after thyroidectomy and a restoration of the basal metabolism to normal limits would indicate that the hyperthyroid state was not alone responsible for the irregularity. Indeed one of the cases had rheumatic heart disease with mitral stenosis, and the other was approaching the older age group with a large heart, the enlargement being confirmed roentgenologically, when auricular fibrillation and hyperthyroidism were first recognized. In such a series one would not expect to find fibrillation of long duration associated with hyperthyroidism without underlying organic heart disease as well.

Non-Valvular Heart Disease Our series contains 17, or 44 per cent, of such cases, five of which (13 per cent of the total) might be considered to have hypertensive heart disease. The relative incidence of hypertensive heart disease was higher in the comparable studies of McEachern and Baker¹⁶ and Willis² so that hypertension would appear to be a somewhat unfavorable factor in this group. The average age at the onset of fibrillation in this group was 50.4 years, which is significantly less than the average of 58 years found by Levine¹⁴ in a comparable group of undetermined duration. Thus, here in contrast with the rheumatic group, the duration of life following the onset of fibrillation is longer in the relatively younger patients. Therefore, it seems that in the group studied there is a difference of about 10 years between the age of onset of fibrillation in valvular and non-valvular cases (39 years and 50 years), as compared with a difference of about 20 years in the two groups of unselected fibrillators.

STATUS OF THE HEART AND CIRCULATION AT THE ONSET OF AURICULAR FIBRILLATION

Heart Size It is generally accepted that a large heart indicates a poor prognosis. However, in this series the examination at the onset of fibrillation indicated some degree of enlargement in 32 instances, and in the others it may have been present but not recognized. In 19 instances the enlargement was marked and in five of these this was confirmed roentgenologically.

Hypertension At the outset of this study it was thought that evidence might be found showing that the presence of hypertension exerted a favorable influence on the course of mitral stenosis (Levine and Fulton¹⁷). However, the data seemed to be too meager either to prove or disprove this conception. Of the 22 rheumatic valvular cases, only two were observed to have a systolic arterial tension above 150 mm. of mercury during the entire period of observation. Furthermore, the average blood pressure for the various decades as observed at the onset of fibrillation follows more closely the normal curve than that found by Levine and Fulton for mitral stenosis. However, a number of our patients developed increasing pressures during the period of observation, five of them reaching pressures above 150. Thus, with seven of the 22 patients having or acquiring pressures above 150, it appeared that hypertension was a little more prevalent in the valvular group (average age 38.7 years) than one might have expected in the average population of the same age period.

Of the 17 patients with non-valvular heart disease five had hypertension when first seen at the onset of fibrillation and in two hypertension developed.

Objective Signs of Congestive Failure Persistent râles at the lung bases, enlargement of the liver or peripheral edema was noted in 16 cases at the onset of fibrillation. In 19, no objective evidences of congestive failure were demonstrable although in some of these there was dyspnea and limitation of normal activity and later the development of congestive failure. This compares with Campbell's¹³ observation that signs of failure are present in about one-half the cases of auricular fibrillation when seen for the first time. Three cases were very striking in having greatly enlarged hearts and marked signs of congestive failure when first seen, two of whom are still living after being followed for nine years and the other having been lost eight years after the onset of fibrillation.

Ectopic Beats A few cases in this series were observed in the period just preceding the onset of fibrillation and they commonly had numerous premature beats. Occasionally these beats were so numerous that differentiation from auricular fibrillation could only be made electrocardiographically. According to White,¹ Wilhus,² Coffen,¹⁸ and also Clerc and Stieffel,⁴ extrasystoles associated with fibrillation indicate a poor prognosis. In this series, however, five cases were encountered in which the initial electrocardiogram showed premature ventricular beats as well as fibrillation. Thus their presence cannot be taken to indicate necessarily an unfavorable outlook. Apart from evidences of right or left ventricular preponderance no other electrocardiographic anomalies were encountered in the initial tracings.

DISCUSSION

It is apparent that no clues to prognosis are offered by the evidence here analyzed. From data obtainable upon examination of a patient at the inception of auricular fibrillation it would seem impossible to predict his life

expectancy in any but the most general way. The most important factor in his longevity is perhaps his good fortune in escaping the serious accidents of the type of heart disease from which he is suffering. In the rheumatic patient with auricular fibrillation the most common cause of death after congestive failure is embolism and pulmonary infarction (Laws and Levine¹⁹). Another frequent cause of death in the patient with rheumatic heart disease is subacute bacterial endocarditis, but it is well known that this is very rare in auricular fibrillation, and there was no instance of it in our series. At least one episode of embolism was noted in 10 of our patients during the period of observation, and many survived a number of embolic phenomena in various organs. In the older age group death is commonly brought on by the vascular accidents of hypertension and coronary artery disease. Coronary thrombosis is recognized as rare in the presence of fibrillation and was observed in only one of our patients during the period of observation. However, two others were known to have survived attacks at or prior to the onset of fibrillation. One patient survived a cerebral vascular accident associated with hypertension. In contrast to the rheumatic group there was a conspicuous rarity of embolic phenomena.

CONCLUSIONS

1. A study was made of a group of 39 patients with organic heart disease who were known to have had auricular fibrillation for long periods of time ranging from 8 to 18 years.

2. Of these 39 cases there were 22 with rheumatic valvular and 17 with non-valvular heart disease. There were no cases of syphilitic or thyroid heart disease.

3. There was a predominance of females in the valvular group and of males in the non-valvular group.

4. Cases were encountered in all decades from the second to the eighth inclusive. The age distribution was quite similar to that of unselected groups reported in the literature except for a slight tendency to an increased predominance of cases in the fifth and sixth decades at the expense of the seventh and eighth decades. The average age in the rheumatic valvular group was slightly older and in the non-valvular group slightly younger than in comparable unselected groups.

5. Hypertension appeared to be slightly more common in the rheumatic valvular group and slightly less common in the non-valvular group than one would expect in the comparable groups of undetermined duration.

6. The majority of the patients had enlarged hearts, some to an extreme degree, at the onset of fibrillation, and almost half had objective manifestations of congestive failure when first seen.

7. It is believed that these patients owe their longevity in large part to their good fortune in escaping or surviving the accidents to which patients

with cardiac disease in general are subject, namely embolism, subacute bacterial endocarditis, cerebral hemorrhage and coronary thrombosis

It is a pleasure to acknowledge the suggestions and criticisms of Dr S A Levine

THE ETIOLOGY OF ABDOMINAL PAIN IN DIABETIC ACIDOSIS¹

By HARRY WALKER, M D , *Richmond, Virginia*

THE usual signs, symptoms, and laboratory findings in prediabetic coma are well known. The clinical picture of dehydration associated with malnutrition, polyuria, and odor of acetone on the breath, decreased intraocular tension, and Kussmaul breathing, when found in conjunction with sugar and acetone bodies in the urine make a clinical picture that could hardly be confused with any other condition. Other laboratory findings are a high blood sugar, a low CO₂ combining power of the blood plasma, and leukocytosis. The white cell count sometimes rises above 65,000¹ per cubic millimeter of blood.

This picture is usually clear cut and offers no difficulty in diagnosis. There are, however, exceptions to this rule, in fact, the picture is occasionally complicated by symptoms and signs referable to the abdomen which may make it difficult or impossible to determine whether the patient has an intra-abdominal surgical lesion, or whether the symptom complex from which the patient is suffering is due entirely to acidosis. Obviously, it is of primary importance promptly to make a differential diagnosis. To subject a patient on the verge of diabetic coma to an emergency surgical operation is never wise unless a true emergency exists, on the other hand, to delay too long an operation in a diabetic that needs emergency surgery is equally unwise.

The following is a case report of this complex syndrome, presenting an excellent example of the difficulty in diagnosis that some of these patients present when first seen.

CASE REPORT

J. B., male, aged 17, admitted to Memorial Hospital March 25, 1933.

The patient, a known diabetic for two years, was discharged from this hospital on November 10, 1932, following treatment for an early diabetic coma. At the time of his dismissal the patient was placed on a diet with 225 grams of carbohydrate, 80 grams of protein, and 60 grams of fat together with 20 units of insulin three times a day before meals. The patient progressed well on this treatment and was followed in the Out-Patient Department weekly. He followed his instructions faithfully until seven days before admission. At this time his supply of insulin became low and he took only 15 units each day instead of his usual 60 units. On the day before admission he did not eat as much as usual and took only 10 units of insulin, before breakfast. On the day of admission he ate practically nothing. The patient went to bed feeling very well but awoke in the early part of the night (about 1 00 a m.) nauseated. He continued to be nauseated throughout the night but did not vomit until the following morning at about 8 00 a m. He continued to vomit throughout the day, vomiting every five to 10 minutes. After each attack of vomiting the

* Received for publication October 21, 1935.

From the Department of Medicine, Medical College of Virginia.

patient would drink a large quantity of water. About 1 00 p m the patient began having a sharp pain in the epigastrium just to the left of the mid-line. The pain increased in severity, was sharp and shooting in character, soon extending over the entire abdomen and radiating up the chest as high as the supra-sternal notch. The pain was increased by deep respiration. Nausea, vomiting, and constant pain continued, all increasing in severity. At about 4 00 p m the patient's mother gave him 40 units of insulin which seemed to have no effect on either the vomiting or pain. All during the day and the night before the patient had passed large amounts of urine, much more than usual. At 6 00 p m the patient was admitted to the hospital.

Physical examination at that time revealed a much dehydrated white boy in agonizing pain. The respiration was shallow. Examination of the head and neck showed nothing unusual. The heart rate was 100 and the blood pressure 120 mm of mercury systolic and 80 diastolic. There was no evidence of cardiac enlargement and no murmurs were present. The lungs were clear. The abdomen was rigid, board-like in character, giving one the impression that one was dealing with a perforated peptic ulcer or some other emergency surgical condition. There was a slight infection of the terminal phalanx of the left thumb. The remainder of the examination was negative.

The laboratory reports were as follows: Urine, amber, clear, acid, specific gravity 1.025, heavy trace of albumin, sugar four plus, acetone four plus, diacetic acid two plus. Red blood count 5,160,000, hemoglobin 95 per cent, white blood count 26,600, 87 per cent polymorphonuclears, 11 per cent lymphocytes, and 2 per cent eosinophiles. The blood sugar was 444, and the plasma CO_2 was 20.2 volumes per cent.

Immediately after admission the patient was given 50 units of insulin, hypodermically, and 1,000 c c of normal saline were given by vein. The abdominal pain immediately began to lessen in severity and within 45 minutes the pain had completely subsided and the abdomen had become soft. At this time the blood sugar was repeated and was found to be 380 mg per 100 c c of blood, the CO_2 was 22, the urine was still positive for sugar, acetone, and diacetic acid.

Confronted with a situation of this kind, how can a differential diagnosis be made? The answer cannot be given without making qualifications. Literature concerning this condition is scarce, however, McKittrick² in a somewhat recent review suggests the following observations as useful. First, he (McKittrick) states in his review of patients who had been operated on and no surgical lesion found, that these patients before operation always suggested some wide-spread abdominal pathologic process as the cause of the abdominal findings. Second, that in diabetic coma, vomiting usually precedes pain, while in pre-coma cases with surgical complications, pain usually precedes vomiting—particularly is this true in acute appendicitis. Third, when appropriate therapy is applied, the signs and symptoms due to acidosis clear up promptly, while, of course, the signs and symptoms in the surgical cases will usually progress. He further states that differentiation is not always possible and, when the patient does not respond in a reasonable length of time, an exploratory laparotomy should be done.

The etiology of this interesting condition has never been satisfactorily explained. Various possibilities, of course, have been suggested and explored. Dilatation of the stomach has been offered as a possible cause, but it is common knowledge that gastric dilatation does not produce a true spasm of the abdominal muscles. It, of course, does produce discomfort

in the abdomen, but rarely if ever agonizing pain. Hepatic engorgement has also been suggested as an explanation, but here again engorgement of the liver as we see it clinically never produces a syndrome comparable to that seen in the case reported here. That the abdominal symptoms in diabetic acidosis could be due to a surgical lesion is ruled out by the fact that recovery is too prompt. In addition to this fact, exploration fails to find sufficient incriminating evidence against any abdominal organ to account for the clinical findings, and the same may be said of autopsy findings in these cases. Neither does dehydration explain all of the facts since it is a routine finding in pre-coma cases, and yet, certainly the majority of even markedly dehydrated patients present no abdominal signs or symptoms. Then again dehydration when found in other clinical conditions does not produce the findings reported here.

It is always dangerous to draw conclusions from one case, yet, in the case history here reported several things stand out. First, the vomiting preceded the pain by several hours, second, the patient received insulin in large amounts before entering the hospital, yet, in an insufficient quantity to control the acidosis, third, prompt relief followed the administration of a small quantity of normal physiological salt solution, fourth, the patient continued to show evidence of acidosis after the pain had subsided. These facts suggest that acidosis was not solely responsible for the symptoms since, when measured by laboratory means, there was no reduction. The history suggests too that insulin was certainly not the sole factor in controlling the symptoms in this case, but rather that the salt solution was responsible for the relief of symptoms. When one thinks of other clinical conditions such as heat cramps and "gastric tetany," the connection seems even more probable.

Heat cramps, a condition described by Edsall,³ is commonly seen in the South, especially in the summer months in those who do manual labor while exposed to the sun or high temperatures. It is well established that this condition is in some way associated with chloride deficiency and is brought about by loss of chlorides, chiefly through perspiration. Salt solution not only promptly controls the symptoms but prevents them. It might be added that the pain in this condition is so severe that it does not readily yield to moderate, or for that matter, sometimes even to large doses of morphine sulphate.

A review of some of the facts known about "gastric tetany" associated with pyloric obstruction makes this explanation even more plausible. Here the patient loses his chlorides by vomiting and not only does abdominal pain follow but so does violent pain in any group of muscles that are vigorously exercised. In view of these facts, it is suggested that the chain of events producing abdominal symptoms in diabetic acidosis probably develops in this order. First, because of improper fat oxidation, acidosis develops, the acidosis in susceptible patients causes vomiting, the acidosis not being controlled, the vomiting continues. Second, the continuous vomiting depletes

the body of chlorides because of loss of hydrochloric acid. The excessive diuresis would produce further chloride loss. Third, in the exercise of abdominal muscles and muscles of respiration, there is brought about a condition in these muscles similar to that which is present in heat cramps and "gastric tetany", hence, the pain, and hence the relief by sodium chloride.

It is regretted that no blood chloride determinations were made on this patient. However, it must be remembered that, when marked dehydration of the body is present, a determination of the plasma chlorides is not a true index of the total body chlorides. In fact, plasma chlorides may remain normal while the chloride content of the body as a whole may be markedly reduced. The chlorides in "gastric tetany," of course, are always low but in heat cramps this is not the case. In fact, chloride determinations were made on the blood plasma of eight patients admitted to our medical wards during the past summer, and in only two of them were the chlorides decreased and in those very slightly. That there is certainly depletion of the body chlorides in diabetic acidosis is a known fact. Peters and Van Slyke⁴ state that the depletion may be brought about in several ways, namely, vomiting, diuresis, and the displacement of chlorine by oxybutyrate anions, the displaced chlorine being excreted as ammonium chloride. Certainly, if this patient's plasma chlorides had been normal, it would not have thrown any light on the total body chlorides and would be no argument against the explanation for his pain given here.

CONCLUSIONS

A patient with diabetic acidosis and associated abdominal symptoms is reported. A review of the history and the prompt relief which followed the administration of sodium chloride suggest that the abdominal pain present in this condition may be associated with depletion of body chlorides.

INTENSIVE LIVER THERAPY IN SPRUE *

By PHILIP CORR, M D , F A C P , *Riverside, California*

A recent report by Rhoads and Miller¹ indicates that adequate liver therapy is as satisfactory in sprue as it is in the somewhat related condition of pernicious anemia. These excellent results with liver therapy have stimulated an increase in the recognition of nontropical cases of sprue which are often reported as cases of chronic idiopathic steatorrhea. Mackie,² in July 1933, was able to find only 28 unquestioned cases of nontropical sprue and he added one of his own. Increased recognition of cases is evidenced by the fact that by March 1935 Snell³ was able to state that there were well over 100 nontropical sprue cases on record. He further stated that 15 cases had been seen at the Mayo Clinic since 1927 with about half of them having been studied during the previous year.

The diagnosis of sprue is made on the basis of finding excess fat in the stools after a history is obtained of gaseous indigestion with marked loss of weight and weakness associated with chronic recurring diarrhea of watery, bulky stools. Intermittent sore mouth and tongue, latent or active tetany, amenorrhea, and an anasarca edema are common symptoms in the more advanced cases. Emaciation with a distended abdomen is often striking. Laboratory findings, in addition to the excess fat seen macroscopically and microscopically in the pale, voluminous, foul stools, include the finding of a hypochromic or macrocytic anemia, hypocalcemia, and a decrease in the serum proteins. The roentgenologic findings include osteoporosis and osteomalacia in the advanced cases. Dilatation and redundancy of the colon have been commonly observed. Recently Camp⁴ has described dilatation of the duodenum and a smoothing out of the irregular shadows of the valvulae conniventes and a clumping of the barium in smooth sausage-like masses in the jejunum and ileum.

Pancreatogenic steatorrhea differs from the steatorrhea of sprue in that the fault is in the decrease or lack of the external pancreatic secretion, and there is no fault in the absorptive power of the intestine. A much higher azotorrhea may be observed in pancreatic disease.⁵ The frequently associated diabetes and the lack of concomitant sprue symptoms resulting from faulty absorption and atony of the intestines usually point to the correct diagnosis of pancreatic difficulty.

Pernicious anemia is characterized by lack of intrinsic factor⁶ with the resultant principal effect upon the hematopoietic system without prominent bowel physiology disturbance. The rather constant presence of free hydrochloric acid in the gastric contents in sprue is a distinct aid in the differential diagnosis.

Pellagra is differentiated at times with great difficulty particularly in the

* Received for publication October 10, 1935

early cases. The skin lesions and the mental symptoms are particularly helpful in the diagnosis of pellagra. Fortunately the treatment in the two conditions is about the same.⁷

The etiology of sprue is debatable but all students agree that there is a dietary deficiency factor. It is generally felt that in spite of Ashford's⁸ work *Mompha albicans* is usually only a secondary invader² which causes much of the frothiness of the stool so often described in tropical cases. This dietary deficiency consists in a lack of an extrinsic factor in the food closely associated, if not identical, with the extrinsic factor of Castle. This lack, perhaps associated with a deficiency or lack of the intrinsic factor in some cases,⁹ brings about the pathology in the small bowel which interferes with the absorption of the hematopoietic substance, fats, and to a lesser extent other food elements.

There is no agreement about a characteristic underlying pathology. Marked reduction to complete absence of fat in the body and a liver considerably reduced in size are the constant evidences of starvation. Reduction in the size of the heart is common from the same cause. It has been felt that the essential lesion is an atrophic enteritis with patchy, transient, inflammatory lesions not always present at autopsy.¹⁰ This may account for the widely divergent autopsy findings noted in the gastrointestinal tract in sprue. Fatal perforation has occurred in the cecum from thinning of the wall.¹¹ A gastro-jejuno-colic fistula has caused sprue-like symptoms,¹² but an extensive chronic ulcerative enteritis seen one year ago did not have sprue-like symptoms.¹³ The most careful work on the bone marrow evidences that sprue in this respect simulates pernicious anemia.¹⁴ Roentgenologic evidence indicates that there is an edema as well as atony in the intestinal tract.³

Manson-Bahr¹⁵ was perhaps wise in saying that nontropical sprue cases in order to be diagnosed as such should present the typical diarrhea, flatulency, anemia, mouth symptoms and the characteristic response to appropriate treatment.

The following recently observed typical case of sprue is presented as a basis for emphasis of many of the interesting features of this symptom syndrome, particularly as to its treatment.

CASE REPORT

History. K. K., an American woman aged 49 years for 12 years a resident of Havana, Cuba, was first seen in consultation with Dr. Bon O. Adams, March 29, 1935. Except for an increasing lassitude which had been present since 1925 she was active and in good health until January 1932 when, for the lassitude, she had all her teeth removed. Sore mouth followed and was present intermittently since the alveolectomy. The sore mouth was troublesome enough for her to get three complete sets of dentures without lasting satisfaction from any of them. Anorexia had been prominent and persistent since the onset of the sore mouth and tongue. The weight dropped from 135 pounds in January 1932 to 69 pounds in November 1934. Since November she had not been weighed, but an increasing edema, which had been transiently present several months before, had increased her weight to a probable 110 or more pounds. Weakness had become so severe that she could barely turn

over in bed unaided. Since the onset of her trouble in 1932 she had a painless, watery, bulky but not foamy diarrhea with passage on an average of three to four stools daily, the number varying from one to nine. Usually there would be three or four stools early in the morning and occasionally a stool before meals when there was an exacerbation. In spite of this copious diarrhea the gaseous distention was so marked that enemas were required twice daily to keep her comfortable. The menses had ceased in 1931 when the patient was 45 years of age. Intermittent and rather marked tingling of the finger tips had been noted for several months.

For a period of 10 months before November 1934 the patient had been carefully and competently studied in the middle west. No diagnosis had been made, but the letters of information she carried with her evidenced that anorexia nervosa was considered to be the most likely explanation of her difficulties. During their observation the hemoglobin dropped from 89 to 50 per cent and the erythrocytes dropped from 3,200,000 to 2,010,000 in spite of temporary improvement from blood transfusions. The leukocytes had dropped from 6,500 with 47 per cent neutrophils, to 3,100 with 47 per cent neutrophils. This macrocytic anemia was accompanied by 13° of free hydrochloric acid in the gastric contents. Stools for blood, parasites and ova, a Kahn test, a basal metabolic rate, liver function tests using both the galactose tolerance and the dye methods, and repeated roentgenologic gastrointestinal examinations were reported as normal. Their therapy had included forced feeding to overcome the effects of previous inadequate protein intake, and a period of intramuscular liver extract therapy which failed to bring about satisfactory hematopoietic response. For some months the patient had been taking six capsules of liver extract (Extralin) and pancreatic extract (Pankreon).

Examination revealed extreme weakness with an extreme degree of edema of the legs and of the abdominal wall, with moderate edema of the arms and face. Fluid was definitely present in the abdomen. The blood pressure was 78/62 with a pulse of 80 and a temperature of 97.8°. The tongue was pinkish-red and atrophic with almost complete absence of papillae. Trousseau's sign was definitely positive.

The stools contained an excessive amount of fat macroscopically and microscopically. Cultures of two stools failed to grow *Monilia*. The hemoglobin was 43 per cent (Sahli) with 1,330,000 red blood cells and a color index of 1.6. The leukocytes numbered 3,000 with 51 per cent neutrophils. The urine contained a trace of albumin. The blood urea was 10 mg per 100 cc.

On the basis of this typical history and the confirmatory findings, a diagnosis of sprue was made. It was felt that previous liver therapy had been inadequate. Beginning April 1, 1935 daily intravenous injections of 20 cc of liver extract (Parke-Davis & Co.) were given for 12 days. This was followed by 16 similar injections given every second day, following which the intervals between injections were gradually lengthened. By September they were being given twice monthly.

The diarrhea promptly stopped after the first injection of liver extract, but for five days there was no other sign of improvement, the patient appearing almost moribund. Severe tetany developed after giving pitressin to relieve the gaseous distress in the abdomen. The use of the tourniquet for the intravenous therapy consistently produced annoying, typical carpal spasms. The blood calcium on April 9 was 7.5 mg and the blood phosphorus 3.5 mg per 100 cc.

Beginning with the sixth day of treatment, improvement in the general condition was dramatic and continuous. By the twelfth day the appetite was ravenous, the patient could sit up in bed with energy to spare, the gaseous distention was much improved, and the tetany had almost disappeared. Vitamin D and calcium was started a few days after improvement in the tetany had begun. The weight was 63 pounds after two weeks of excessive eating but by that time the edema had practically disappeared. Subsequently there was a steady increase in weight so that by September the weight had reached a level at 120 pounds. The sore mouth disap-

Physical examination revealed no changes since the previous entry. The urine was now free from albumin and blood. The basal metabolic rate was still low (minus 26 per cent). A dextrose tolerance test showed a fasting blood sugar of 81 mg per 100 c.c., rising to 112 mg one hour after ingestion of dextrose and receding to 101 mg in two hours, to 99 mg in three hours, and to 94 mg in four hours. Blood calcium was 10.7 mg, phosphorus 3.7 mg, phosphatase 9.7 units. She was discharged with instructions to resume treatment with ephedrine.

The third hospital entry was in September 1935. She had stopped taking ephedrine two and one-half months before because it was no longer effective. She had reverted to her previous state with the attacks as frequent as before. There was no change in the physical examination. Inhalation of benzedrine sulphate was begun. On the following day she had only one attack of somnolence and the day after that none at all. On the third day the drug was given orally in tablet form, 10 mg three times a day, and, although there were no attacks on that and the following day, she believed that inhalation was superior to the tablets. She was discharged with instructions to continue treatment by inhalation. About a month later she was advised to try the tablets again and to report after two weeks of treatment. She took 10 mg three times a day and in a letter wrote that "they were much more effective than the inhaler. I did not fall asleep once all day while I was taking the pills." She was then advised to omit the treatment to note whether the complaint would return. The following report was received: The attacks "started again two days after I stopped taking [the tablets]. Upon resuming the treatment I was able to stay awake from 6.30 in the morning until 10 or 11 o'clock at night."

Case 4 R. R., an American bank clerk, aged 32, entered the hospital complaining of falling asleep in the daytime. The illness had begun insidiously about 15 years ago. At first, he could control the attacks by force of will, but the degree of somnolence had increased gradually until recently he could not control it at all. It was especially troublesome during any monotonous action, such as signing checks or riding in a train. He slept poorly at night, and had frequent unpleasant dreams. An attack lasted only a few seconds. Whatever he was doing (talking, riding or driving an automobile) he often carried on automatically during an attack. He had had two narrow escapes from accidents while driving an automobile. The tendency to sleep was worse after meals and in the middle of the afternoon. The sleep was not deep and sometimes merely a sort of semi-consciousness. He responded when spoken to and was easily aroused. There were no prodromal symptoms or after effects except anger at having been unable to prevent an attack. Hearty laughter and violent anger have produced slight cataplectic symptoms consisting of fluttering of the eyelids and a momentary weakness of the legs followed by twitching. They have been much less frequent during recent years. Nocturnal sleep was poor and often disturbed by vivid and sometimes unpleasant dreams. A year before, he had had thyroid and pituitary medication without benefit.

The family history revealed that his father had hay fever. Both parents had died of kidney trouble at age 50. There were no siblings. He was married and had four living and well children. There had been one miscarriage. During the last three years his sexual life had been unsatisfactory, apparently because his wife objected to other pregnancies. He had had measles, mumps, chicken-pox, whooping cough and scarlet fever as a child and malaria 20 to 25 years ago. The highest weight, that on admission, was 140 pounds.

Physical examination revealed abdominal obesity. The heart and lungs were normal. The systolic blood pressure was 130 mm mercury, the diastolic 78 mm. The pulse rate was 88 per minute. He wore glasses for astigmatism. The pupils were not round. The fundi were normal. He was observed during a narcoleptic attack which he induced by reading. The sleep appeared normal, he snored heavily. Respirations were 15 per minute. The eyeballs were not rolled upward, but had a

tendency to wander. The pupils were very small. Attempts to elicit the reflexes aroused him. He answered a few questions in a normal manner and then again fell into a deep sleep.

The urine contained a very slight trace of albumin, but was otherwise normal. The blood count was normal. The non-protein nitrogen of the blood was 28 mg, uric acid 3.7 mg, sugar 96 mg, calcium 10.7 mg, phosphorus 2.9 mg, and cholesterol 190 mg in 100 c.c. The Wassermann and Kahn tests were negative. The basal metabolic rate was minus 14 per cent, the galactose tolerance was slightly diminished. Roentgen-ray examinations. The skull plates showed expansion of the diploë with hyperpneumatization of the sinuses and beginning sclerosis of the vault. There was calcification of the pineal gland. The sella turcica measured 7 by 12 mm, and was regular in outline. Dextrose tolerance test. Fasting 100 mg, one-half hour after dextrose, 191 mg, one hour, 200 mg, two hours, 193 mg, three hours, 129 mg, four hours, 75 mg, five hours, 71 mg, six hours, 90 mg.

He was discharged with instructions to use benzedrine by inhalation. He reported later that the treatment produced no appreciable effect. Oral treatment, 10 mg three times a day, was then begun. The attacks were completely controlled. At present, after several weeks of continuous medication, he is free from symptoms, except some drowsiness while riding on a train. He sleeps well at night and is not troubled by unusual dreams. At first, he had had an occasional slight feeling of nausea when he took the tablets without water, but that is no longer troublesome.

Case 5. P. S., a colored girl, aged 12½ years, complained of frequent attacks of sleeping. There was a history of a fall at age four which her mother believed to have been responsible for the illness, although there had been no immediate ill effect. She had not been unconscious. The diurnal naps became particularly noticeable when she entered school. The teacher reported that the child went to sleep during class hours. Her mother stated, however, that she had taken long daily naps before that. The tendency to somnolence was more pronounced on hot days, but there was no predilection for a special time of the day. It occurred only when she was quiet or performing a monotonous task (knitting) and never while she was at play or when something was holding her interest. The duration of the attacks was usually an hour or two. She was easily aroused but went to sleep again if permitted to do so. She did not continue to perform previously begun actions during an attack. Cataplectic symptoms had not been noted, but at times she twitched while asleep. Treatment with thyroid, prescribed elsewhere, had been without benefit.

The family history was not relevant. Birth and infancy had been normal. She had had measles, mumps, chicken-pox, pertussis and scarlet fever. Frontal headaches were frequent, especially in hot weather. Occasionally there was tinnitus in the right ear. Her feet swelled and were cold during cold weather. Constipation was controlled by the regular use of mineral oil. Menstruation had begun six months before and had been normal except for dysmenorrhea on the first day. She tired easily, was slightly nervous and very irritable. She slept well and was not troubled abnormally with dreams. The highest weight, that on admission, was 95 pounds. Physical examination revealed nothing abnormal except flat and pronated feet which an orthopedic consultant believed to be congenital.

The urine was normal. Blood. The hemoglobin was 12 to 14 grams per 100 c.c. (74 to 78 per cent), erythrocytes numbered 3,570,000 to 3,970,000 per cu. mm, leukocytes 8,500 to 9,700, of which 12 to 21 per cent were eosinophiles. The non-protein nitrogen was 26 mg, uric acid 2.8 mg, sugar 80 mg and cholesterol 202 mg in 100 c.c. blood. Feces. No ova or parasites were found. Dextrose tolerance test. The fasting blood sugar was 83 mg, one hour after dextrose it was 141 mg, in two hours it was 121 mg, in three hours, 115 mg, in four hours, 112 mg, in five hours, 83 mg, and in six hours, 93 mg. The basal metabolic rate was minus 23 per cent. The galactose tolerance was moderately diminished. Roentgen-ray examinations.

The skull was normal, the sella measured 6 by 12 mm and was regular in outline. The sinuses were normal. Cerebrospinal fluid. Manometric readings were normal, cells numbered 1 per cu mm, the sugar content was normal, globulin not increased, the colloidal gold and Wassermann tests were negative.

Benzedrine sulphate, 10 mg three times a day, was prescribed. It gave marked relief, but some degree of somnolence still occurred at the end of the morning and toward evening. The amounts of the drug taken in the morning and at noon were then increased to 20 mg each, the evening dose remaining at 10 mg. Since then she has been free from attacks throughout the day, except slight drowsiness in late afternoon. Her mother reports that she appears normal in every way but that the increased medication induced an additional menstrual period (3 periods in 1 month). An occasional feeling of fullness at meals, not noticed before, has been present during the past two weeks.

Case 6 W L, a Nova Scotian farmer, aged 22, complained of "falling asleep in the middle of the day's work." The illness began about six years ago with what he described as "a breakdown in health," consisting of nocturnal insomnia, nervousness, excitability and increased drowsiness in school. He stated that before that time he was well, but more searching questioning elicited the information that he had had mild attacks of sleepiness in school during the preceding year or two.

Recently the attacks of diurnal sleep, about four or five a day, have lasted from a few seconds to several minutes. They have occurred at any time of the day. He has been easily aroused but has been irritated thereby. If he awoke spontaneously, he felt refreshed. A warm room, monotonous procedure and inactivity favored the onset of an attack. Automatic action was frequent. He slept poorly and had unpleasant dreams about being pursued by animals. Excitement, anger, or hearty laughter often caused his muscles to relax, "they would not do what I wanted them to do." During these cataplectic spells he was unable to speak but remained conscious. Their duration was but a few seconds. He believed that they were less frequent than they had been at the beginning of the illness. Sedative medication for insomnia has been used. Constipation has been marked and began just before the onset of the narcolepsy. He has had frontal headache for several years when he strains his eyes (reading, watching motion pictures). There has been a gain of 30 pounds in weight during the past six years. The weight at examination was 190 pounds.

Physical examination revealed nothing remarkable. He had the appearance of an exceptionally rugged youth, large of frame and only moderately obese.

The urine was normal. The blood count showed a mild eosinophilia (8 to 9 per cent) but was otherwise normal. Chemical and serological examinations of the blood were normal. The basal metabolic rate was plus 4 per cent in the first test, and minus 15 per cent and minus 20 per cent in two subsequent examinations. Roentgen-ray examination of the skull showed expansion of the diploe and hypopneumatization of the sinuses. The sella turcica measured 5 by 8 mm and was regular in outline. The heart and lungs were normal.

Inhalation of benzedrine sulphate was used for two days and gave slight relief. Oral medication, 10 mg three times a day, has been followed by marked improvement, although there is still some drowsiness when he is inactive. He states that he can now read for several hours at a time, whereas before treatment was begun he fell asleep a few minutes after beginning to read. Insomnia is much less troublesome, but he still has occasional unpleasant dreams.

SUMMARY

Our experience with narcolepsy supports the statement that the disease may occur at any age and that in the majority of cases it begins before age

Tabular Summary of Important Findings in Six Cases of Narcolepsy

Case Sex, Age	Narcolepsy						Cataplexy		Treatment			Miscellaneous Findings					
	Age at Onset	Duration in Years	Length of Attacks	Aggravation	Pro- dromes	Automatic Actions	Length of Attacks	Exciting Cause	Ephedrine	Benzedrine			B M R	Dreams	Irrita- bility	Obesity	Constipation
										Inhalation	Orally	Toxicity					
I M F 52	49	3	Few seconds to several minutes	Monotony after meals, morning cold days, very warm room	Diplopia and dull feeling in eyes	At times	Few seconds or minutes	Hearty laughter, excitement	Slight relief	Not used	Complete relief	Possibly aggravation of existing gastric symptoms at first	-24%	Unpleasant, insomnia (relieved by treatment)	Yes	Moderate, especially since onset of narcolepsy	No
II C D B ♂ 17	10	7	Up to 1 hour at first, now only a few minutes	Monotony, warmth, fatigue	None	Writing, walking (has lost his way)	Few moments (none for 6 months, fre- quent at first)	Excitement laughter	No relief	Not used	Complete relief	Anorexia for first few days	-24%	Many, some of them horrible less troubled in last year No insomnia	Yes	Obese before fall since onset	No
III A H ♀ 16	10	6	10-20 min utes	Monotony, forenoon	None	Walking rarely	5-20 minutes	Hearty laughter, anger, fear	Moderate relief at first, later none	Moder- ate relief	Complete relief	None	-16% -22% -26%	"Horrible" at first, less recently	Rare	Gradual gain since onset of narcolepsy	Moderate
IV R R. ♂ 32	17	15	Few seconds to several minutes	Monotony inaction, warmth, 11 a m -2 p m., after supper	Momen- tary cloud in front of eyes	Frequent. Writing, driving, talking	Momentary (rare slight attacks)	Hearty laughter, sudden anger excitement	No relief	No relief	Marked but not complete relief	Occasional slight nausea at first taking tablets without water	-14%	Unpleasant, insomnia, (relieved by medicine)	No	Slight	No
V P S ♀ 12½	4(?)	8(±)	Few minutes to several hours	Monotony, warmth, inaction	None	None	No cataplectic seizures	No cataplectic seizures	Not used	Slight relief	Almost complete relief with 50 mg	Added menses, feeling of fullness with meals	-23%	Not abnormal Sleeps well	Marked	None	Marked
VI W L ♂ 22	14-15	7-8	Few seconds, rarely a few minutes	Monotony, warmth, afternoon	None	Walking frequently, other ac- tion rarely	Few seconds	Excitement, sudden anger, hearty laughter	Not used	Slight relief	Marked but not complete relief	None	+ 4% -15% -20%	Unpleasant, insomnia	Only when aroused	Moderate	Very marked began just before onset of narcolepsy

twenty-five All of our patients are especially prone to become sleepy under monotonous actions or influences The early part of the day is particularly conducive to drowsiness in two of our cases, in two there is a post-prandial inclination, and one patient is more susceptible in the afternoon In two cases there is no predilection as to time of day Warm weather or a warm room is a factor in three cases Two show no seasonal influence and one, contrary to general observation, is worse on cold days Unpleasant dreams are recorded by four of the patients Cataplectic seizures are present in five cases, but not in case 5, the youngest of the series The basal metabolic rate in all of our cases is lower than the mean rate in the large series reported by Daniels³ The reason for this is not apparent

Oral treatment with benzedrine sulphate has been followed by marked relief in all cases of our series The effective daily amount of drug varied from 20 to 50 mg Inhalation was tried in four cases, with slight benefit in case 5, moderate in cases 3 and 6, and none in case 4 It appears that the difference between inhalation and ingestion is quantitative One patient complained of slight nausea at the beginning of oral medication, another's gastrointestinal symptoms were aggravated during the first period of treatment, but not subsequently, and a third had slight temporary anorexia at the beginning of each period of treatment One patient, a colored girl, aged 12½, had an additional menstrual period while taking 50 mg of the drug and has complained recently of a slight feeling of fullness at mealtime

ABDOMINAL DISTENTION IN LOBAR PNEUMONIA

By JOEL GOLDMAN, M D, and ABRAHAM COHEN, M D, *Philadelphia, Pennsylvania*

IN scanning the literature on meteorism we found a most interesting lecture, written by Francis Sibson¹ in 1873. We wish to quote from this classic

You will at once see how seriously distention of the colon must affect the organs of the chest, not only the lungs, but also the heart, by displacing that organ to the left, whereas, in the case of the stomach, its displacement tended rather to the right

We find that the heart and the lungs are put to an immense disadvantage—that the lungs are compressed and the reserved air driven out of them—that the heart is compressed and the blood driven out of it—that the ventricles are diminished in size and are incapable of receiving so much blood as they did before—that there is an obstacle to their action, and that they are incapable of sending out the blood that they have already received with the ease that they did before,—again, if you look at the walls of the chest and the diaphragm, you see what an obstacle is put to the very limits, by which, as it were, the lungs expand and the heart is moved. The cartilages of the ribs are pushed aside and lifted upwards. The cage of the chest has reached the limit of its power by the elevation given to it, and permanently given to it by the distention of the abdomen. Again look at the diaphragm, lifted up by this immense distention. How can it act downwards? If the diaphragm is affected by peritonitis, the inflammation paralyzes the inflamed muscle. The whole content is then narrowed to the smallest bounds, and the whole work of respiration must be done by the few ribs remaining unassailed at the top of the chest. In cases of peritonitis respiration is what is very well called high. The whole of the breathing is performed by the labored lifting up of the upper cartilages, the upper ribs and the clavicles—all the muscles that act—the sternocleid, the scalen, the levators of the ribs and the scapulae, are hard at work, and in spite of that, you see visible in the face that the patient is undergoing chronic asphyxia, and must soon die unless his breathing is relieved

THE ORIGIN OF GASES IN THE INTESTINAL TRACT

We are not concerned here with the ordinary accumulation of gas in the intestinal tract, but with the excessive formation of gas which results in flatulent distention

According to the work of Schoen, McIver, Redfield and Benedict,² the only gases of importance in distention are those which are not readily absorbed, hydrogen, nitrogen and methane. Other gases, however, may accumulate in the intestinal tract if their rate of formation exceeds their rate of absorption

Cutting³ believes that the origin of intestinal gas is three-fold (1) decomposition of foodstuffs, (2) diffusion of gas from the blood stream, and (3) swallowed atmospheric air. He states that gases are produced

* Received for publication August 12, 1935

From the Pneumonia Wards of the Philadelphia General Hospital

by the action of bacteria on sugars in the lower portion of the small intestine and by the action of bacteria on any residue of cellulose which remains after digestion is complete. Free nitrogen occurs in the blood stream under a pressure of about four-fifths of an atmosphere, while oxygen and carbon dioxide occur in chemical combination. The nitrogen is free to leave the blood stream to replace other gases in the intestines when pressure relationships are favorable, whereas in order for oxygen or carbon dioxide to leave the blood stream, not only must pressure relationships be upset, but also conditions must be favorable for the liberation of these gases from their chemical combinations.

McIver⁵ states that normally the amount of gas in the intestinal lumen is minimal because gases diffuse into the blood stream about as rapidly as they are formed. The presence of distention, however, indicates that formation has outstripped diffusion.

In his paper entitled "Constipation," Spencer⁶ points out that the same laws apply in gas exchange between the blood stream and the intestinal lumen as apply to the gas exchange between tissues and blood, and blood and the pulmonary air. In speaking of flatulence he makes the significant statement that "whenever the condition can be anticipated, measures for precaution will prove more valuable than will measures for relief."

Alvarez⁷ feels that flatulence with abdominal distention can become a serious complication during the course of pneumonia. He states that Boothby so far has had little or no trouble with flatulence in a series of patients with severe pneumonia treated in a chamber containing 50 per cent oxygen because in such an atmosphere more of the nitrogen in the bowel can diffuse out.

Wiggers⁸ agrees with other writers that putrefactive and fermentative changes are of minor importance, compared to disturbances in the diffusion of gases. In addition embarrassment of the circulation results from mechanical interference with the splanchnic circulation or from compression of the heart through the diaphragm.

In summary, these authors believe that gaseous distention depends chiefly upon alterations in the interchange of gases between the gastrointestinal tract and the blood. The normal equilibrium may be affected by disturbances in the toxicity and motility of the gastrointestinal musculature, or by interference with the local circulation from various causes. Fermentative processes and aerophagia may be contributory factors. It has also been suggested that the diminished capacity of the lungs in pneumonia may be in part responsible for the distention which is commonly associated with this disease.

Numerous drugs have been utilized to combat distention, none of which are satisfactory in all cases. Saline cathartics or even hypertonic salt solution (Ori¹⁴) may be helpful. While various opiates have been used extensively, there is still a difference of opinion as to their effect upon the movements and tone of the intestine. Nothnagel¹⁶ concluded that small

doses of morphine increased the tone of the intestine while large amounts decreased it. Uhlmann and Abelin¹⁷ demonstrated that the reverse occurred in etherized rabbits and guinea pigs, and Plant and Miller¹⁹ found that morphine and other alkaloids of opium produced a decided increase in tonicity. Eserine has been used with indifferent success for more than half a century. Pitressin and pituitin stimulate contraction of the smooth muscle, and are sometimes very effective. Choline and acetylcholine have been shown by a number of investigators^{22, 23, 24, 25, 26} to stimulate the gastrointestinal musculature. Others,^{27, 28} however, have not obtained constant or conspicuous results with them.

TREATMENT BY SUCTION SIPHONAGE

In June 1933, Paine, Carlson and Wangensteen⁹ described a form of continuous lavage of the duodenum through a nasal tube which was effective in relieving postoperative distention, nausea and vomiting, and they suggested that this form of therapy be employed following gastric, biliary tract, intestinal, and kidney operations. In our paper it is suggested that a modification of this apparatus be made use of in lobar pneumonia and other conditions accompanied by abdominal distention. Distention is a symptom of decided importance since through its mechanical effects and through the distress and fatigue it causes the patient it may well have a decided effect upon the mortality rate in pneumonia and other febrile diseases. We have found the treatment of distention by rectal suction siphonage safe, inexpensive and simple. The results obtained in a large group of patients with lobar pneumonia at the Philadelphia General Hospital are here presented.

From December 1, 1934, to May 20, 1935, 335 cases of lobar pneumonia (220 men and 115 women) were treated in the special fever wards. This hospital accepts only charity cases for treatment. In most of them the disease was far advanced at the time of admission, and, since they were from the poorer sections of the city, their powers of resistance were not of the best.

Of these 335 cases of lobar pneumonia, 129 or 38.6 per cent were clinically distended (39.5 per cent of the men and 36.5 per cent of the women). The distention was of sufficient degree to necessitate active therapy. In comparison, there were few other complications. Our experience indicates that abdominal distention is by far the most common complication of lobar pneumonia.

In previous years, distention had been treated by various accepted routine procedures. The results obtained were far from satisfactory. This year we have used a combination of the laxative action of saline cathartics with the mechanical action of continuous suction siphonage as described below.

Many of the patients entered the hospital with distention, while others developed it as the disease progressed.

The degrees of distention have been classified as follows Grade 1 or minimal, Grade 2 or moderate, and Grade 3 or marked distention A summary is shown in table 2

Early in the series many patients with Grade 3 distention were selected for treatment by suction siphonage, as the treatment was found to be successful, earlier cases were selected until late in the series nearly all were Grades 1 and 2 As has been discovered by other workers, early distention responds to treatment much more readily than when far advanced Grade 3 cases were, at times, most difficult to deflate and to keep deflated, on the other hand, distention in Grade 1 or 2 cases rarely recurred once they were successfully deflated It was finally decided to start suction siphonage on all cases that showed the earliest signs of distention These were easily controlled, and the deflation was maintained in practically all so treated However, many cases admitted with Grade 3 distention were refractory

TECHNIC OF RECTAL TUBE SUCTION SIPHONAGE

The apparatus used is almost the same as that described by Paine, Cailson, Wagensteen,²⁹ and Paine and Phillips,³⁰ in the treatment of postoperative distention, nausea and vomiting by nasal catheter suction siphonage, with the exception that a soft rubber rectal tube (French²⁸) has been substituted for the Levin duodenal tube (Figure 1)

The patient who has become distended is given cleansing soap suds enemas until the return flow is fairly clear or until a successful return of fecal material has been obtained Usually one or two soap suds enemas are sufficient For a successful deflation the feces must be liquefied since solid stools and hard fecal masses will block the rectal tube A liquid stool is obtained by giving the patient, daily, one ounce of saturated magnesium sulphate solution Once a liquid stool is obtained, the dosage of the saline laxative may be reduced However, in dehydrated patients or in older individuals with fecal impactions, large doses of the drug may be necessary Most of the failures occurred in patients with hard, impacted feces which were resistant to laxative action

A soft rubber rectal tube is inserted from two to three inches into the rectum If the tube is forced any farther into the rectum it will coil on itself, balloon out the rectum and give the patient a false rectal impulse (figures 2 and 3) The tube is lubricated with either vaseline or an astringent rectal jelly The latter is used to allay the slight tenesmus which may appear in those cases which are under treatment for fairly long periods of time The following is a description of the apparatus, quoted from Paine and Phillips³⁰ In our apparatus a rectal tube is used in place of the nasal tube

"The apparatus consists of two bottles with the capacity of four liters each One bottle is hung inverted from an irrigation standard by a canvas sling or bag (or by a wire basket as shown in figure 1) The other bottle

is set on the floor at the foot of the standard. A two-holed rubber stopper with two glass tubes fits into the mouth of the inverted bottle. One of these tubes is short (about four inches long) and the other is longer (about 14 inches long) and extends almost to the bottom of the inverted bottle, that is, to the end which is uppermost as it hangs. A rubber tube connects

FIG 1

the longer glass to the nasal tube (or rectal tube), and another leads from the shorter glass tube to the bottle which is situated on the floor.

"To start the suction, the upper bottle is filled completely with cold tap water, and the rubber stopper with the tubing attached is put into place in the bottle neck. The rubber tubing leading to the longer glass tube is not yet connected to the nasal tube (rectal tube). Both rubber tubes are clamped off, and the bottle inverted and hung on a standard at a convenient height, about six feet from the floor. The end of the rubber tubing from the shorter glass tube is placed in the floor bottle, and enough water is added

to cover the end of the tube well. This point is very important in order that a closed system will be made and a constant suction insured. The clamps on the rubber tubing are then removed while a finger is held over the end which will later be attached to the nasal tube (rectal tube). If

FIG 2 A rectal tube inserted the wrong way

suction is not immediately felt by the finger there is air in the tubing leading to the lower bottle. This can easily be removed by injecting a few cubic centimeters of water with a syringe into the tube which is connected to the longer glass tube. When suction is perceived, the tube is connected with the nasal tube (rectal tube)."

The return of gas and liquid feces is not measured for there is no

danger of dehydration as long as the urinary output is sufficiently high (from 800 to 1200 c.c. daily)

The rectal tube and the connecting rubber tubes are irrigated at least every four hours by forcing fluid through them with a syringe. If the

FIG 3 A rectal tube inserted the right way

tubes are blocked by fecal masses they must be thoroughly cleaned or replaced. The apparatus is sterilized by boiling when it is no longer in use.

The rectal tube is used only as long as is necessary to reduce the distention. If it is used excessively long there may be rectal irritation. If distention recurs it may be necessary to repeat the procedure. The continuous use of this method was not insisted upon. If the patient desired a

bed pan it was given to him. From time to time enemas were given. The criticism may logically be offered that the enemas may have relieved the distention, but we have seen hundreds of cases in which they did not.

Pituitrin was found to be nearly ineffectual in stimulating peristalsis in these cases, but Pitressin did help occasionally. No other drugs were used to assist in combating the distention.

The only untoward effect noted after the prolonged use of the rectal tube was tenesmus. This occurred chiefly in those patients who had previously existing internal hemorrhoids, and was easily alleviated by the use of an anesthetic astringent rectal jelly. No rectal bleeding was noted.

The above described procedure has been very successful in combating the abdominal distention of lobar pneumonia. We are presenting the results of such treatment in 100 unselected cases. The following table summarizes the duration of the lobar pneumonia when treatment was first instituted.

TABLE I

12 to 24 hours	2 to 4 days	4 to 6 days	Longer than 6 days
12 cases	23 cases	25 cases	40 cases

It will be noted that 65 per cent of these cases were seen relatively late, four days or later, in the course of the pneumonia. Of these, the degree of distention was as follows: Grade 1, 7 cases, Grade 2, 53 cases, Grade 3, 40 cases.

The length of time the rectal tube suction siphonage was used is shown in table 2.

TABLE II

	12 to 24 hrs	2 to 4 days	4 to 6 days	Longer than 6 days
Successfully deflated	69 cases	6 cases	3 cases	9 cases
Partially deflated—6 cases	<i>Total—87% successfully treated, 6% partially successfully treated, 7% complete failure</i>			
Unsuccessfully treated—7 cases				

Most of the cases were controlled within 24 hours, only 18 per cent of the successfully treated cases requiring a longer period for control. The partially deflated and unsuccessfully treated were treated over an indefinite period before being discontinued. It was in these 13 per cent that the rectal irritation occurred.

The rate of death and recovery of these cases is as follows:

TABLL III

	10 to 19 yrs old	20 to 29 yrs old	30 to 39 yrs old	40 to 49 yrs old	50 to 59 yrs old	60 to 69 yrs old	70 to 79 yrs old	80 to 89 yrs old
Lived	8	10	16	18	4	4	0	0
Died	1	8	8	6	8	6	1	2
Total	9	18	24	24	12	10	1	2
Total died Total lived				40% 60%				

It was noted that in 34 per cent of these cases the distention was completely controlled without influencing the fatal termination of the disease. In only two cases unsuccessfully treated did the distention seem to be a direct cause of death. However, we believe that the distention was a true indication of the degree of toxemia present, the severest distention invariably occurring in the most toxic patients.

In addition to the actual deflation the procedure has been of great value in other ways. Our patients have received more rest (the prime requisite in any régime of treatment for lobar pneumonia) than they did before the introduction of this treatment. The patient does not need a bed pan frequently, and there is no straining to add to the load of a weak heart. We have had patients so treated who have not needed a bed pan for 96 hours during which they were perfectly at rest. The procedure has been especially helpful in this respect in the case of patients treated in oxygen tents. The nursing problem is simplified by lesser need of moving the patient. Incontinence of feces occurred only twice in the 100 cases reviewed. Our experience with the practical application of this method of treatment makes us feel that it is very well adapted to use in the home as well as on the hospital wards.

CONCLUSIONS

1 Abdominal distention is the commonest complication in lobar pneumonia. When extreme it may be a contributory factor in the mortality rate.

2 Rectal suction siphonage is a safe, inexpensive, and effective method of relieving abdominal distention, and has been a great comfort to our patients.

The authors wish to express their appreciation to Miss Blanche Loeb Langsdorf for her valuable assistance in collecting statistics for this paper.

THE RÔLE OF ACCIDENTAL PUNCTURE OF VEINS IN THE PRODUCTION OF ALLERGIC SHOCK

By G L WALDBOTT, M D , F A C P , and M S ASCHER, M D ,
Detroit, Michigan

IN spite of many publications on the prevention of allergic shock following injections of pollen and serum, there remains a great deal of uncertainty concerning its causes and prevention. This is well illustrated by the fact that even those clinicians who are most experienced in the administration of hypodermic medication are still completely at loss to explain certain reactions. Piness,¹ for instance, stated, in 1934, that despite the most careful gauging of doses there are reactions for which we are unable to account.

The importance in this connection of accidental intravenous injection of the allergen is not sufficiently stressed. In a paper dealing with the prevention of reactions, Rudolph and Cohen² fail to emphasize the rôle of accidental puncture of veins in the production of reactions. Others (Duke,³ Insley⁴) have proposed valuable measures to prevent shock, but do not propose means practicable for the general practitioner to prevent accidental intravenous injections. Commercial houses marketing serum and pollen extracts have greatly neglected to stress this feature in their directions to physicians. Yet, with few exceptions, the accidental intravenous administration of serum or pollen accounts for the fatal outcome in most cases of sudden death reported in the literature following injections.⁵ It will be shown below that this constitutes a great menace in the giving of pollen injections.

Within the past few years we have been able to reduce the incidence of reactions from pollen injections to a marked degree by observing certain precautions outlined elsewhere.⁶ These measures take into consideration the fact that severity of a reaction depends upon the state of sensitivity,[†] the rapidity of absorption of the antigen, and the degree of the overdose. In addition to an actual overdose due to error, to incorrectly judging the patient's degree of sensitivity or to switching from an old to a new extract, the following factors may contribute to the effect of an overdose. Simultaneous absorption of the same or another antigen to which sensitivity exists, by either the intestinal route (food), the respiratory route (pollen), or from the site of previous injections, or simultaneous absorption of bacterial materials from an infection present in the system.

Regardless of these precautions which were directed toward prevention of an overdose, reactions occurred, and, as a rule, were decidedly more

* Received for publication June 29, 1935.

† Whether this sensitivity is inherited (atopic) or acquired ("anaphylactic") does not alter in the slightest degree the symptomatology of shock.

severe than those formerly encountered During the past hay-fever season we made observations concerning the relative frequency of accidental puncture of small venules, the diagnostic features connected with a reaction so produced, and the best methods of avoiding such mishaps

DIAGNOSTIC CONSIDERATIONS

A puncture of a vein may result in two clinically distinct types of reactions, depending upon whether the extract is injected directly into the blood stream ("intravenous" reaction) or seeps into a small punctured venule soon after the injection ("backseepage" reaction)

1 *Intravenous Reactions* The characteristic features of this type of reaction are the unusual severity of the manifestations and the absence of a local swelling at the site of injection In a reaction due to inaccurate dosage, no matter how large the overdose may have been, there is always a time interval of a few minutes during which a more or less marked wheal arises on the site of injection Often a reddened, more or less itchy, area can be noted along the lymph channels, similar to that seen in lymphangitis, before generalized urticaria and respiratory symptoms occur In an "intravenous" reaction proper, skin manifestations are usually of little moment throughout There is a decided prevalence of internal manifestations, particularly, of symptoms which can be attributed to edema of the lungs, and probably, of the liver This is well in accord with Kahn's⁷ recent observations that in shock produced in animals by the intravenous route there are considerably less skin-reacting antibodies present than if the shock-producing injection is made subcutaneously Another distinctive feature is the absence of allergic symptoms after the reaction is controlled While in "non-intravenous" reactions urticaria and other allergic symptoms may recur several hours after their control by epinephrine, an "intravenous" reaction produces its full effect immediately, little, if any, after-effect is noticeable with the exception of a generalized weakness or a low-grade pulmonary infection This latter condition has been explained as due to secondary infection of residual areas of pulmonary edema (Waldrott and Snell⁸) The following is an instance of an "intravenous" reaction

Case 1 J K, a 17 year old hay-fever patient, had been successfully treated in 1932, in one of the dispensaries with which we are connected He had the eighteenth injection of 1933, consisting of 10,000 units each of small and giant ragweed and cocklebur on July 7 On July 14, at 10 01 a m, he received 12,000 units of the same pollen extracts Within 20 seconds following the injection, he noticed a strange taste in his mouth, "tingling around the heart" and difficulty in breathing Ten seconds afterwards he collapsed and became pulseless A tourniquet was immediately applied by the attending nurse and 0.5 cc of epinephrine was given subcutaneously (10 03) The same amount was repeated at 10 05 by Dr S R After the second injection of epinephrine the pupils reacted slightly to light and consciousness was regained for about three minutes The pulse was not palpable at the time At 10 08, 10 cc of epinephrine was given intramuscularly The pulse became noticeably stronger and the respirations assumed a more regular character From 10 03 to

10 55 the tourniquet was loosened only three times for a period of a few moments, and entirely removed at 10 55 Outside of the usual effect of epinephrine and an unusual degree of general weakness which lasted for several days there were no noticeable allergic symptoms after the incident There was no urticaria, either localized or generalized Not the slightest local reaction was present at the site of injection Although no further treatment was given during the balance of the hay-fever season, the boy remained free from hay-fever

Comment One is particularly impressed first with the unusual severity of the clinical manifestations, resulting in this case in complete pulselessness, and second with the absence of urticaria and local swelling, and of any material after-effect We feel that in this case the life of the patient was saved by the immediate administration of large doses of epinephrine, and that the application of the tourniquet was of no avail

CHART I
Differential Features of Intravenous Reactions

	Overdose	"Backseepage"	"Intravenous"
Premonitory Evidence	Rapid appearance of local wheal	Bleeding at site of puncture or bloody suffusion	
Local Reaction	Speed of appearance and size of wheal indicates severity	Occasionally bloody suffusion under skin	None
Time Interval	Proportional to amount of overdose (5 minutes to 2 hours)	Between one to five minutes	10 to 30 seconds
<i>Symptoms</i> Urticaria	Marked	Extreme at onset	Little, if any
Respiratory	Hay-fever, bronchitis, asthma	Hay-fever, bronchitis, asthma	Pulmonary edema
Collapse	Negligible	Marked	Extreme
Others	Flare-up of previously existing allergic or non-allergic foci		Prostration, cyanosis
Duration	Prompt control by epinephrine Urticaria may recur	Symptom-free after control	Generalized malaise for several days
After-Effects	Relief of allergic symptoms unless the overdose too drastic		Broncho-pneumonia may ensue
Response to Treatment Epinephrine	Promptly to 1/10 to 3/10 c c , repeated if symptoms recur	Larger doses (0.5 to 1.0 c c) needed immediately	
Tourniquet	Useful In extreme cases incision of site of injection	Useful	Of no avail

2 "Backseepage" Reactions While to our knowledge only four truly "intravenous" reactions were encountered within the past three seasons in a series of 41,037 injections, there is another more common source of dangerous reactions, which has not been sufficiently emphasized i.e., the puncture of a vein and backseepage into the blood stream This occurred 34 times in this series In the hypodermic administration of pollen and serum, it is relatively common that a small venule or capillary is punctured Should any of the injected material ooze into the punctured venule, the reaction resulting would be similar to that of a true "intravenous" reaction This type of reaction can usually be recognized by the following evidence Presence of blood on the site of injection or a bloody suffusion under the skin which becomes rapidly replaced by a wheal Generalized allergic symptoms occur within one to five minutes and are unusually severe They consist of both cutaneous and internal manifestations, in contradistinction to the true "intravenous" reaction where skin manifestations are either absent or slight Deimal edema is intense and can often be seen to spread rapidly from the site of injection over the entire body surface Collapse occurs within a few minutes if the reaction is severe or not immediately controlled Since instituting the precautions mentioned below, the incidence of these reactions has been reduced but not entirely eliminated Chart 2 is a tabulation of the incidence of the different types of reactions, chart 1 presents their differential diagnostic features

CHART II
Incidence of Reactions Encountered During 1932-1934

Year	Number of Injections	Reactions Encountered					
		Total Number	Incidence	"Intravenous"	Incidence	"Back-seepage"	Incidence
1932	9898	36	1 276	1	1 9898	11	1 899
1933	12364	44	1 280	1	1 12364	14	1 883
Total 1932-1933	22262	80	1 278	2	1 11131	25	1 890
1934	18775	61	1 308	2*	1 9387	12	1 1564

* Only a small portion of the extract was injected since the accidental puncture of the vein was recognized during the injection (repeated retraction of plunger of syringe)

EVALUATION OF THE CUSTOMARY MEASURES OF CONTROL

The measures which have been advocated for the control of reactions from pollen extracts are the application of a tourniquet above the site of injection and the administration of epinephrine^{3,4} Recently, Rice⁹ demonstrated that the absorption of epinephrine may be controlled similarly to

that of the pollen extract by applying a second tourniquet above the site of the injected epinephrine. In extreme cases incision of the site of injection after the application of a tourniquet above may be resorted to.

These measures, although they are entirely satisfactory for reactions due to overdose, in our experience have proved inadequate to prevent reactions due to puncture of veins. Duke³ considered the accidental puncture of venules when he advocated the administration of epinephrine and ephedrine simultaneously with a small portion of the pollen extract. Only after noting a preliminary subcutaneous blanching does he inject the remaining amount. There are two definite disadvantages to this procedure. First, these drugs delay or prevent the occurrence of a local swelling which serves as a gauge for subsequent injections and thus make further treatment more difficult. Second, there is the well-known effect of even small doses of epinephrine which has often discouraged patients from continuing further treatment.

CHART III
Comparison of Potential and Actual Reactions in 1934
(In 18,775 Injections)

	Number	Incidence
Blood in Syringe (Retraction of plunger)	12	1 1564
No Times Blood on Cotton	104	1 180
"Intravenous" Reactions	2	1 9387
"Backseepage" Reactions	12	1 1564

PREVENTION OF "INTRAVENOUS" AND "BACKSEEPAGE" REACTIONS

If for these reasons, one does not wish to avail himself of Duke's method, the following precautions are suggested for the prevention of reactions due to puncture of a vein.

1. Care in selecting an area for injection which is not highly vascularized. Such a suggestion may seem superfluous, had we not encountered patients in whom blood was noted on retracting the plunger on repeated occasions. In five cases this occurred more than twice in the same person and, in one individual, blood was recovered on four different occasions. After a more careful inspection of the skin we were able to discern small veins which had been punctured and which we had previously overlooked. We are now in the habit of inspecting the prospective area very carefully, paying attention to good lighting conditions, and having the patient open and close the fist after the venous return had been compressed manually.

* The value of the last mode of treatment is well illustrated by the following case. In a patient (E. P.) an extreme overdose of cotton extract had been given because of an incorrect estimation of the patient's degree of sensitivity. Within two minutes after the injection a markedly itching area had arisen and generalized symptoms seemed imminent. Upon incision of the wheal after a tourniquet had been applied above the site of injection, most of the extract mixed with blood was recovered and relatively little epinephrine was required to prevent disagreeable after-effects.

above the elbow. The injections are given in the subcutaneous regions of the extensor surface of the forearm, in order that sufficient space for the application of a tourniquet and the administration of epinephrine be available.

2 Repeated withdrawal of plunger. This precaution, we feel, constitutes a definite aid in the prevention and control of intravenous reactions. As shown in chart 3, there were 12 occasions in a series of 18,775 injections during the course of which blood appeared in the syringe. In two different instances blood was noted only after the second or third retraction of the plunger and after a small portion of the extract had been administered. This was apparently due to the fact that the needle was displaced after its first insertion into the skin. Although the needle was immediately withdrawn, the ensuing reactions were unusually severe. How small a fraction of a routine dose may thus account for rather alarming symptoms can be seen from the following instances.

Case 2 Mr. A. M., a pollen asthmatic undergoing perennial treatment, had reached 7200 units of both small and giant ragweed on July 26. On August 2, he was to receive 7500 units of the same pollen extracts. After a preliminary withdrawal of the plunger, after only about one-fifth of the contents of the syringe had been administered, a second withdrawal of the plunger disclosed blood in the syringe. The needle was immediately withdrawn. Almost immediately the patient noticed a marked burning sensation in the abdomen and about the mouth. He became extremely short of breath. In the meanwhile, he was given 10 c.c. of epinephrine and a tourniquet was applied above the site of injection. Marked cyanosis and collapse ensued. At that time a slight edema of the face was noted. A second injection of epinephrine, 10 c.c., was given subcutaneously. After three minutes he regained consciousness, his breathing became easier, and within a short time no symptoms were noticeable other than those attributable to the effect of epinephrine.

Case 3 Dr. E. J., a 52 year old pollen asthmatic, was to receive an injection of 10,000 units of small and giant ragweed on July 24. The needle was inserted and the plunger withdrawn without noticing any blood in the syringe. After only a few drops of the extract had been injected, a second withdrawal of the syringe disclosed blood in the syringe. The needle was immediately withdrawn, a tourniquet applied above the site of injection. Within 45 seconds the patient complained of a spastic contraction of his chest, followed by marked wheezing and dyspnea. Epinephrine (0.5 c.c.) had already been given by this time. No dermal manifestations or collapse occurred. The reaction gradually subsided.

At several occasions it was found that in spite of repeated retractions of the plunger, no blood was noted in the syringe even though a venule had evidently been punctured. The plunger used was obviously not sufficiently tight-fitted. We, therefore, replaced the syringes with asbestos-wrapped pistons by syringes with more tight-fitting glass plungers for the administration of pollen extracts. We feel that this has contributed to the reduction of the incidence of this type of reaction.

3 Watching the area of injection for blood. Another means of recognizing a punctured vein is the appearance of blood at the site of injection. While the presence of blood does not always indicate an imminent reaction, a precautionary small dose of epinephrine (0.2 c.c.) and the application of

a tourniquet will largely obviate the danger of a "backseepage" reaction, considering the fact that there is always a time interval of from one to five minutes before "backseepage" reactions occur

4 Tight pressure upon the injected area It is impossible to furnish data to prove the effectiveness of this procedure, but it is felt that it tends to prevent the occurrence of "backseepage" reactions by occluding through pressure small venules which might have been punctured

5 Epinephrine It may seem that the measures suggested here are concerned with the prophylaxis of reactions due to punctured veins rather than with their treatment Since the outcome of the treatment depends entirely upon the rapidity with which epinephrine can be administered, the early recognition of this type of reaction is of the utmost importance

Every patient should be instructed about the symptoms of "intravenous" reactions If there is the slightest suspicion of the puncture of a vein, 0.2 to 0.3 cc of epinephrine should be given immediately If the symptoms of an impending reaction should then ensue, the first injection of epinephrine should immediately be followed by a larger amount (0.5 to 1.0 cc) of epinephrine

While these observations were made on patients receiving pollen extracts, they are applicable to injections of serum or of any other antigen to which unusual sensitivity exists

DISCUSSION

It may seem unusual that small amounts of intravenously-administered pollen extract are of such significance in the production of severe reactions inasmuch as Lichtenstein¹⁰ has shown that pollen treatment can be given by the intravenous route In his procedure, however, he was required to give initial doses, which were much smaller than is customary in ordinary treatment, and thus he probably built up a specific protection for this type of treatment If, as Kahn's⁷ work suggests, in intravenous therapy a different type of antibody is prevalent, one may assume that hyposensitization treatment by the subcutaneous route does not produce the protection required for intravenous treatment, and vice versa

Concerning the medico-legal aspect of this problem, the liability to which physicians are susceptible in pollen therapy should be pointed out, if they have not available for immediate use a fresh solution of epinephrine Some physicians have their nurses administer the injections of pollen and serums Others make it a practice to allow their patients to administer the injections themselves, especially those who have been in the habit of giving themselves epinephrine An emphatic warning must be given against such practice The neglect to observe the patient for at least five to ten minutes after the injection is another matter, which, in our opinion, may involve legal entanglements As pointed out, the reactions due to "intravenous" administration occur within a relatively short interval, and, moreover, the beginning of a reaction due to an overdose will become noticeable within that period of time, by the appearance of an unusually marked local edema

SUMMARY

1 In the treatment with pollen extracts, the accidental puncture of veins and administration of the extract into the blood stream constitutes a grave emergency

2 In 41 037 injections 38 such reactions were encountered, 4 of which were due to direct introduction of the extract into the blood stream ("intravenous" reactions) The remaining were "backseepage" reactions due to subsequent flow of the extract into a previously punctured venule

3 A clinical differentiation of true "intravenous" and "backseepage" reactions from those due to an overdose is outlined

4 Only a small fraction of the routine dose, if accidentally introduced into the blood stream, is necessary to cause unusually severe symptoms

5 The measures usually advocated for the prevention and treatment of reactions are discussed as adapted to reactions due to punctured veins The following additional suggestions for their early recognition and control are presented Care in avoidance of visible veins in the selection of the site of injection repeated withdrawal of the plunger before and during the injection for evidence of blood, watching the site of injection for subsequent bleeding and subcutaneous hemorrhage, and pressure upon the site of injection

6 The rapidity with which epinephrine is given determines the course of the "intravenous" and "backseepage" reactions The application of a tourniquet is an aid in controlling a "backseepage" reaction, but is of no avail if the pollen extract has been injected directly into the vein

7 In contrast to an incidence of one "backseepage" reaction in 890 injections, only one such reaction in 1564 injections was noted in 1934 since instituting the above precautions In the two instances of "intravenous" reactions, only a small portion of the routine dose was administered due to early recognition

SCHILLER, THE GREATEST OF THE MEDICAL POETS

By LOUIS H. RODDIS, F A C P, Commander, Medical Corps, U S Navy

JOHAN CHRISTOPH FRIEDRICH SCHILLER, the poet and friend of Goethe, was born November 10, 1759. November 10 was the birthday of another medical poet, Oliver Goldsmith, born 31 years before in 1728.

Schiller's place of birth was the little town of Marbach in Wurtemberg, Germany, situated in a district of the Rhine valley long famous for the beauty of its scenery and the richness of its agriculture. The eminent German soldier Von Hutten, known to medical men principally for his connection with the early history of syphilis, who spoke with authority for he had travelled in all parts of the Fatherland, said of Wurtemberg in a letter written in May 1517, "There is scarcely a more beautiful neighborhood in all Germany than the Province of Wurtemberg. The soil is excellent, the climate mild and wholesome, mountains, valleys, meadows, streams and forests interspersed in pleasing variety. The products of the earth are unusually abundant, the wine is like the country. The Suabians call Stuttgart the Earthly Paradise, so charming is the situation of the town." This encomium is well deserved. The pine clad slopes of the Black Forest bound it on the south, while vineyards, fields, villages, cities, cathedrals, and ruined castles along the Rhine and the Neckar add to the scenic beauty of the district and make it an idyllic homeland for a poet. Schiller's attachment to his home was deep and romantic, and this feeling exercised a powerful influence over his life and poetry.

The father of the poet had himself been apprenticed to a surgeon, and served in that capacity in the Bavarian Army throughout the campaigns in the Netherlands during the Wars of the Spanish Succession. Later he was commissioned as Ensign and Adjutant by the reigning Duke of Wurtemberg who, after the Peace of Paris, continued him in his service, advanced him to the rank of Captain and Major, and employed him as his chief forester. This was a task to which he was peculiarly suited as he had a great interest in forestry and landscape gardening. The remainder of his life was spent in the establishment of nurseries, the planting of trees and the improvement of the grounds at the Duke's beautiful forest castle "Die Solitude" or "The Solitude." He is said to have planted and raised from seeds 60,000 forest trees. He published a book on forestry, and lived to enjoy the fame of his son. He was evidently a man of forceful character, practical, conscientious

* Received for publication December 2, 1935

This is the seventh of a series of portraits of medical poets. Those which have previously appeared in the ANNALS OF INTERNAL MEDICINE are: Joseph Rodman Drake, February, 1929; Oliver Wendell Holmes, June, 1930; Oliver Goldsmith, May, 1932; Wm. Savage Pitts, January, 1933; Lieutenant Colonel John McCrae, June, 1933; Dr. Richard Shuckburgh, June, 1934.

and deeply religious. The mother had a less strongly marked personality though she was affectionate and devoted. While it has been the fashion to state that the remarkable qualities of so many great men were received from their mothers, it seems more than likely that in the case of Schiller much of his strength and ability were derived from his sire.

Fritz, as most German boys named Friedrich are called, received his first school instruction from Philip Moser, the Lutheran pastor at Lorch, for though born in southern Germany where Catholicism was the prevailing religion, Schiller's people were Protestants. It was the desire of the parents that their boy should enter the church, and indeed he seems to have had an inclination for it. We have a charming account, by one of his biographers, of Schiller as a boy of five or six years playing at being a pastor. He would tie one of his mother's black aprons about his neck in the manner of a surplice, put on a cap, and standing on a chair as a pulpit he would deliver a sermon, very serious about it all and much offended if anyone laughed at him.

The reigning prince of Württemberg was a petty tyrant, full of energy and bustle, who, after a life of extravagance and dissipation, proposed to devote the later years of his life to good works. One of his hobbies was a military academy at Stuttgart, and here was placed young Schiller to be educated at the expense of the prince. The boy, however, had no choice as to the course he should like but was compelled to study law though his parents desired him to study theology. He finally obtained permission to give up the law but only on the condition that he would study medicine. His entrance into our profession was, therefore, due to chance and necessity rather than to any interest in the subject.

The life of the students at the Academy was more like that of prisoners than scholars, and the strictest military formalities were observed. "It was a strange sight," says Nicolai (*Travels Through Germany*) who visited the Academy, "when at the dinner hour the pupils, in two columns, the nobles to the right and the burghers to the left, filed solemnly into the dining hall without the slightest betrayal of pleasure so natural to boys at the sight of food. 'Front,' 'to the right,' 'to the left,' were called out as they reached the tables. When the command was given with a loud clap to say grace, all hands were folded, and, the prayer ended, each unfolded his hands, took hold of the chair to perfect time, pulled it out and sat down, just as a battalion of soldiers fire at command. Indeed, I am almost sure they kept time as they put their spoons into the soup."

It was in such an atmosphere that Schiller pursued his medical studies. His favorite reading was Luther's translation of the Bible, and Plutarch, and the German poets Lessing, Goethe, and Klopstock. The birthdays of the reigning prince and of prominent members of the court were celebrated by plays and musical festivals. Schiller wrote his first published poem for one of these occasions, printed in the *Suabian Magazine*, a local monthly periodical. In 1779 he produced a thesis "The Philosophy of Physiology," first

FIG 1 JOHAN CHRISTOPH FRIEDRICH SCHILLER

written in German and then translated into Latin. This essay did not receive the approbation of the authorities and Schiller was compelled to spend an additional year in study. The following is the Prince's comment to the Principal of the Academy: "I must confess there are some fine points in

pupil Schiller's essay and plenty of enthusiasm. But I do not wish it to be published and think it will be better for him to remain in the Academy another year until his enthusiasm has cooled off somewhat and then, if he continues to be industrious, he may become a great man." For once condescending mediocrity was right. Pupil Schiller did become a great man. The august and pedantic old prince did not realize that he really was a prophet.

The next year Schiller was more successful with his essay "The Connection of the Animal Nature of Man with the Spiritual." This was published as was a Latin dissertation required of him on inflammatory and putrid fevers.

He was now considered to have completed his professional training and was appointed Surgeon to the Regiment of Grenadiers, then in garrison at Stuttgart. As a free pupil at the Academy he was bound to the service of the reigning ducal house of Wurtemberg. Thus at 21 he found himself a military surgeon with a salary scarcely sufficient to support himself. He lodged with a former comrade at the Academy, Lieutenant Kapf, in a house in the Eberhards Strasse kept by a blond widow of 30, Frau Wischer or the "Vischerin." Kapf and Schiller shared a little room here which they referred to as "The Kennel." Here they occasionally entertained their bachelor friends with smoked sausage, potato salad and beer with plenty of tobacco smoke for a background. They had a soldier servant, Private Kronenbitter, with a uniform "adorned with patches." The poet Scharffenstem, who was a frequent visitor, describes Dr. Schiller as rigged in "a uniform of the old Prussian cut, rolls (which were intended for curls) on each side of his face, the military hat which was hardly large enough to cover his head and from under which hung his long thick queue. Around his neck he wore a stiff stock of horsehair."

During the later years at the Academy and the first months as an Army surgeon Schiller wrote his first great work, the tragedy called "The Robbers." The appearance of that poem and its almost immediate success on the stage soon made the 21 year old Army doctor famous throughout Germany. Scherr tells of his stealing away at this time from his duties without leave, accompanied by a comrade journeying to Mannheim to see a performance of his play, and "very near being too late, detained by the charms of a pretty barmaid on the way." "Happy carelessness of youth," says this biographer, "which, even on the threshold of a great event, could be stayed by the bright eyes of a barmaid."

The tyrannical old Prince of Wurtemberg did not approve of his Army surgeons becoming poets. He felt it was a waste of state education, and some of the liberal sentiments expressed in "The Robbers" were also not to his liking. Schiller was forbidden to publish any more poetry without first passing it through the hands of the censor. This and the fear of imprisonment led to Schiller's decision to flee from the service of the Prince and to devote himself entirely to literature. It was a decision which of

couse separated him from any hope of official position in Wurtemberg and also separated him from medical practice, though to the end of his life he maintained considerable interest in medicine and on a number of occa-

FIG. 2 The statue of Schiller in Como Park, St. Paul, Minnesota

sions when in isolated situations in the country he rendered professional services to persons in need of them

Schiller's next great literary work was the drama of "Don Carlos" which further increased his fame and led to the beginning of his friendship with Goethe and Humboldt. He began also his historical studies and in 1789 he was called to Jena to become the Professor of History at that cele-

brated university. The next few years saw his reputation as a historian established by his "History of the Revolt of the Netherlands," the "History of the Thirty Years War," and his historical essays. He also became deeply interested in philosophy and aesthetics, and his essays in these fields such as that on "Grace and Dignity," and "The Aesthetic Education of Man" still further enhanced his fame. It is unfortunate that a long cherished project for a German biographical collection modeled on Plutarch was never begun.

In February 1790 Schiller married the younger of two sisters, Charlotte, or as she was generally called, Lotte Lengenfeld. Schiller's pet name for her was "Lolo." The older sister Caroline also loved him but later married her cousin William von Wolzogen. His marriage was an extremely happy one, as nearly ideal apparently as it was possible to be. In 1797 he purchased a comfortable home near Jena surrounded by a pleasant garden and with an admirable view. He wrote in the spring of that year to Goethe "I salute you from my garden to which I removed today. A lovely landscape surrounds me, the sun is smiling with a friendly adieu and the nightingale is trilling. Everything around is cheerful and my first evening in my own house is of the happiest augury." This house stood on a gentle eminence at the end of a hedge-lined path called "Monks' Alley." Behind it on a slope of the hill was the garden full of flowers and vegetables planted together as was the custom in old-fashioned gardens. At the top of the slope was a clump of trees beyond which the ground fell away precipitously to the bed of the Leutrabach whose rushing waters could be heard below. At the top of the slope under a linden, a fir, and an acacia stood a little one room cottage which served as the poet's study. It is now torn down and a stone marked with the inscription "Here Schiller wrote his *Wallenstein*" indicates its former location. Beside it in an arbor was an old stone table where Schiller often sat when writing and where he often talked with Goethe. Here too he wrote many of his most famous lyrics including the "Song of the Bell," "The Glove," "The Hymn of Joy," "The Ring of Polycrates," and "The Dignity of Man." The dramas that followed, "Maria Stuart," the "Maid of Orleans," "William Tell," "Wallenstein," and the "Bride of Messina" placed Schiller among the greatest of the dramatic poets.

Though he had many love affairs before marriage Schiller was one of the most domestic types of men and was happiest in the enjoyment of his home and family life with his wife and four children. His literary success also gave him great pleasure. Both of his parents lived to see him recognized as one of the greatest poets of all time. But despite the happiness and satisfaction from these things his last days were clouded by ill health and financial worries. The latter were partly alleviated by a pension from the Duke of Weimar but work and pleasure were marred by frequent attacks of illness. The first of these attacks began in Jena in 1790 and was apparently a cholecystitis and hepatitis. Later attacks became more fre-

quent and severe and in the spring of 1805 a broncho-pneumonia as a complication ended his life. This was the year of Wagram and Trafalgar. He was but 45 years of age. As he was dying he replied to a question as to how he felt, "calmer and calmer." His widow and two sons and two daughters survived him. The news of his death, in the words of Carlyle, "Fell cold on many a heart, not in Germany alone but over Europe it was regarded as a public loss by all who understood its meaning." This well expresses the affection felt toward him by all ranks of society as a lover of human kind and a spokesman of the best and noblest feelings of humanity. He was beloved for these qualities as well as respected and admired for his genius. Modesty, uprightness, manliness, and love of liberty, and affection and devotion to friends and family were outstanding characteristics.

Physically he was tall and slender, blond, with abundant red hair. His countenance and head were fine and his expression and smile attractive and amiable. He usually held himself with almost soldierly erectness, a heritage in part of his earlier military training. In later years when walking by himself he often went with his eyes cast upon the ground so that he would often nearly pass acquaintances without speaking but when he heard their salutation "he would catch hastily at his hat and give his cordial 'Guten Tag'."

Schiller's intellect was remarkable for power, clearness and comprehensiveness. The nobility of his nature is seen throughout his works which shine with his love of God, country, liberty, home, men, women, children, nature, and life. A patriot in the best sense of that abused word he was able in "William Tell" to interpret nationalism in Switzerland and Germany, and in the "Maid of Orleans" the national aspirations of France.

His relatively short life had been full of accomplishment. A quotation again from Carlyle furnishes the most suitable conclusion to this sketch of the greatest of the medical poets, of whom medical men and particularly military medical men should be especially proud.

"The kingdoms which Schiller conquered were not won from one nation at the expense of suffering to another, they were soiled by no patriot's blood, no widow's, no orphan's tear. They were kingdoms conquered from the barren realms of Darkness, to increase the happiness and dignity and power of all men, new forms of Truth, new maxims of Wisdom, new images and scenes of Beauty won from the 'void and formless Infinite,' a possession forever to all the generations of the Earth."

Bibliographical Note Scherr, *Life and Times of Schiller*, written about 1860, can scarcely be spoken of too enthusiastically. It is a classic of biography, worthy to stand beside Lockhart's *Scott* or Boswell's *Johnson*. Other works of importance are Pallaske (2 volumes), Carlyle (a short but striking character study and appraisal of Schiller's genius), and the highly interesting biography by his sister-in-law, Caroline von Wolzogen.

The picture of Schiller reproduced here forms the frontispiece of Scherr's biography. The statue, a very handsome one, stands in Como Park, St. Paul, Minnesota, and is from a photograph taken by the writer.

CASE REPORTS

FELTY'S SYNDROME, REPORT OF A CASE WITH NECROPSY FINDINGS *

By ROBERT H WILLIAMS, M D, *Nashville, Tennessee*

In 1924, Feltv¹ reported five cases in which the chief disturbances were chronic arthritis, splenomegaly and marked leukopenia

In 1932, Hanrahan and Miller² reported a case with characteristics closely resembling those of Felty's cases, for which a splenectomy was performed with benefit both objectively and subjectively

In March 1934, Craven³ added another case, likewise treated by splenectomy with improvement Also in March 1934, Alessandrini⁴ reported a similar case in which splenectomy was advised, but refused by the patient

In April 1934, Price and Schoenfeld⁵ reported a case with complete post-mortem findings

Until the present, only nine cases with this unusual and interesting syndrome have been reported, and the case to be presented in this paper is, as far as can be determined, the second autopsy report of such a case

F R, a white male, married, chaplain, aged 54 years, was admitted to the Second Medical Service, December 1, 1933, with the complaint of migratory joint pain of 10 days' duration

Family history was irrelevant He was born in Ontario, lived in Boston for the past 37 years and was never in the tropics No history was obtained of malaria, typhoid, scarlet fever, tonsillitis, chorea or rheumatism before the present illness He had had no serious illnesses and had always been in good health Sore throats, colds and dental troubles have been rare No symptoms had been present referable to the cardio-respiratory, gastrointestinal or neuro-muscular systems For the past three years there had been nocturia, twice per night

The present illness had begun with chilliness, feverishness and languor two months before admission These symptoms had persisted, and 10 days before admission, following exposure to a cool breeze for 12 hours, there was an aching and swelling in the left hand, disappearing spontaneously after 16 hours Two days later there were pain and swelling in the right ankle, which cleared up considerably after 12 hours Three days later the left hand became quite weak but not very painful The day before admission, the feet began to swell and were very painful This was soon followed by pain and swelling of the left shoulder and right knee, the pain disappearing in 12 hours On the morning of admission there developed severe pain on motion in the right elbow

On examination, the patient was found to be well developed and nourished, with a richly tanned skin The eyes, nose, mouth, throat and chest showed nothing remarkable In the infraclavicular regions, there was slight dullness, bronchovesicular

* Received for publication September 6 1935

From the Mallory Institute of Pathology, Boston City Hospital

breath sounds and a few crackles following cough. There was also slight dullness over the apices, posteriorly. The firm, smooth, sharp edge of the spleen was felt two cm below the left costal margin. The liver was not felt. There was free motion of all joints, except the right elbow, with relatively little discomfort. Very slight distress was experienced in both ankle joints. The left hand and wrist were definitely swollen and showed slight pitting edema. There was slight pitting edema of the right hand. The right elbow was held in a slightly flexed position, and the patient could not achieve complete extension without suffering severe pain. There were no objective signs about this joint except limitation of motion. The right knee showed nothing remarkable. There was a small amount of fluid in the left knee, and the patella floated. Both feet from the ankles down showed slight increase in heat and definite pitting edema.

The patient stayed in the hospital for about seven weeks during which time the spleen remained palpable two cm below the costal margins. The total white count ranged around 3000. Roentgenograms on admission showed cloudiness of the outlines of the right elbow joint and hypertrophic arthritis of both knees with effusion. Roentgen-ray of the sinuses showed clouding of the right antrum. Prostatic smear revealed no gonococci. Two electrocardiograms, a roentgen-ray of the chest, two aerobic and anaerobic blood cultures, two agglutination tests for *B. melitensis*, two stool cultures, several urine examinations and a Wassermann test were all negative.

8/26/34	3 2	34		3	2	24	36				
8/27/34	2 9	12		2	3	49	28	1			

On tapping the left knee, December 9, 50 c c of yellow turbid fluid were obtained, the total proteins of which were 4.5, the non-protein nitrogen 29, sugar 124, polymorphonuclear leukocytes 60 per cent, eosinophiles 2 per cent, lymphocytes 2 per cent and monocytes 2 per cent. No organisms were found by smear or culture.

The patient's treatment consisted chiefly of salicylates orally, physiotherapy and free fluids. By December 17, he had obtained free motion in the right elbow and shoulder. By December 29, there were no joint symptoms except stiffness in the right shoulder and right elbow. During the last week, he was given mild exercise for the various joints. Preparations were made for him to convalesce in Florida.

During his stay in the hospital there was an elevation of the temperature from 99 to 100°, almost every evening, but never above 100.5°. The pulse likewise was elevated from 85 to 100.

peared with the beginning of the improvement in April and has not recurred. The tongue appears to be normal. Nor has there been any return of tetany. By June 4 the blood calcium was 10.5 mg per 100 cc. The appetite remained a ravenous one until about the middle of August since which time it has been normal. Bowel movements for months have been normal with one movement daily. The stools are not bulky and microscopically there is no excess fat. The abdomen is not distended nor has there been any gaseous indigestion the past several weeks. The patient enjoys a normally active life. There is still a small amount of edema of the ankles which disappears overnight. On June 3 the serum albumin was 3.9 per cent and the serum globulin 2.1 per cent. At that time being up and around a very little resulted in a rather marked leg edema. On September 25 the serum albumin was raised to 5.1 per cent and the serum globulin was 1.3 per cent. It was felt that the inanition edema was increased by a weakness of the heart muscle from starvation in spite of the rise of the blood pressure to 122 mm mercury systolic and 74 diastolic, a rise which has persisted up to the last examination.

The response of the blood was at first satisfactory although it was not remarkable in view of the considerable amount of parenteral liver given. The reticulocytes rose only to 4 per cent. After the initial rise to 59 per cent hemoglobin with a 2,790,000 erythrocyte count on the twelfth day there was difficulty in improving the blood picture. On the twenty-ninth day the hemoglobin had dropped to 47 per cent with 2,710,000 red blood cells. By that time the patient could tolerate iron without added abdominal distress so one gram of ferrum reductum was added daily to the other therapy. This resulted by September 25 in a hemoglobin of 84 per cent (Dare) with 4,590,000 erythrocytes, a color index of 0.9, the white blood cells numbering 6,450 with 58 per cent neutrophils, 39 per cent lymphocytes, 2 per cent monocytes and 1 per cent basophiles.

Characteristic roentgen-ray pathology was not disclosed in the gastrointestinal examination conducted after recovery from the severe symptoms had taken place.

DISCUSSION

Although sprue is uncommon in Cuba¹⁶ this case must be considered as one of the tropical variety in spite of the fact that no *Monilia* could be found in the stools.

While there may have been a dietary deficiency before 1932 there certainly was a dietary deficiency after the teeth were removed. The sore mouth of the alveolectomy shortly became the sore mouth of sprue. There ensued a functional as well as perhaps an anatomical interference with the absorption of fats and other food elements. Anorexia, weakness, emaciation, flatulent indigestion, and fatty, bulky diarrhea resulted. Inanition caused a severe edema, a marked drop in blood pressure and a cardiac weakness. The hypocalcemia is explained on the basis of faulty absorption and reabsorption of calcium in the bowel because of formation of calcium soaps with the excess fat in the intestine as well as by poor absorptive power of the small bowel due to edema, atony, and from possible inflammatory changes.

Faulty absorption as well as inadequate ingestion of iron is an important consideration. It has been found that it is often necessary to give large doses of iron in order to obtain satisfactory blood response.⁹

For many years bizarre diets, all more or less rich in the extrinsic factor, have been moderately successful in the treatment of sprue.¹ Reduction

of fats in the diet has always been stressed and was followed in the beginning in this case. Snell⁸ emphasizes the use of vitamin D and calcium.

Since the introduction of the liver diet in the treatment of these cases by Bloomfield and Wyckoff¹⁷ in 1927, liver therapy has been found to be most satisfactory, probably because it contains more of the extrinsic factor as well as the hematopoietic substance. However, it was found that faulty absorption occasionally prevented adequate utilization of the liver, and parenteral liver extract was then used. According to the experience of Rhoads and Miller¹ much more liver extract was necessary to control the sprue symptoms than is commonly necessary in pernicious anemia. Their report detailed four cases which had been treated previously with rather large doses of parenteral liver extract and which did not respond until daily doses such as were given in this case were administered.

CONCLUSION

A case of sprue is reported illustrating the effectiveness of liver therapy.

LOCALIZATION OF THE SITE OF EXPERIMENTAL PREMATURE CONTRACTIONS AND BUNDLE BRANCH LESIONS BY MEANS OF MUL- TIPLANE CHEST LEADS*

By JOSEPH WEINSTEIN, M D , and DAVID I ABRAMSON, M D ,
Brooklyn, New York

IN A recent publication,¹ the authors presented the results obtained in detecting and localizing experimental myocardial lesions by means of certain chest leads,² which differed in a number of respects from the others thus far employed. These experimental leads (designated as multiplane chest leads) consisted of combinations of linear electrodes placed on the anterior and posterior surfaces of the chest parallel to and beyond the estimated borders of the heart, in contra-distinction to the conventional chest leads, advocated by other investigators^{3, 4, 5} in which at least one electrode of sufficiently large circumference was placed on the anterior or posterior chest wall directly over the heart itself. In our experimental leads a number of recording planes were employed, these appearing to be responsive to electrical changes of even small magnitude. It was found that superficial cauterization of various parts of the epicardial surface of both ventricles consistently produced RS-T changes in the experimental chest lead tracings, whereas in only one-half of these cases were similar alterations noted with the standard three leads, and in two-thirds with Lead IV. At the same time it was found that the experimental chest leads generally indicated the ventricle involved.

The present work was undertaken in order to investigate in more detail the question of the value of these leads in localization. It is the purpose of this communication to report the electrocardiographic alterations observed in the experimental chest lead tracings following first, the artificial production of premature contractions from various parts of the ventricles, and second, the transection of either one or the other branches of the Bundle of His.

METHOD

The experiments were performed on cats under "Dial" anesthesia (intraperitoneal). The German silver electrodes used in our previous experiments were replaced by ones of steel wire (1/32 inch in diameter), since polarization was less often present with the latter. The sites of insertion of the electrodes, as well as the manner in which the animal was prepared

* Received for publication May 30, 1935

From the Department of Physiology and Pharmacology, Long Island College of Medicine, and from the Medical Service and Cardio-Vascular Laboratory of the Jewish Hospital of Brooklyn

With the technical assistance of Pearl Kramer

and the heart exposed, were similar in all respects to those used in the previous work¹

The following leads were employed (figure 1)

FIG 1, *A* and *B* Diagrammatic representation of the position of the experimental chest electrodes *A*, Anterior surface *R*, right electrode located some distance to the right of the sternum *L*, left electrode, extending in the left anterior axillary line parallel to electrode *R* *I*, inferior electrode, inserted somewhat above the level of the ensiform cartilage and extending across the chest *B* Posterior surface *S'*, superior posterior electrode, extending across the back at about the level of the superior border of the scapulae *L'*, left posterior electrode placed so as to correspond in position to *L* (left anterior electrode) *C* and *D* Cross section and lateral view of chest illustrating the various electrode combinations *L'R*, left posterior and right anterior electrodes *RL*, right anterior and left anterior electrodes *S'I*, superior posterior and inferior anterior electrodes

- 1 *L'R*—(*L'*) electrode placed on the posterior chest wall at the level of and grossly parallel to the left border of the heart and (*R*) electrode placed on the anterior chest wall at the level of and grossly parallel to the right border

- 2 RL—Both electrodes placed on the anterior surface of the chest, one (R) at the level of and grossly parallel to the right border of the heart, and the other (L) at the level of and grossly parallel to the left border
- 3 S'I—(S') electrode placed at about the level of the spines of the scapulae on the posterior chest wall and extending practically across it, and (I) electrode situated at the level of and grossly parallel to the inferior border of the heart on the anterior chest wall and extending across it

As in the former investigation, the electrodes were led to a selector switch by means of which any chosen pair could be connected to the standard Lead I contacts of the electrocardiograph. The posterior electrode in each combination was attached to the right arm lead wire of the galvanometer and the anterior electrode to the left arm wire. In the case of Lead RL, in which both electrodes were situated anteriorly, the right electrode was combined with the former and the left electrode with the latter.

The premature contractions were produced by stimulating the ventricles by means of induction shocks from an inductorium, the primary circuit of which was broken by the ordinary Harvard spring interruptor. The latter was so arranged that the number of stimuli per minute was about 10 or 15 in excess of the heart beat. Besides the experimental chest leads, the conventional three leads and Lead IV were generally obtained for each site of artificial impulse formation. In a number of experiments, after the extrasystoles were recorded, the heart was pulled and rotated either to the right or left by means of hooks inserted into the outer wall or by the gloved hand, and then another set of tracings taken under these conditions.

The branches of the Bundle of His were cut according to the method advocated by Roberts et al.⁶ At the end of the experiments (12 in all) the hearts were examined grossly (and in two histologically as well) for evidence of complete transection of the desired branch.

Localization of Site of Origin of Premature Ventricular Contractions by Means of the Experimental Chest Leads Examination of table 1 and figure 2 reveals that consistently the main deflection in Lead RL was upwardly directed when premature contractions were produced from any part of the right ventricle, base or apex, anterior or posterior surface, and downwardly directed in the case of impulses arising from comparable spots on the left ventricle. In Lead L'R the reverse was true, impulses arising from any portion of the right ventricle resulting in negative main deflections, whereas those from the left ventricle produced positive ones. Stimulation of the anterior and posterior aspects of the septum intervening between the outer walls of the ventricles gave variable types of changes in these leads. With Lead S'I, premature contractions originating from any part of the anterior surface of the heart, either right or left ventricle (with the exception of certain instances in the case of the left apex anteriorly), caused the

main wave to be upwardly directed, while stimulation of any portion of the posterior surface, either right or left ventricle, resulted in a negative main deflection. Impulses arising from the lateral surfaces of the right and left ventricles produced changes which fell into either one or the other category or contained characteristics of both. In other words, the main deflection

FIG 2 Curves produced by stimulation of the ventricles *A* Stimulation of anterior surface of the heart, *a* Right ventricle, *b* Left ventricle *B* Stimulation of posterior surface of the heart, *a* Right ventricle, *b* Left ventricle

in Lead S'I in cases of artificial stimulation from these sites was positive or negative, or both positive and negative. As regards the anterior aspect of the apex of the left ventricle, in a number of instances (3 out of 12) the main deflection was downwardly directed. Stimulation of any part of the anterior aspect of the septum consistently produced upright main deflections

in Lead S'I while stimulation of its posterior surface resulted in negative waves. It would therefore appear that the direction of the main deflection in either Lead RL (combination of electrodes on right and left borders of the heart anteriorly) or L'R (one electrode on left border posteriorly and other on right border anteriorly) will localize the site of origin of premature contractions to one or the other ventricle, while the direction of the main deflection in Lead S'I (one electrode on superior border posteriorly and other on inferior border anteriorly) limits it generally to either the anterior or posterior surface of the heart.

Effect of Change in the Position of the Heart on the Direction of the Curves Resulting from Artificial Stimulation. In order to test further the accuracy of the experimental chest leads in localization, a procedure similar to that of Katz and Ackerman⁷ was carried out in the present investigation. In seven instances, the heart was pulled and rotated to the left so that its anterior surface consisted almost entirely of right ventricle, and in six, traction was applied in the opposite direction so as to cause more of the left ventricle to be situated anteriorly. Records of extrasystoles, arising from the two surfaces of the ventricles close to their lateral borders, were obtained before and after the above manipulations and these were compared as to the direction of the main deflection. In nine out of 13 trials a change was noted in Lead S'I. In nearly every instance the alteration in direction could be explained by the fact that the extent of rotation of the heart was usually sufficient to change a previously posterior position to one now anteriorly situated, and vice versa, these results therefore coincided with the differences noted in S'I as one or the other surface was stimulated with the heart in the normal position. In one case, the main deflection in RL was reversed, but in no instance was a change noted in Lead L'R, even in the face of marked rotation and traction of the heart.

In the case of the standard leads and Lead IV considerable alterations were observed following the procedure, the results in these conforming generally to those reported by Katz and Ackerman. In five out of 13 cases the main deflection of the extrasystolic wave was reversed in Lead I and in nine cases, in Lead III. The main deflection in Lead IV was altered in all seven instances in which it was recorded. One can therefore conclude that generally the main deflection in the experimental chest lead which designates the ventricle involved (Lead L'R) is less susceptible to change with alteration in the position of the heart than is the main deflection in the standard leads and Lead IV.

Relative Position of the Electrodes in the Experimental Chest Leads

As in the previous investigation, steps were taken to determine whether or not the most accurate results in localization would be obtained only if the two linear electrodes in the combination were situated on the chest and in a certain definite relationship to each other. Accordingly, various substitutions for one or the other of the two electrodes in Leads L'R (which

TABLE I
Localization of Premature Contractions by Means of the Multi-Plane Chest Leads

Site of Stimulation	Multi-Plane Chest Leads									
	L'R			S'I			RL			
	No of Cases	Main Wave Positive	Main Wave Negative	No of Cases	Main Wave Positive	Main Wave Negative	No of Cases	Main Wave Positive	Main Wave Negative	No of Cases
Right ventricle, anterior surface	10	0	10	8	8	0	8	8	0	0
Left ventricle, anterior surface	10	10	0	12	9	3	7	0	7	7
Septum, anterior aspect	2	0	2	3	3	0	2	2	0	0
Right ventricle, posterior surface	8	0	8	8	0	8	8	8	0	0
Left ventricle, posterior surface	8	8	0	8	0	8	5	0	5	5
Septum, posterior aspect	3	0	3	4	0	4	3	3	0	0

designated the ventricle) and S'I (which designated surface of heart) were made. These modifications consisted of

- 1 Substituting a large oval electrode situated on the anterior chest wall, so as to overlie the heart, for the anterior linear electrodes R and I in Leads L'R and S'I respectively
- 2 Substituting a similar type of electrode placed on a corresponding spot on the back for the posterior linear electrodes L' and S' in the same leads
- 3 Combining first the posterior linear electrode and then the anterior one in each of the two experimental chest leads with an 'indifferent' electrode on the left leg

In the case of the various modifications of Lead L'R employed, it was found that results, which could be utilized for localization of the site of stimulation to one or the other ventricle, were obtained only when the right anterior linear electrode was combined with an 'indifferent' one on the left leg. In all other combinations, inconstant non-specific changes were observed.

In the case of the various modifications of Lead S'I employed, only in those instances in which the anterior inferior linear electrode was combined with a large oval electrode placed on the heart posteriorly were results comparable with those of Lead S'I obtained.

Besides the above, Lead IV was also recorded in order to observe comparable results with a lead in which two relatively large oval electrodes were placed on the chest anteriorly and posteriorly, directly over the heart. Of six instances in which the right ventricle anteriorly was stimulated, in five the main deflection in this lead was upwardly directed while in the remaining one it was negative. In reference to the posterior surface of the same ventricle, in two it was up and in the other two down. In the left ventricle anteriorly, in all instances the main deflection was positive, while in the case of the posterior sites in three it was negative and in one, positive.

To summarize, the most accurate results in localization were consistently obtained when both electrodes in the combination were situated at the estimated borders of the heart. In the case of the modifications of these leads, although some appeared to be equally efficient in localizing the surface and others the ventricle, no one type of combination was of value for both. Lead IV, in which the two electrodes were placed over the heart, was likewise of little use in this respect. On the other hand, with Leads S'I and L'R, both surface and ventricle could be localized in every instance.

Changes Observed in the Experimental Chest Leads Following the Transection of One or the Other Branch of the Bundle of His. The right branch of the Bundle of His was transected in two instances and the left in three. Consistent results were obtained in all experiments. In the case of a lesion of the right branch the main deflection in Leads RL and S'I was

negative while in L'R it was positive (figure 3A) On transection of the left branch, exactly the reverse findings were observed The main deflection in RL and S'I was consistently positive while this wave in L'R was negative (figure 3B)

The deflections in the standard leads conformed to the new classification

FIG 3 Curves produced by transection of the branches of the bundle of His *A* Transection of right branch, *a* Normal, *b* After transection *B* Transection of left branch, *a* Normal, *b* After transection

of bundle branch block^{6,8,9} while the changes in Lead IV were not characteristic In the latter, the main deflection in both right and left branch lesions was downwardly directed

Comparison of the above findings with those obtained as a result of artificial stimulation of the heart reveals that activation of one ventricle before the other, either because of a bundle branch lesion or because of the origin of the impulse in one ventricle, produces similar types of alterations in the experimental chest leads

SUMMARY AND CONCLUSION

Further evidence is presented to show that certain chest leads, employing combinations of linear electrodes placed parallel to and beyond the estimated borders of the heart, are of considerable value in (1) localizing the site of artificial impulse formation to one or the other surface of the heart as well as to one or the other ventricle, and (2) in designating the branch involved

in experimental bundle branch lesions The tracings of premature contractions obtained with some of these leads remained unchanged even in the face of sufficient traction and rotation of the heart to produce marked alterations in the standard lead and Lead IV curves

In view of the consistent results obtained in the present investigation, as well as in the previous one on experimental ventricular cauterizations, it seems reasonable to assume that these experimental chest leads should be of value when applied clinically in the identification and localization of comparable conditions

THE EFFECTIVENESS OF ACETYL-B-METHYLCHOLINE GIVEN BY MOUTH AS A VASODILATING AGENT *

By GRACE A. GOLDSMITH, M D , *Rochester, Minnesota*

CHOLINE and its compounds have been investigated extensively in recent years. Acetylcholine was first prepared by Baeyer in 1867 but remained of chemical interest only until Hunt and Taveau in 1906 noted its marked physiologic activity. Both choline and acetylcholine have been isolated from animal tissues, Dale obtaining the latter in pure chemical form in 1929. Acetylcholine owes its present importance to the almost certain proof that it is the chemical intermediary between parasympathetic nerve stimulation and tissue response (Dale and Alles).

Acetylcholine has three important actions: (1) a parasympathetic effect, inhibiting cardiac action and increasing intestinal tonus, (2) a vasodilating effect, and (3) a nicotine-like effect, causing a rise in blood pressure when its other actions have been abolished by atropine. Acetylcholine has not been useful in clinical medicine as it is rapidly destroyed on contact with blood by enzymic catalyzed hydrolysis.

Acetyl-B-methylcholine was synthesized by Major and his colleagues, and its physiologic properties were tested first by Simonart and later by Comroe and Starr. The effects produced were similar to those caused by stimulation of the parasympathetic nervous system and were accompanied by dilation of peripheral blood vessels. The drug, being less readily destroyed by the body esterases than acetylcholine, was effective when administered orally and subcutaneously.

Starr, Elsom, and Reisinger found that acetyl-B-methylcholine given subcutaneously in doses of 2.5 to 25 mg. caused a fall in blood pressure, a rise in pulse rate, flushing, and sweating. The action began within one minute and lasted from 15 to 20 minutes. Acetyl-B-methylcholine given orally caused a fall in blood pressure, a diminution in the pulse rate, and increased intestinal peristalsis. Effective dosage by mouth was from 50 to 100 times that of subcutaneous injection. The action began 15 to 75 minutes after administration and lasted from a half to one hour. Skin temperature was slightly increased in three of five cases.

Starr gave acetyl-B-methylcholine orally to four patients with Raynaud's disease, with resulting partial relief of the spasm that is excited by mild degrees of cold. One patient with thromboangitis obliterans had a rise in skin temperature of 1.8°C after taking 300 mg. of acetyl-B-methylcholine by mouth. The drug caused temporary reduction in blood pressure in most cases of hypertension in his series.

* Submitted for publication August 16, 1935.
From the Mayo Clinic, Rochester, Minnesota.

Kovacs and Kovacs used acetyl-B-methylcholine by iontophoresis in chronic arthritis and in a few cases of peripheral vascular disease. They obtained an increase in skin temperature in the areas treated which lasted from two to eight hours. Two patients suffering from digital ulcers in cases of Raynaud's disease exhibited rapid healing of the lesions.

Page, who administered this drug subcutaneously to hypertensive patients, found a drop in blood pressure and an increased temperature of the skin of the face and trunk, the hands and feet being almost unaffected. The electrocardiogram often showed an inverted T-wave. The heart rate was increased. Given by mouth in doses of 4 gm the blood pressure was affected little or not at all.

The present study was undertaken to investigate further the effects of the oral administration of acetyl-B-methylcholine (mecholin)* on the temperature of the skin, pulse rate and blood pressure of subjects who had disease of the blood vessels. The drug was given to 29 patients in doses of 50 to 1500 mg. Experiments were conducted in a room of constant temperature, the subject having rested a half hour or more to allow the blood pressure, pulse rate, and skin temperature to reach a constant level. The temperature of the skin was determined by thermal junctions attached to the fingers and toes. Readings were taken at intervals of 15 minutes for a period of several hours.

EFFECTS OF ACETYL-B-METHYLCHOLINE ADMINISTERED ORALLY

Effect on Skin Temperature The effect of the oral administration of acetyl-B-methylcholine on the temperature of the skin in the cases studied is given in table 1. Any rise of 2°C or less was considered insignificant. Only three patients failed to show such an increase, and of these two received small and insufficient doses. The average maximal rise was 5.82°C and the average high temperature attained in the digits was 33.1°C .

In 13 cases there was a rise of more than 6°C . In cases in which vascular spasm rather than organic occlusion predominated, namely, in cases of hypertension and Raynaud's disease, vasodilation was greatest. Smaller doses (50 to 100 mg) were effective in some instances in cases of Raynaud's disease, whereas in cases of arteriosclerosis and thromboangitis obliterans from 1,000 to 1,500 mg were needed to produce significant vasodilation. In eight cases a rise in temperature occurred in the fingers but none in the toes. Three of these patients received doses of less than 200 mg. Larger doses seem necessary to open up the vessels in the feet. Particularly in Raynaud's disease the fingers were more readily affected.

There was marked variability in the rise in cutaneous temperature in the various digits in cases of Raynaud's disease, and less variability in cases of arteriosclerosis and thromboangitis obliterans. In one case of Raynaud's

* Acetyl-B-methylcholine (mecholin) for this investigation was furnished through the courtesy of Merck and Company.

TABLE I
Effect of Acetyl-B-Methylcholine on Skin Temperature

Diagnosis	Cases	Maximal rise in skin temperature, degrees C	Actual skin temperature, degrees C
Hypertension	4	Average 6.62 Range 3.1 to 9.6	34.7 33.4 to 36.0
Raynaud's disease and scleroderma	8	Average 7.45 Range 3.0 to 9.9	32.65 27.0 to 35.0
Thromboangitis obliterans	7*	Average 3.67 Range 0.9 to 7.0	32.80 29.6 to 35.6
Arteriosclerosis	5*	Average 4.72 Range 1.0 to 7.3	32.58 27.4 to 35.9
Miscellaneous	5*	Average 6.65 Range 1.5 to 10.5	32.54 26.4 to 36.9
Total	29	Average 5.82	33.11

* In one case in each of these groups there was no appreciable rise in skin temperature (less than 2.0° C)

disease the rise in the temperature of the fingers varied from 1.9° C in one digit to 8.1° C in another. In one case of arteriosclerosis there was a rise of 1.6° C in one toe and of 7° C in another. Organic occlusion of smaller vessels would readily explain this variation. The patients who had hypertension and those of the control group gave evidence of a uniform rise in all digits.

The action of acetyl-B-methylcholine began from 15 minutes to two and a half hours after its oral administration, in 50 per cent of the cases it took effect in from 30 minutes to an hour. The maximal rise in skin temperature usually was attained in from one to three hours. The height of vasodilation was reached in less than one hour in three cases in which small doses were given and in more than five hours in two cases in which 1500 mg of the drug were given. The duration of the rise in cutaneous temperature varied from one to six hours. In seven cases it was more than four hours, and in six additional cases more than three hours. Many experiments were terminated before the temperature returned to the original level. By repeating a dose of 1500 mg in three or four hours vasodilation could be maintained for seven or eight hours. The effect of the drug in a case of thromboangitis obliterans in which the patient was given 1500 mg at the onset of the experiment and four hours later another 1500 mg is shown in figure 1. Seven hours after the first dose the cutaneous temperatures were still considerably elevated. Room temperature remained at 24° C. The other digits behaved similarly. Variations in blood pressure and pulse rate, as can be seen, were too small to be significant.

In three cases a comparison was made between the efficiency of acetyl-B-

FIG 1 The effect of repeated doses of acetyl-B-methylcholine on skin temperature

methylcholine and typhoid vaccine as vasodilators. If the latter is assumed to be 100 per cent efficient, acetyl-B-methylcholine in these instances averaged 75 per cent in vasodilating ability.

Effect on Exposure to Cold in Raynaud's Disease A patient with Raynaud's disease was given an ice water test to ascertain the effect of acetyl-B-methylcholine on the reaction of the blood vessels in the fingers to exposure to cold. Skin temperatures of the digits were taken until they reached a stable level. The hands were then immersed in ice water at 13.5° C for three minutes. The color reactions were noted, and the temperatures were recorded immediately after removal of the hands from the water and at intervals thereafter. The next day, the entire test was repeated one hour and again two hours after 1 gm of acetyl-B-methylcholine was given by mouth. Changes in color were less marked, and the temperature of the skin did not fall to quite as low a level after the drug had been administered as it had during the control test. In addition to this the hands warmed up much more quickly in the tests performed after acetyl-B-methylcholine had been given and returned to normal in less than 30 minutes, whereas in the control test it took from one to one and a half hours for all the digits to reach their original temperature levels.

Effect on Pain of Peripheral Vascular Disease The administration of acetyl-B-methylcholine did not relieve any of the severe grades of pain in occlusive disease of the blood vessels. Patients with mild discomfort experienced a sensation of warmth and often remarked that their extremities were more comfortable after taking acetyl-B-methylcholine. One patient with ischemic neuritis due to thromboangitis obliterans was given 7.5 gm of acetyl-B-methylcholine in 48 hours without relief from pain. Another patient who had pain caused by an ulcer received 6 gm in 36 hours without relief.

Effect on Intermittent Claudication Acetyl-B-methylcholine was given in two cases in which intermittent claudication was a prominent complaint. The patients were tested by the standard exercise test before the drug was administered and at the height of the ensuing vasodilation. The pain of claudication appeared after the same amount of walking during the control and test periods.

Effect on Blood Pressure Acetyl-B-methylcholine given by mouth had no appreciable effect on the blood pressure in this group of cases. Spontaneous variations in blood pressure, even in a resting condition, are considerable, so any change of less than 15 mm of mercury was not considered significant. Using this standard, 16 of 27 cases showed no change in the systolic and 22 cases no change in the diastolic pressure. Seven cases showed an increase and four a decrease in the systolic pressure. Five cases showed a rise and none a fall in diastolic blood pressure. The disease from which the patient was suffering did not influence the blood pressure as to whether it rose or fell. The response of the blood pressure to the cold test (Hines and Brown) was determined in 10 cases before and at the height of the reaction to acetyl-B-methylcholine. No change was noted.

Effect on the Pulse Rate The pulse rate was observed in 23 of 29 cases. In 14 cases there was no change. In four cases there was a rise of 10 beats or more per minute and in five cases a fall of similar degree. Three of the four patients who showed an increased pulse rate received more than 1500 mg of the drug.

Additional Effects In this series of cases additional effects produced by acetyl-B-methylcholine given by mouth were (1) a sensation of warmth, localized or generalized in 50 per cent of the cases, (2) flushing of the hands or face in 25 per cent, (3) increased perspiration in 20 per cent, and (4) a mild laxative effect, in most of the cases. The only untoward symptoms were mild gas pains and nausea in two cases, one after a small dose of 50 mg and one after 1000 mg of the drug had been given.

EFFECTS OF SUBCUTANEOUS ADMINISTRATION

Acetyl-B-methylcholine was given subcutaneously to two patients who had hypertension and to one patient who had thromboangitis obliterans. The typical effect of a dose of 20 mg was an immediate and marked fall in

systolic and diastolic blood pressure, a rise in pulse rate, flushing of the face, sweating, and salivation. Nausea and substernal pain were noted in one case. There was a fall in the temperature of the skin of the feet which was probably a compensatory phenomenon. The action began within two minutes after injection and lasted 30 to 45 minutes.

The differences in the effects of subcutaneous and oral administration of the drug are striking. When taken by mouth, the vasodilating action predominates and there is little influence on blood pressure and pulse rate. Large doses are needed and the reaction is slow and prolonged. Subcutaneous administration affects primarily the blood pressure, causing uncomfortable side actions of sweating, salivation, and nausea, the action being rapid and evanescent.

° SUMMARY AND CONCLUSIONS

Acetyl-B-methylcholine administered orally to 29 patients in doses of 50 to 1500 mg. caused an average maximal rise in the temperature of the skin of the digits of 5.82°C . Vasodilation failed to occur in only one case in which an adequate dose was given. The vasodilating effect of acetyl-B-methylcholine varies tremendously with different patients, in different pathologic conditions and in the different digits of a given individual.

The vasodilation resulting from the oral administration of acetyl-B-methylcholine is slow in onset and is of relatively long duration. An adequate dose seems to be between 1000 and 1500 mg., and this dose may be repeated every three or four hours to maintain vasodilation. No untoward results have followed the administration of 3 to 4.5 gm. in 24 hours.

No significant changes were produced in blood pressure or pulse rate in the cases studied.

Acetyl-B-methylcholine seems to be a promising drug for use in peripheral vascular disease because of its vasodilating properties, its prolonged action, its safety, and its ease of administration. The clinical use of this drug is limited at present owing to its relatively high cost.

BLACKWATER FEVER. A CLINICAL REVIEW OF FIFTY-TWO CASES¹

By M. FERNÁN-NÚÑEZ, M.D. (Madrid), *Milwaukee, Wisconsin*

THE conquest of the diseases of the tropics by modern medicine has been one of the most dramatic applications of science during the progress of civilization. The causative agent of practically every tropical disease has been discovered and an effective sanitary protection and specific treatment provided against each one.

The population pressures and economic difficulties of life in the more crowded countries of the world demand that the fertile and sparsely peopled tropical lands be made available for settlement. In the tropics there still remains one major disease, hemoglobinuric fever, which is the terror of the white man. To it an enormous amount of research has been devoted with but little addition to our knowledge of its etiology and therapy.

The objective of this paper is to emphasize a different line of investigation which offers a promise of affording insight into the mechanism of this terrible malady, and to restate briefly most of the important established facts concerning it, giving to the whole an interpretation based upon the experience of the writer in the treatment of 52 cases of hemoglobinuric fever and the observation of as many more patients of other practitioners in tropical practice.

This disease syndrome has received various designations: Hemoglobinuric Fever, Blackwater Fever, Hemorrhagic Malarial Fever, Black Jaundice, Canebroke Yellow Fever, etc. The descriptions in the literature indicate that it has often been confused with the bilious types of malaria, with yellow fever, with the ictteroid manifestations of various spirochetal infections (icterohemorrhagic fever, relapsing fever, dengue, etc.) and with toxic and symptomatic hemoglobinurias.

Early accurate clinical descriptions of it were written by physicians in New Orleans (1832), Georgia (1835), the Wabash River valley of Indiana (1837), the White River valley of Illinois (1843), and subsequently in the Great Lakes region and Canada, the Pacific coast, New Jersey, Pennsylvania, New York, Connecticut and Rhode Island.

Since its discovery in the United States and Europe it has become more frequent in the tropics due to the increased migration there of the white races, in which it is chiefly found. Its incidence and geographical distribution parallel exactly those of estivo-autumnal (malignant subtertian) malaria, of which the *Plasmodium falciparum* is the known causative agent.

* Received for publication November 23, 1935.

ETIOLOGY

With a disease so spectacular in its manifestations and mortality, and in which no specific causative agent has yet been discovered, it is quite natural that many theories should have arisen to explain it.

The Malaria Theory The disease appears only in malarial districts and in persons who are being treated for malaria, its ratio corresponding almost exactly to the percentage of estivo-autumnal malaria in a community.

The Quinine Theory The attacks often follow immediately on the taking of quinine, and sometimes the patient's condition improves on the stoppage of quinine.

The Allergic Theory The present writer believes that blackwater fever is merely an allergic manifestation of malaria in which quinine, exposure and various other resistance-reducing agencies aid in precipitating the attack. It occurs chiefly in Europeans who have had one or more attacks of estivo-autumnal fever during a residence usually of at least two years in the tropics. In such an individual sensitized by previous attacks a new attack of estivo-autumnal malaria or the administration of quinine in a latent case brings on the acute syndrome by the liberation of allergens.

The author's intradermal test with suspensions of *Plasmodium falciparum* rendered non-infective (Plasmodoid) was applied in a group of persons of Caucasian extraction who had resided in an endemic area of Colombia for more than six months. Following the removal of those showing a positive sensitivity, blackwater fever disappeared from that area.

SYMPTOMS

In typical cases the patient suffers a sudden attack which resembles a rather severe paroxysm of malaria with chill, fever, sweat, headache, and more marked exhaustion than accompanies the usual malarial attack. This is followed by hemoglobinuria. The patient is greatly depressed and very ill. The mind is clear but there is restlessness and anxiety. In favorable cases improvement is observed on the second day.

Urine The fresh urine contains oxyhemoglobin, an increase in urobilin, an unknown pigment (hemozoin?), and a marked albuminuria. Upon standing methemoglobin quickly forms and the urine turns black (blackwater). Red cells are absent and the fresh urine is usually clear, not smoky as when unaltered blood is present. The specific gravity is around 1.025. On shaking the foam is pinkish in color. The reaction is markedly acid and acetone bodies are present. There are granular and pigmented casts. In the average case the hemoglobin in the urine is equal to that in 300 c.c. of blood, but the red cell destruction is often many times as great as the amount of blackwater would lead us to suppose, since much of the pigment is broken down or deposited in the reticulo-endothelial system throughout the body.

Often in the ambulant type the first intimation the patient has that anything is the matter is the passing of black urine. He may feel extraordinarily well and pyrexia may be absent, but the pulse rate is usually increased¹. At times hemoglobinuria may be entirely absent, due to the breaking down of the pigments by the reticulo-endothelial system, or it may appear on and off. Specimens should be collected in separate containers at different time intervals.

Fever The fever at the beginning is usually around 101° F but may run up to 104° or 105° F quickly, then subside somewhat after the sweat, but does not always return to normal, being continuous or remitting, and at times resembling the temperature curve of spirochetal relapsing fever. In atypical (ambulatory) cases the temperature may be subnormal.

Jaundice This comes early, is intense and appears at the same time as the hemoglobinuria. Being a hemolytic jaundice it differs from the obstructive type in that there is no retention of bile salts in the blood. Itching of the skin is not marked, there is no bradycardia, no prolongation of the coagulation time and no hemorrhages due to injury of the capillary endothelium by bile salts.

Vomitus This is "leafy green" and accompanied by epigastric distress. The feces always give the reaction for occult blood, and in severe cases blood and hemoglobin may be passed per anum, as in dysentery.²

The *pulse* is rapid, 110 to 150 per minute, feeble and of low tension, in severe cases resembling that of shock. It differs thus from the slow pulse of yellow fever and obstructive icterus.

Blood Within 24 hours the erythrocytes may be reduced to 2,500,000 and later in the attack to 1,000,000 per cu mm. The hemoglobin is correspondingly decreased, but hemoglobin estimations are very inaccurate since the plasma is deeply colored with free hemoglobin. The leukocyte count shows an increase in the phagocytic melaniferous monocytes (up to 24 per cent), which is explained by their being a part of the reticuloendothelial system. The sedimentation time is decreased, and there is reduction in the coagulation time.³ During the first 48 hours approximately 20 per cent of cases show malarial parasites in the blood, chiefly subtertian rings, which usually rapidly disappear.

Five c.c. of blood placed on ice for 5 minutes, then incubated at 37° C for one hour, show no hemolysis, thus differing markedly from the blood in paroxysmal hemoglobinuria ("autolytic reaction").⁴

The *spleen* is enlarged and tender. Tissue smears from the splenic pulp and rib marrow reveal parasites in 30 per cent of cases.²

Anuria is the most feared complication. It is practically complete, but the patient remains perfectly *compos mentis* and with no edema for 12 to 14 days, and then dies after a few hours of increasing unconsciousness. Patients seldom recover if the suppression lasts more than 24 hours.

Antecedent abdominal disease is apt to light up. Appendicitis, intus-

seption, gastritis, cholecystitis, severe colics, relapse of amebic dysentery, obstinate constipation may occur

Relapses are exceedingly common in cases which have moved or been moved, or are even restless in bed, in from 48 to 72 hours, and such relapses may be more than six in number, each one leaving the patient in a weaker state. Cases moved are liable to very sudden and alarming jaundice. Severe anemia and nephritis increase the tendency to relapses.¹

PATHOLOGY

Few reports of systematic postmortem studies of hemoglobinuric fever cases are available and our knowledge of the pathognomonic pathology is rather meager. Necropsies are usually performed 8 to 10 days after the beginning of an attack and, as death is then due to anemia or urinary suppression, these examinations may show little evidences of malaria. The writer performed autopsies on 11 cases of fatal blackwater fever and the observations are here summarized.

In 20 per cent of cases of estivo-autumnal malaria one ordinarily finds in the peripheral blood only the early ring forms of schizonts and the gametocytes (crescents). The later stages of schizogony are carried out in the internal organs. The large segmenting forms are held in the capillaries by the reticulo-endothelial cells, which accounts for their tendency to agglutination with occlusion of vessels supplying important organs, and explains why the pernicious forms of malaria (comatose type, etc.) are found chiefly in malignant tertian.

During the anaphylactic attack which initiates the hemoglobinuria the parasites are destroyed along with the parasitized red cells, parasites rarely being found in great numbers during the illness or postmortem, but the pigment from the parasites remains and is deposited in the reticulo-endothelial cells of all organs of the body.

The *kidneys* are swollen and the surface is a deep red or mottled red and yellow. The cortex is widened and ecchymotic due to the hemoglobin in the tubules, and yellowish if the jaundice is severe. The pyramids are a deep purple color and sometimes show minute hemorrhages.

Microscopically the glomerular tufts show thromboses of degenerated parasites and pigment. There is cloudy swelling of the tubular epithelium which contains great quantities of hemosiderin, as shown by the Prussian-blue reaction. The tubules, especially the loops of Henle, are obstructed with hemoglobin, agglutinated erythrocytes and epithelial casts, the markedly acid urine favoring coagulation of the hemoglobin.

The *spleen* weighs 400 to 600 grams, is very friable, and presents a soft bright red or purple velvety pulp. Its capsule is smooth and thin. The malpighian corpuscles are grossly opaque and well outlined.

The splenic sinuses are distended with blood and agglutinated cells with marked phagocytosis of the red cells by the reticulo-endothelial elements.

Malarial pigment is usually abundant. The Prussian-blue reaction for hemosiderin shows focal necrosis due to infarction.

If there has been chronic malarial splenomegaly the spleen will be slaty or jet black due to the large amount of pigment, and the walls of the blood vessels will be thickened.

The *liver* is enlarged, of a pale chestnut brown color and shows focal necroses of toxic origin. The sinusoids are dilated and erythrocytes are seen agglutinated around the Kupffer cells. The hepatic cells, especially around the central vein, show increase in the albuminous granules. Small hemorrhagic areas are present in the midzonal region of the hepatic lobules. The Prussian-blue reaction for free iron is intense.

The bile is usually very thick in the gall-bladder due to the sudden and enormous destruction of red cells and some times may be turned out as a solid mass. In ordinary malaria the hemolysis is not sufficiently intense to lead to formation of pigment concretions but in hemoglobinuric fever inspissated nodules may quickly form and cause symptoms of cholelithiasis. The gall-bladder wall shows no changes referable to the blackwater fever itself except deep pigmentation of the mucosa.

The *brain* is pale and waxy. On microscopic examination it may show edema and various capillaries filled with malarial pigment and hemoglobin. Hemorrhages and thrombi are sometimes seen. There is no staining of the brain substance by the jaundice as is notable in the other tissues of the body.

The *heart muscle* is soft and flabby and microscopically shows swelling of the muscle cells, considerable loss of striation, deeply staining nuclei, albuminous and fatty degeneration.

The *bone marrow* is usually hyperplastic as a result of the anemia, and its vessels and macrophages contain much pigment.

The mucosa of the *stomach and intestines* shows marked discoloration due to hemoglobin.

There is rather intense yellowish discoloration of all the tissues of the body, due to the presence of bile pigment in the blood plasma.

DIFFERENTIAL DIAGNOSIS

Paroxysmal hemoglobinuria may be impossible to differentiate from hemoglobinuric fever. It is much more common in cold climates and should always be suspected when cases of the latter disease seem to appear in non-malarial districts. There is practically always a definite history of chilling of the body immediately preceding the paroxysm. The patient is usually in much better general health and recovers from the attack much more quickly than is common in blackwater fever. It is never fatal.

Yellow Fever. On the fourth day hematuria (not hemoglobinuria) with smoky urine, and progressive jaundice begin and "black vomit" appears. Faget's sign, high temperature (104° F) with slow pulse (60), is observed. The spleen is not enlarged.

Bilious Malaria The urine is yellowish (bile) The jaundice is not so intense and the yellowish vomitus not so dark as in yellow fever or hemoglobinuric fever The pulse is slower than that seen in the "shock" (anaphylactic?) of blackwater fever There is usually marked splenomegaly (up to 1000 grams)

PROGNOSIS

An individual healthy in other respects usually recovers, provided he is correctly treated and *submits to it* With urinary suppression the prognosis is extremely bad Persistent vomiting, hiccough and relapses are ominous The general mortality is 20 to 30 per cent

TREATMENT

Blackwater fever must be thoroughly and carefully treated from the very beginning and to the end of the illness Good treatment, including good nursing, saves lives in this disease Early apparent improvement should not lead to slackening of treatment—relapses are common and dangerous! When the patient has recovered he should change his residence to a healthful climate as he will be prone to subsequent attacks which might cost him his life

After experience with all the accepted methods of treatment the routine here given was adopted

Nursing The patient should be put to bed and *not moved* lest his hemoglobinuria increase, or, if already stopped, recur Absolute rest in bed with good nursing is essential Avoid chilling, eliminate unnecessary noise, keep visitors away, and use every possible means to keep the patient quiet From the first moment push fluids and nourishment (barley water, albumin water, broths, fruit juices, glucose, etc.) Do not allow a return to normal diet until convalescence is well advanced, as hemoglobinuria may reappear

The weakened heart muscle requires that the patient be kept in absolute relaxation for three to six weeks after the acute attack Then he may be allowed up very slowly At the end of the second week permit an additional pillow a day until the patient is sitting up, and very gradually allow him out of bed Lack of care in this matter will often bring on a relapse and may cost the life of the patient

Arsphenamines The writer found the use of the arsphenamines so superior to quinine that he practically abandoned the latter in this disease Neoarsphenamine ("914"), 0.2 gram in 2 c.c. of sterile distilled water, by vein often gave spectacular relief if used early in the disease Thereafter weekly injections of 0.2 to 0.4 gram proved of great aid in combating the severe anemia and strengthening the patient during convalescence Neoarsphenamine is possibly contraindicated in patients showing signs of toxic necrosis of the liver

A freshly prepared solution of 5 grains (0.325) of sodium thiosulphate (hyposulphite) in 5 c.c. of sterile distilled water should be injected intravenously (through the same needle used for the "914" while in place). This will prevent any untoward effects of the neoarsphenamine without impairing its therapeutic efficiency.

Sodium thiosulphate apparently has a very specific effect on the hemoglobinuria, often stopping it within a few hours. If preferred, the drug may be given by mouth in 10 to 30 grain (0.6 to 2.0 grams) doses daily.

Acidosis As many of the features of the attack suggest acidosis, and a condition of acidosis seems to favor hemolysis, it has been the author's custom to use intensive alkali therapy routinely. Sodium bicarbonate, 300 to 500 c.c. of a 2 per cent solution, is given intravenously daily. As the bicarbonate changes to the carbonate on prolonged heating it is best to sterilize the solution at 7 pounds pressure in a live-steam autoclave. If this is not convenient the water should be boiled, allowed to cool down to near the desired temperature for injection, and the bicarbonate added. A dilute (0.5 of 1 per cent) bicarbonate solution may be given also by the Murphy drip.

Glucose, 300 c.c. of a 5 per cent solution, daily by vein, and additional quantities by the Murphy drip are useful in combatting the acidosis and general toxemia and in nourishing the patient.

Anuria The sodium bicarbonate and glucose solutions administered as above will aid in increasing the flow of urine and by thus eliminating the products of hemolysis from the blood shorten the period of hemoglobinuria. Early injections, before the anuria appears, may prevent the suppression. High enemas, as hot as can be borne, with a return flow tube, are often of great aid in starting the urinary flow since they bring heat directly to the splanchnic area. For the pain resulting from renal congestion hot fomentations applied to the loins are often very efficacious.

Vomiting Alkaline waters (0.5 of 1 per cent solution of sodium bicarbonate) may be freely used. Carbonated beverages (ordinary "soda-pop") are often better tolerated by the patient than anything else, and the sugars they contain are nourishing. Iced lemonade is usually well borne. Morphine and atropine may be required.

The rapid dehydration caused by vomiting may need to be combated by saline transfusions (intravenous drip is especially useful), or 300 c.c. may be introduced high into the bowel through a rectal tube every four hours.

Magnesium citrate or other mild saline laxatives daily are usually tolerated and are very necessary for cleansing the intestines of the bile and toxins. During convalescence calomel in fairly large doses (5 grains), followed by a saline laxative, is especially indicated in clearing up the jaundice.

Stimulants All forms of alcohol should be avoided.

Caffeine sodiobenzoate, 3 grains (0.2) twice daily, intramuscularly, stimulates the weakened heart and promotes diuresis. Adrenalin, 8 minims, (0.5 c.c.) of a 1/1000 solution, is administered intramuscularly at once and

every three hours until a total of four doses is given. This may be repeated on the second day of the disease if hemoglobinuria persists. Aside from its aid in relieving hypotension, it has a specific effect in relieving the anaphylactoid symptoms. Ephedrine in equivalent dosage, subcutaneously or orally, can be tried instead of adrenalin.

Quinine If neoarsphenamine is not available quinine administered as here outlined may be substituted. The hemolysis of the attack causes auto-destruction of the malaria parasites in 70 per cent of cases. Quinine should only be administered in those 30 per cent of cases still showing parasites in the peripheral blood. Five grains are given the first day by mouth or intramuscularly, 10 grains (0.65 gm.) the second day, 15 grains (1.0) the third day and thereafter. After convalescence, if malarial parasites are still present in the peripheral blood, quinine may be cautiously given, watching for a return of the hemoglobinuria.

Quinine idiosyncrasy should always be tested for. Inject 1 gram (0.065 gm.) of quinine dihydrochloride or bisulphate. If there is no reaction in an hour, inject 4 grains (0.25). If there is quinine hypersensitiveness this will almost surely produce a reaction. If the reaction is slight, the injection is repeated in 12 hours, otherwise it is postponed for 24 hours. The injections are continued daily until the malaria is cured. To avoid abscesses the injections should be given intramuscularly in a dilution of 1 gram in 1 c.c. of sterile water, and the skin at the site of injection thoroughly sterilized.

It is extremely doubtful whether plasmochin (plasmoquin) should ever be used in blackwater fever, except possibly in cases where there is a quinine idiosyncrasy. This drug is highly toxic, affecting especially the liver, and often causes cyanosis and hemoglobinuria in itself. Its action on the subtertian parasites is not nearly as effective as it is on the tertian. If employed at all, not over 0.03 gram, twice daily, intramuscularly, should be administered to hold the infection under control until the acute stage of hemolysis has subsided and quinine can be more safely given.

Atebrin, orally in 0.3 gram doses daily, for three doses, may be tried instead of plasmochin. As it colors the urine and skin yellow it may appear to make the disease worse.

Other Drugs Our somewhat limited experience with the following measures did not convince us of their general utility. For anuria—tincture of cantharides (Trout), bichloride of mercury (Healey), cyanide of mercury, novasural and salyrgan. For hemoglobinuria—calcium lactate (Castellani), hemostatic serum (Aguilar), *Streptococcus hemolyticus* antiserum (Crawford), Bothropic antivenin (Makel) and cholesterin.

Blood transfusions in six cases left us uncertain as to their value. If used at all we would urge a careful direct matching of the bloods of the recipient and donor and repeated transfusions of small amounts (100 c.c.)

CONCLUSIONS

1 Blackwater fever is practically the one remaining tropical disease whose etiology has not been definitely solved

2 The theory is submitted that it is an allergic manifestation of estivo-autumnal (malignant subtertian) malaria

3 Reference is made to the author's intradermal test for the detection of individuals allergic to estivo-autumnal malaria, who if attacked again by the disease would be potential victims of hemoglobinuric fever

4 The symptoms, pathology and treatment of blackwater fever are reviewed on the background of the writer's experience in the personal management of 52 cases of the disease and the observation of an equal number of patients of other physicians

THE TREATMENT OF NARCOLEPSY WITH BENZEDRINE SULPHATE ⁶

By HELMUTH ULRICH, M D , F A C P , CARL E TRAPP, M D , and BEN VIDGOTT M D , *Boston, Massachusetts*

INHALATION of benzedrine (synthetic racemic benzyl-methyl carbinamine $C_6H_5CH_2CHNH_2CH_3$,¹) for the relief of nasal congestion was found by one of us to be followed by sleeplessness, an experience that suggested the use of this method in the treatment of narcolepsy. Clinical trial showed, however, that inhalation of the drug produced very slight results, whereas oral medication was uniformly successful in preventing narcoleptic seizures. Six cases of narcolepsy have been treated by us and form the basis of this report. Prinzmetal and Bloomberg,² also, in a recent report published since the inception of our study, found oral treatment with benzedrine to give complete relief in nearly all of their cases.

Narcolepsy is a disease characterized by recurring attacks of diurnal sleep †. In many cases there occur also periods of muscular atony or helplessness (cataplexy). The fundamental nature of the disease is not understood. It is possible that the underlying defect is often congenital and that infections and other exciting causes (trauma, etc.) act as precipitants.³ There is no convincing evidence, however, that the disease is hereditary or familial. It is believed by some to be the result of disturbance in the region of the basal ganglia (thalamus,^{4, 5} floor of third ventricle³), although other portions of the brain also have been incriminated. In several reported cases of narcolepsy, the onset followed acute infectious disease, especially influenza and encephalitis.³ Trauma⁶ and over-exertion⁷ also have been held responsible in a few instances. Attempts have been made to incriminate the endocrine glands, chiefly the pituitary,⁸ because a tendency to obesity has frequently been observed to develop simultaneously with the onset of narcolepsy and also because in many cases the somnolence had its initial appearance in the years of adolescence.⁶ A few cases have developed at the menopause. No age is exempt, although in the majority of the reported cases the onset of the disease occurred before the age of twenty-five.

The fact that six cases were admitted to the Evans Memorial within a period of one year indicates that the disease occurs with increasing frequency. It is chronic and usually incurable,⁹ although spontaneous amelioration has been noted in several untreated cases, and the condition does not preclude a long and otherwise healthy life.³ Symptoms and signs other than diurnal somnolence and loss of muscular tone include disturbed nocturnal sleep (insomnia, unpleasant and often terrifying dreams), irri-

* Received for publication January 8 1936

From the Evans Memorial of the Massachusetts Memorial Hospitals, Boston, Mass

† For a detailed discussion and comprehensive bibliography of narcolepsy the reader is referred to Daniels' excellent thesis.³

tability, nervousness, obesity, dermatographia, diminished libido, and a low basal metabolic rate. The disturbance of nocturnal sleep appears to be the most common. The other symptoms are said to occur with varying degrees of frequency.

Several forms of treatment have been recommended, including psychotherapy, endocrine medication (thyroid, pituitary), caffeine, and especially ephedrine sulphate, which was used first by Janota.¹¹ None of these, with the exception of ephedrine sulphate, has been notably successful.

Benzedrine is closely related to ephedrine but, according to Alles¹² has a more marked effect as a stimulant of the central nervous system. In the series of six cases reported herewith, consistently good results were obtained with the oral use of benzedrine sulphate.¹

Case 1 Mrs M F, an American housewife, aged 52, entered the hospital on March 4, 1935, with the chief complaint of falling asleep during any monotonous procedure such as riding in an automobile, listening to a sermon, etc. The onset was three years ago. The attacks of sleep were more frequent after meals, shortly after getting up in the morning, and in extremes of heat or cold (very cold winter days or a very warm room). The duration of an attack was a few seconds to several minutes. On one occasion, she fell asleep while mixing dough and continued the operation throughout the narcoleptic attack. At times she took part in a conversation during an attack. A slight stimulus was sufficient to awake her. Prodromal symptoms consisted of diplopia and a dull feeling in the eyes.

In addition to the narcoleptic seizures, she had attacks of loss of muscular tone that were usually brought on by excitement or hearty laughter. If she was standing, she fell to the ground unless a support was at hand to lean against. During these cataplectic attacks she was fully conscious, but could not move. They lasted a few minutes and were not followed by any unpleasant sensations. Nocturnal sleep was poor and often disturbed by unpleasant dreams.

The family history was not remarkable. The previous personal history revealed that she had measles and pertussis in childhood, chicken-pox at age 21, and mumps at age 25. A year ago, a diagnosis of gastric ulcer had been made because she complained of gas and distress after meals. The menstrual history was normal. The last period occurred six months ago. She was nervous and irritable and tired easily.

There was moderate generalized obesity, the present and highest weight being 169 pounds. She had always been slightly obese, but a marked increase in weight began with the onset of narcolepsy. The teeth were in poor condition. Examination of the ocular fundi revealed moderate vascular sclerosis and an enlarged left optic spot. Pelvic examination disclosed hypertrophy, bilateral laceration and inflammation of the cervix of the uterus. Otherwise physical examination was negative.

The urine contained a slightest possible trace of albumin and was otherwise normal. The blood count revealed slight anemia (hemoglobin 78 per cent, erythrocytes 3,970,000), but was otherwise normal. The non-protein nitrogen was 34 mg, uric acid 3 mg, sugar 100 mg, calcium 11.5 mg, and phosphorus 2.4 mg in 100 cc of blood. The Wassermann and Kahn tests were negative. The basal metabolic rate was minus 24 per cent. Cerebrospinal fluid: The fluid was slightly tinged with cells, other than blood discs, numbered 21 per cu mm, the sugar was 67 mg per 100 cc, the Wassermann test was negative. Roentgen-ray examinations of the skull and French

* The benzedrine sulphate used in this study was supplied by Smith, Kline and Laboratories of Philadelphia.

normal, the sella turcica measured 8 by 11 mm and was regular in outline, the heart and lungs were normal

Treatment with ephedrine was tried, but brought only very slight improvement. Oral benzedrine sulphate medication, 10 mg three times daily, was begun after she left the hospital. At the end of two weeks' treatment she reported that "the first week I felt more like myself than I had for months. My whole system seemed to be alive. My head cleared and I did not have any of these peculiar spells (losing control of arms, legs, etc.) At the end of two weeks I stopped taking the tablets, and in a day or so the drowsiness returned and a slight tendency toward the peculiar spells [cataplexy]. I began taking the tablets again and that condition improved."

The treatment was omitted a second time. Two weeks later she wrote "my old spells are back upon me and seem to be just as bad. My hands are almost purple. My feet feel as if they were on ice, and across my forehead cold waves come and go and I just collapse, but pick myself right up and am all right until I have another. They certainly are very disagreeable, but not so very painful, unless I hit my head against a radiator as I have just done this evening."

She reported also that during the first period of medication the gastrointestinal symptoms recorded in the history (heartburn, gas and distress after meals) were present in an aggravated form, although she was not sure that the treatment was responsible for it. Later there was no evidence of gastrointestinal irritation by the drug. Since taking benzedrine she has slept much better and is no longer troubled unduly by unpleasant dreams.

Case 2 C E B, an American boy, aged 17, was admitted with the chief complaint of a constant tendency to fall asleep. This trouble began about seven years ago, was very pronounced during the subsequent three years, and then gradually subsided a little to reach its present level. There was no history of an immediately preceding illness.

He would fall asleep at any time, but especially while performing monotonous tasks (writing). Recently the attacks have lasted only a few minutes, but at first the duration was usually longer. Drowsiness has been more pronounced during warm weather and in a warm room. Occasionally he has had an attack while walking, and has lost his way. There have been no prodromal symptoms. He was easily aroused, but was made irritable thereby. There were also infrequent attacks of loss of muscular tone during which he did not lose consciousness but felt "as if my muscles won't hold me up." Such attacks have been usually elicited by excitement or laughter. They are much less frequent than they were formerly.

The family history was not relevant. The previous personal history revealed that he had mumps and pertussis before he was six years old. He was obese as a child. At age 10, at the onset of the present illness, he suddenly began to grow tall and is not obese at the present time. The present and highest weight is 155 pounds. There was slight tenderness in the right lower abdominal quadrant. The post-auricular lymph-nodes were palpable. The heart, lungs and ocular fundi were normal. The systolic blood pressure was 120 mm mercury, the diastolic was 60 mm.

The urine and blood count were normal. The non-protein nitrogen of the blood was 34 mg, uric acid 3.8 mg, sugar 87 mg, calcium 10.5 mg, phosphorus 4.1 mg, and cholesterol (whole blood) 130 mg per 100 cc. The blood phosphatase was 11.2 units. The Wassermann and Kahn tests were negative. Dextrose tolerance test: Blood sugar, fasting, 92 mg; one-half hour after dextrose, 111 mg; one hour, 105 mg; one and one-half hours, 105 mg; two hours, 93 mg. Cerebrospinal fluid: Cells numbered 2 per cu mm, the sugar was normal, globulin not increased, and colloidal gold and Wassermann tests were negative. The basal metabolic rate was minus 24 per cent. Roentgen-ray examination of the skull showed marked hyperostosis of the vault and retarded development of the sinuses, the sella turcica measured 6 by 9 mm and was regular in outline.

Treatment with ephedrine sulphate was tried without benefit. Benzedrine sulphate, 10 mg three times a day, was then given for two weeks with complete relief. The attacks of sleep recurred when the treatment was stopped. Resumption of the treatment was again followed by complete relief. The patient complained of slight anorexia for a few days at the beginning of each period of treatment. Ten mg twice a day were tried. This smaller amount of medication, taken over a period of several weeks, has been practically as efficient as the larger amount. Only an occasional slight drowsiness has been present after severe physical exertion, but he has not fallen asleep.

Case 3. A. H., an American girl, aged 16, was admitted in September 1934, with the chief complaint of frequently falling asleep. In 1928, she had a febrile illness with pain in the jaw that was believed to have been mumps, although the diagnosis was not definitely established. Recovery was prompt. The tonsils were removed under ether anesthesia about a month later. About a week after that (at age 10), she fell asleep in school. Since then she has had frequent attacks of somnolence, sometimes five or six a day. They have lasted 10 to 20 minutes and usually have occurred in school, in church, in the theater, or during meals, rarely while she was walking. They were most frequent in the forenoon. An hour's sleep after the noon meal had a tendency to prevent attacks in the afternoon. Hearty laughter and, less often, anger or fear produced great weakness and a feeling of utter helplessness, as a result of which her head fell forward on the chest, and she was unable to raise or turn it. These cataplectic spells lasted five to 20 minutes. A nudge from a bystander quickly terminated them. She has had "horrible" dreams about snakes, beasts, etc., but they have been less troublesome at present. She has gradually gained weight since the onset of the present illness and now weighs 156 pounds.

Menarche occurred at age 11, one year after the onset of the narcolepsy. The periods have been normal. Thyroid medication, pushed to the point of making her nervous, has been used without benefit.

The family history was not contributory. There were no siblings. In addition to the questionable attack of mumps, she had measles at age five and chicken-pox at age eight.

Physical examination revealed moderate generalized obesity, slight hypertrichosis of the face, chest, abdomen and legs, and an oily skin. The labia minora were markedly hypertrophied. Otherwise the pelvic organs were normal. The ocular fundi, heart, lungs and abdomen were normal. The reflexes were hyperactive. The systolic blood pressure was 110 mm mercury, the diastolic 85 mm. The pulse rate was 72 per minute.

The urine contained a very slight trace to a trace of albumin, one to four blood discs per high power field, and increased indican, but was otherwise normal. The blood count was normal. The basal metabolic rate was minus 16 per cent and minus 22 per cent in two tests. Roentgen-ray examinations. Intravenous Graham test was negative, the skull was normal, the sella turcica measured 6 by 11 mm and was regular in outline, the heart and lungs were normal. The audiogram was normal. An electrocardiogram showed simple tachycardia (108), but was otherwise normal.

A diagnosis of narcolepsy and cataplexy, possibly on an encephalitic basis (mumps?), was made. Treatment with ephedrine sulphate was followed by moderate improvement. She was discharged with instructions to continue the treatment.

She reentered the hospital in April 1935 and reported that the medicine helped her for a few weeks after she left the hospital, but after the supply given her at the hospital was exhausted, she stopped taking it. Her physician then prescribed ovarian pills, apparently without effect. The attacks of somnolence were as frequent as before, and the cataplectic spells occurred about once a month and, as before, were induced by hearty laughter. She had no other complaints.

Having been at home for two weeks, during which time he had an irregular evening fever, he developed a sore throat. He was admitted to the Haines Memorial Hospital where he showed extensive ulceration of the soft palate and tonsillar pillars. The ulcerations were shallow, covered with a thin, white exudate and appeared like those seen in agranulocytic angina. The total white blood cell count was 2500 of which 35 per cent were polymorphonuclear leukocytes. Following nucleotide treatment the count rose to 3500, with 70 per cent polymorphonuclear leukocytes, and the throat rapidly cleared, but in spite of continued nucleotide treatment the count soon dropped once more to 2500 with 35 per cent polymorphonuclear leukocytes.

February 21, 1934, he was admitted to the Thorndike Memorial Laboratory with the complaint of soreness and stiffness in his joints and a drop in weight from his average of 137 pounds to 118 pounds, 15 pounds of this having been lost in the five preceding months.

Upon this admission, there was noted a pallor of the palms of the hands and nail beds. The firm, non-tender edge of the spleen was still felt two cm below the costal margin. The liver edge was not felt. There was slight enlargement of the inguinal lymph nodes. No abnormalities of the joints were noticed.

The blood findings were as follows: white blood cells 3,300, 55 per cent neutrophils, 4 per cent myelocytes, 6 per cent metamyelocytes, 28 per cent lymphocytes, 1 per cent monocytes, 6 per cent young neutrophils, red blood cells 2,700,000 and hemoglobin 62 per cent.

The basal metabolic rate, and the results of the phenolsulphophthalein kidney function test and of gastric analysis were found normal.

Sternal puncture, February 24, 1933, showed numerous normoblasts and nucleated red blood cells, some stem cells, only a few granulocytes and those mostly myelocytes, rare adult polymorphonuclear leukocytes, numerous megakaryocytes.

After eight days in the hospital, during which time there was no essential change, he was discharged to convalesce in Florida. He returned for a check-up, May 17, after having spent three months in the South, looking much improved. He had gained 21 pounds, had a deep tan, felt generally better but still had some pains in his joints though to a lesser extent.

Examination showed as the essential features: slight stiffness of the elbow joints and an easily palpable spleen two cm below the costal margin. The red blood cells had risen to 4,600,000, but the white count was only 3,200.

The patient got along quite well and was relatively free of arthritic symptoms until about August 10, 1934, at which time he began to have fever and chills, followed in a few days by a productive cough. On August 20, he was admitted with symptoms and signs of bronchopneumonia in the left upper lobe which soon spread to all lobes. At no time did the white count rise above 3,200 in spite of the fact that 40 c.c. of nucleotide per day were given beginning August 24. The patient died on August 28.

An autopsy, restricted to the chest and abdomen, was performed two hours post-mortem. The lymph nodes at the head of the pancreas and around the celiac axis were moderately enlarged, firm and uniformly light pinkish-yellow on cut section.

The visceral surfaces of the lungs were covered with a thin fresh layer of fibrin, and there were 400 c.c. of thin, straw-colored fluid in each pleural cavity. The left lung weighed 700 grams and the right 900 grams. All lobes were heavy, uniformly firm, very slightly crepitant and on cut section presented a uniform light gray, glistening surface, from which a small amount of seropurulent fluid could be scraped.

The spleen was moderately enlarged, weighing 260 grams. The capsule was smooth gray and glistening and the pulp dark red, firm, smooth, relatively dry. The cut surface yielded little on scraping. The trabeculae and Malpighian corpuscles were not very distinct.

The liver was moderately enlarged, weighing 2000 grams. The capsular and cut surfaces were smooth, firm, light brown and showed the lobules fairly distinctly.

In the distal three feet of the colon were many diverticula, averaging 5 mm in length and 4 mm in width. The mucosa of some of the diverticula was injected though not ulcerated.

The bone marrow in the middle of the femur and in the tibia consisted of fat, whereas in the upper end of the femur it was yellowish-red. Sternal and lumbar marrows were grayish-red and firm. There was moderate lipping of the bodies of the vertebrae and an increase in density of the bone.

Microscopic examination of all lobes of the lung showed an advanced organization with a diffuse infiltration consisting of a moderate number of polymorphonuclear leukocytes though there were almost as many plasma cells, lymphocytes and macrophages.

The Malpighian corpuscles of the spleen were not very large or distinct. The sinuses were inconspicuous. The pulp was highly cellular, consisting chiefly of red blood cells, lymphocytes and plasma cells. There was also a moderate number of macrophages, a few nucleated red blood cells and rare stem cells. A few macrophages had phagocytosed red blood cells. Polymorphonuclear leukocytes were scarce. The liver showed extensive hydropic degeneration. There was a slight increase in lymphocytes and plasma cells in the sinusoids and a few Russell's "fuchsin bodies."

In one adrenal was a focus of plasma cells, lymphocytes and macrophages.

Sections of the tracheal and mesenteric lymph nodes showed an obliteration of the normal architecture by the diffuse infiltration with plasma cells. There was a moderate number of macrophages and Russell's "fuchsin bodies" and a few stem cells and myelocytes irregularly scattered. Some of the macrophages had phagocytosed lymphocytes and red blood cells.

The lumbar marrow showed a moderate erythroblastic and lymphocytic hyperplasia. There were also many megakaryocytes, stem cells and plasma cells, myelocytes occurred in moderate numbers but adult polymorphonuclear leukocytic cells were quite scanty. The sternal and femoral marrows appeared similar though not quite as active.

The pathological diagnoses were bilateral organizing pneumonia, bilateral serofibrinous pleuritis, hepatomegaly, splenomegaly, enlargement of mesenteric and tracheal lymph nodes, hypertrophic arthritis, diverticulitis and diverticulosis of colon, hyperplasia of bone marrow with maturation arrest of the neutrophilic series (dysoremos neutrophilia).

Cultures of the heart's blood and spleen showed no growth while those of the lungs showed *Streptococcus viridans*.

ANALYSIS OF CASE REPORTS

As the clinical and pathological features of the above case conform rather closely to the nine previously reported cases they will all be discussed together.

All cases have been in individuals between 45 to 65 years, equally distributed between the sexes. The cases have been widely scattered geographically. The occurrence of a marked loss of weight, six to 65 pounds has been usual, with an average loss of about 40 pounds. Intermittent periods of moderate fever have been noted, rarely going above 101° F. The arthritis is invariably of a chronic type—only one case had less than two years' duration—showing repeated acute migratory exacerbations, characterized by pain, tenderness, limitation of motion, and less often by local heat and redness. The ankles, wrists or knees frequently are the first joints involved, but before this acute manifestation has subsided, the shoulders, elbows, interphalangeal and other joints are involved in rapid succession. After the acute phase, stiffness and slight limitation of motion not infrequently exist. Roentgenologically, the changes in the articular cartilages

and in the bones have not been marked. Six cases showed changes suggestive of infectious arthritis, and three showed only minor indeterminate changes. One case showed complete ankylosis of some of the joints.

A firm, smooth, non-tender, persistently enlarged spleen has been noted in all cases, the inferior edge having been palpated at various points between the left costal margin and the level of the umbilicus. The enlargement is usually quite definite and the spleen extended to the umbilicus in four cases. Very little variation in size has been noted in the different cases upon repeated periodic examinations. Four spleens have been studied pathologically, two as surgical specimens and two as necropsy specimens. In three cases there was found dilatation of the sinuses, thickening of intersinusoidal spaces, enlarged Malpighian corpuscles with prominent germinal centers, and many plasma cells diffusely distributed. In two cases there were a few phagocytosed red blood cells. In the case of Craven and in that of Price and Schoenfeld there was noted an increase in eosinophiles. In the case here reported the splenic corpuscles were not large and the sinuses inconspicuous. There were many plasma cells, rare stem cells, occasional phagocytosed red blood cells, a few nucleated red blood cells, and relatively few polymorphonuclear leukocytes.

In only two cases was the liver palpable clinically. In the two cases operated upon the liver was found moderately enlarged, and the livers examined in the two necropsy cases weighed 2100 and 2000 grams, respectively. Sections of liver in three cases examined showed nothing remarkable.

In six cases there was noted pigmentation of the skin, confined chiefly to exposed surfaces.

In five cases, there was more or less slight general lymph node enlargement. Price and Schoenfeld noted "myeloid changes" in the material they examined. In my case, sections of tracheal and mesenteric nodes showed an obliteration of the normal architecture by the diffuse infiltration with plasma cells, a few stem cells, rare myelocytes, and an occasional phagocytosed lymphocyte and red blood cell.

All cases upon admission have shown a total white count varying from 800 to 4,200 with an average of about 2500. The admission differential showed the adult polymorphonuclear leukocytes varying from 14 to 79 per cent with an average of about 50 per cent, eosinophiles 1 to 12 per cent, 4 cases showing an eosinophilia at some time during the course of the disease, lymphocytes 14 to 86 per cent with an average of about 40 per cent. There was no mention of young cells of the granulocytic series, except in Price and Schoenfeld's case, where 3 per cent of myelocytes were found on one occasion, and 2 per cent another time. On one examination 20 per cent stabs were found. In my case, myelocytes were frequently found, on one occasion to the extent of 9 per cent. Young polymorphonuclear leukocytes were frequently found to exceed 30 per cent. In most cases there was a great variation in the proportion of adult polymorphonuclear leukocytes from time to time.

The red blood cell count varied from 3,000,000 to 4,800,000, and in all cases where many counts were performed, at some time in the course of the disease there was a drop below 3,500,000. The hemoglobin changes corresponded fairly closely with those of the red blood cells. The morphological characteristics of

the red blood cells showed few changes. The platelets have occurred in normal numbers. The bleeding time and clotting time have been found essentially normal.

Bone marrow studies have been made only in the two necropsy cases. Price and Schoenfeld found the sternal marrow to show "hyperplasia of marrow for patient's age with few bone marrow giant cells. Active myelosis throughout." The lumbar marrow in my case showed a moderate number of megakaryocytes, plasma cells and stem cells. The most notable feature was a partial maturation arrest of the neutrophilic series (dysoremos neutrophilia), there being a moderate number of the younger cells, but adult polymorphonuclear leukocytes being rare. The sternal and femoral marrows were similar though less active.

Examination of the vertebral column in my case showed nothing more than the changes of hypertrophic arthritis. Price and Schoenfeld found the knee joint, in their case, to show active chronic inflammation of the periarticular tissue and a marked infiltration of the adjoining periosteum with lymphocytes and plasma cells.

Urobilin was found in the urine in four cases. In several cases the urine was not tested for this.

Two cases in which glucose tolerance tests were performed showed a decreased tolerance.

Bacteriological studies have been negative.

COMMENT

The etiology of this disease remains to be proved. No explanations beyond those suggested by Felty have been advanced, namely, that there is one pathological process, caused by a toxin, which concomitantly affects the spleen, blood and joints, or that the arthritis is a process different from the remainder of the picture.

That there may be a blood dyscrasia is worthy of consideration, though further study is necessary to establish this as a fact. In Alessandrini's case what was thought to be a large spleen was found four years before the symptoms of arthritis began. In the other cases the relation is not known. Although the joint symptoms dated back for some time, the size and character of the spleens indicate that they had been enlarged for some time. In my case, the joint symptoms began only 10 days before admission, whereas the spleen was found two cm below the costal margin, and in view of its pathological characteristics and the fact that it stayed at the same level, there is reason to believe that it may have been enlarged for some time.

The fact that soon after the splenectomy in Hanrahan and Miller's case there was a definite improvement of the arthritic symptoms, objectively as well as subjectively, within five weeks, and the fact that within four months the red and white counts were normal, suggest that the two processes are related and that a hematological basis may be the underlying cause. After splenectomy in Craven's case there was similar improvement, though not as marked. However, both from an etiological and therapeutic point of view it would be interesting to know the present status of these two patients, as not infrequently in other blood dyscrasias the improvement following splenectomy is only transitory.

In my case, a few stem cells and nucleated red blood cells were noted in the spleen, whereas adult neutrophils were relatively rare. In the lymph nodes were seen a few stem cells and myelocytes. The most significant hemopoietic changes were found in the bone marrow, which showed a hyperplasia of all series, and although many stem cells and myelocytes were seen, adult polymorphonuclear leukocytes appeared rather rare, there apparently being some inhibiting factor preventing many of these granular cells from reaching maturity. This condition of the marrow, though not as marked, is analogous to that seen in cases of agranulocytosis showing maturation arrest as described by Fitz-Hugh and Krumbhaar⁶ and later by Jackson and Parker.⁷ This inability of the bone marrow to generate many mature neutrophils was further manifested in my case at the time when with a severely ulcerated and sore throat, and later with a pneumonia, there was no increase in the polymorphonuclear leukocytes. There was a similar failure of response in Price and Schoenfeld's case during an attack of acute fibrinous pericarditis, and in all the other cases during the periods of acute exacerbation of the joint symptoms. Furthermore, if the bone marrow could generate polymorphonuclear neutrophils in a normal manner, the pneumonic lung in my case should have contained more polymorphonuclear leukocytes, whereas those present no more than equalled the number of lymphocytes and plasma cells. One would also expect the fibrinous pericarditis of Price and Schoenfeld's case to show a reaction consisting chiefly of polymorphonuclear leukocytes, but they describe the cellular reaction as consisting chiefly of lymphocytes, plasma cells and eosinophils. Additional evidence of a blood dyscrasia is the fact that with nucleotide treatment for several weeks there was no appreciable change in the white blood cell count in my case.

The number of adult polymorphonuclear leukocytes in the blood has sometimes been 20 per cent or less, and the bone marrow apparently attempts to compensate by sending out the younger forms into the peripheral blood.

With such lowering of so highly a potent barrier to infection, it is easy to see how noxious agents may gain a foothold, either through allergic mechanisms or by actual bacterial invasion, and produce the inflammatory changes noted in these cases. Just as in agranulocytosis there is a predilection for infections of the throat, so in these cases there is a predilection for the joints. Yet either may show manifestations elsewhere, such as acute fibrinous pericarditis, and pneumonia. One would expect to find associated inflammatory conditions more frequently if carefully sought for.

If one assumed allergy to play a role, it would be easy to explain the eosinophilia, the plasma cell and eosinophile infiltration in some of the organs and the rapid onset and disappearance of the acute arthritis without many sequelae. However, such an assumption is mere speculation.

Though agranulocytosis and Felty's syndrome seem to have many features in common, they are entirely separate entities. The former usually has a more sudden onset, is rapidly fatal if not treated, has a predilection for females, is very frequently associated with angina, and rarely has as high a white count. Of 103 cases analyzed by Jackson and Parker, 58 had white counts less than 1000 and only seven had a count of more than 2000. Moreover in agranulocytosis there is a more marked neutropenia, eosinophils are quite rare or absent, the spleen is rarely obviously enlarged and never greatly so, and the bone marrow shows but few if any adult neutrophils.

Still's⁸ disease is similar in that there is a chronic arthritis, splenomegaly, enlargement of the lymph nodes, fever, emaciation, occasional eosinophilia, secondary anemia and rarely subcutaneous nodules. It is different in that it occurs in children, usually has a leukocytosis rather than marked granulopenia and neutropenia, and is characterized by a more crippling form of arthritis.

Many of the features of these cases are similar to those of other forms of chronic rheumatoid arthritis. Of 250 cases of chronic arthritis studied by Eaton⁹ there were only three cases with a normal blood picture. The hemoglobin was below 75 per cent in 68.8 per cent of the cases and below 60 per cent in 15.2 per cent, the red blood cell count was below 4,000,000 in 10.4 per cent, the white blood cell count below 6000 in 22 per cent, the polymorphonuclear leukocytes under 60 per cent in 43.2 per cent, the lymphocytes over 35 per cent in 47.2 per cent. A marked shift to the left occurred in 37.2 per cent, with 2 to 15 per cent juvenile polymorphonuclear leukocytes in 44 per cent, and 5 per cent or more eosinophiles in 9.2 per cent. Pemberton and McRae each analyzed a large series of cases and, though differing to some degree in the figures, found essentially the same general changes. Slight enlargement of the spleen and eosinophilia associated with chronic arthritis have been frequently described. However, in no case have I been able to find such persistently marked leukopenia or granulopenia (adult polymorphonuclear leukocytes sometimes being less than 10 per cent). Nor has there been such failure of response of the white count in the presence of swollen, hot, painful joints or such acute infections as fibrous pericarditis (Price and Schoenfeld), angina and pneumonia.

SUMMARY

1. The cases of Felty's syndrome which have been reported have shown it to be a disease of middle-aged individuals characterized by migratory, polycyclic chronic arthritis, splenomegaly, marked leukopenia, marked granulopenia, distinct loss in weight, slight secondary anemia and intermittent fever. Less often there have been noted enlargement of lymph nodes, pigmentation of the skin, urobilinuria, enlargement of the liver and eosinophilia. Two cases have been treated with some improvement by splenectomy.

2. A case of this disease with autopsy is reported.

3. An attempt has been made to explain the primary disturbance as a blood dyscrasia in which there is an arrest in the maturation of the polymorphonuclear leukocytes (dysoremos neutrophilia).

NEUROCIRCULATORY ASTHENIA REPORT OF A CASE TREATED BY ADRENAL DENERVATION *

By JOHN P ANDERSON, M D, F A C P, *Cleveland, Ohio*

THE term, neurocirculatory asthenia, is used to represent a syndrome characterized by a sense of fatigue, palpitation, precordial pain, and a tendency to giddiness. The symptom complex it presents is almost as definite as that of angina. It has been called by various other names, for example, irritable heart, effort syndrome, and disordered action of the heart, but none is quite so descriptive as neurocirculatory asthenia.

Persons afflicted with this condition are usually thin and asthenic in stature and appearance. They have quick, nervous temperaments and are intelligent. They have a marked degree of initiative but usually lack the physical stamina to carry on sustained activity without suffering undue fatigue. Whether this is essential to the syndrome or incidental is unknown. It would appear that they have been unable to train their involuntary nervous systems and still react to fear, joy, sorrow and other emotions as adolescents, but whether this is due to lack of effort on their part or to a hypersensitive involuntary nervous system is uncertain.

Dr Crile has suggested that the condition of neurocirculatory asthenia is caused by excessive adrenal activity which produces increased drive on the whole involuntary nervous system. On this basis he has advocated adrenal denervation, and this report illustrates the beneficial effects of the operation in controlling the circulatory symptoms in a patient with neurocirculatory asthenia.

CASE REPORT

A single girl, aged 21 years who was employed as a secretary, first consulted Dr Crile in 1921 for nervousness and enlargement of the neck. Her birth had been premature (at seven months) and difficulties had been encountered in maintaining her nutrition. She had always been considered as a delicate child. She had had diphtheria in childhood, and following this a tonsillectomy had been performed. The menses were regular and normal with no pain.

She stated that her neck had been slightly enlarged and that she had been a little nervous for several years, but that during the last year these symptoms had progressed. She also suffered from insomnia. She noticed palpitation and slight dyspnea with effort and also had difficulty in swallowing when she was nervous, she said she felt as if she had a lump in her throat. There had been no loss of weight. Her appetite was good and she had had few digestive upsets. The bowels were regular,

* Received for publication January 2, 1935

and there was no bladder frequency or nocturia. She had very few colds, but complained that she tired very easily.

On examination, she was 5 feet, 7 inches tall and weighed 130 pounds. There was a slight symmetrical thyroid enlargement with increased pulsation of the superior thyroid vessels. The heart was not enlarged. The pulse rate was 120. The diagnosis was mild hyperthyroidism, and an operation was performed at which 40 grams of thyroid tissue were removed. This the pathologist reported as colloid goiter with no hyperplasia.

In 1923, the patient reported that she still fatigued easily, was less nervous, but still had palpitation. Her weight had not changed. It was thought that she probably had recurrent hyperthyroidism and sedatives were prescribed.

From 1923 to 1930 she worked steadily as a stenographer and secretary for a busy executive. She was annoyed by palpitation and fatigued easily. She was full of ambition but lacked the physical ability to accomplish what she wished without undue fatigue, and she had to force herself to get through her work.

I first saw her in June 1930, when she consulted me for an examination of her heart condition. This was prompted by the fact that she had twice been refused life insurance and had been unable to obtain permission to swim in a Y W C A pool, because of a rapid heart rate. At that time, she still weighed 130 pounds. The temperature was 98.6° F, the pulse rate 126, and the blood pressure 138 systolic, 70 diastolic. She had no exophthalmos and no lid lag, and there was no palpable thyroid tissue, but she displayed some digital tremor and seemed nervous. Her extremities were clammy. The heart was not enlarged. The sounds were clear and without any murmurs. There were no signs of congestive failure in the lungs, liver or extremities and no cyanosis of the extremities.

My first impression was that she had recurrent hyperthyroidism but the basal metabolic rate was —11 per cent, which immediately raised the question of neuro-circulatory asthenia. Lugol's solution was administered daily for one month. The patient was still nervous and irritable and the pulse rate varied between 100 and 120. There was still some digital tremor. The Lugol's solution was continued for another month. She then had no digital tremor, the basal metabolic rate was —7 per cent and the pulse rate 88.

In October 1930, she had been working hard and was excessively stimulated. She was troubled with insomnia, her hands were cold and clammy, the pulse rate was 150 and the blood pressure 130 systolic, 70 diastolic. The administration of Lugol's solution was renewed daily, and a month later the pulse varied from 96 to 108, and she had a marked sinus arrhythmia. An electrocardiogram showed nothing abnormal aside from the sinus arrhythmia. The Lugol's solution was discontinued and a month later the pulse was 130.

Her condition remained unchanged for four months until April 1931. At that time she was working very hard and felt nervous, and her ankles were swollen. Digitalis was prescribed (1 gram three times daily). This induced nausea on the eighth day but the edema had disappeared. The pulse rate was 100. The digitalis was continued, but even very small doses induced nausea and she refused to take any more. In July 1931, ammonium chloride and salyrgan were started and were continued on an average of once a week for six weeks. The pulse rate averaged 130 each time she was observed, but the salyrgan controlled the edema of the legs. There were never any pulmonary congestive râles or tenderness of the liver.

In November 1931, she made a trip to California and had no trouble on the way. Her nervousness subsided while she was away. In December 1931, her ankles were still slightly swollen and her extremities were cold, clammy and mottled.

In July 1932, her chief complaint was easy fatigability and aches at the back of the neck. She said that she had noticed the cold a great deal during the past winter and always required about twice as many bed clothes as other persons. She had

recognized no edema during the last year. Her heart continued to thump at the slightest provocation and her extremities continued to sweat easily. She had used no medicine.

At examination on July 16, 1932, that is, two years after my first examination, the temperature was 99°, the pulse rate 126 and the blood pressure 130 systolic, 80 diastolic. The hands were warm and clammy. She displayed no cyanosis, no thyroid or lymph glandular enlargement, and the lungs were clear. The heart borders were 3 and 10.5 cm, the sounds were regular with a systolic murmur at the apex. The remainder of the examination, including a blood count and urinalysis, was normal. An electrocardiogram showed normal rhythm and conduction with inverted T₃. Vagal pressure, eye ball pressure, or bending over and compressing the abdomen caused no appreciable change in the pulse rate, but lying down reduced it from 126 to 108.

She received Lugol's solution (8 minims twice daily) for two weeks, but this produced no change in her condition. The pulse rate when standing was 120, when lying down, 72 to 88, after touching toes 15 times, 132, after lying down it reached 72 with marked sinus variation. Deep inspiration caused marked slowing of the pulse with sinus arrhythmia, whereas before she had taken the Lugol's solution, this had produced no change.

After consultation with Dr. Crile, she was advised to have an adrenal denervation and she entered the Cleveland Clinic Hospital in September 1932, with symptoms of tremor, cold hands, palpitation, tachycardia (pulse rate 130), nervous excitability and fatigability, and flushing of the neck and chest. The basal metabolic rate was -8 per cent.

Dr. Crile performed a left adrenal denervation on September 28, 1932, and right denervation on October 11, 1932. She was in the hospital 23 days. On discharge, her hands were warm and dry and she had no tremor. She was sleeping well and could relax easily without any sense of inward nervousness and had no palpitation or precordial distress. The pulse rate was 80. One month later she was feeling well and the pulse rate was 74. The extremities were dry and warm, she had no palpitation and the flushing of the neck had disappeared.

For one year she lost an average of two pounds each month. In February 1933, her menses became irregular. One period interval would be four weeks and the next two weeks. Examination showed that the right ovary was about twice the normal size and the presence of a retention cyst was suspected. Six injections of antuitrin S were administered and the menses became regular.

During the hot weather that summer there was some aching under the left scapula but the patient had no palpitation or edema. The pulse rate remained between 72 and 78. The menses became irregular again in August 1933. Antuitrin S seemed to help regulate them, but when larger and larger doses were required, its use was abandoned.

The patient then had irregular menses with periods of amenorrhea for two to four months. In September 1933, one year after the operations, her weight had fallen from 129 to 100 pounds, and she then complained of marked urinary frequency and urgency. The urine was examined and showed no pus or casts but 1+ albumin, the specific gravity was 1.033. Another specimen was collected in the early morning and showed no albumin which indicated that the albuminuria might be postural. A 24 hour output was then recorded and it was over 4 liters, of which the night specimen was 1125 c.c.

Several doses of pitressin were given hypodermically and the 24 hour urinary output was recorded afterwards. These were 3000, 2000 and 1500 c.c. respectively. There was no further loss of weight after these injections, and three months later she had gained five pounds. Although the pulse rate and blood pressure did not change, the injections of pituitary extract always caused a little shock and nausea and the

patient preferred not to continue them. Whole pituitary substance was given in doses of 5 grams daily, but caused very little effect, so it was discarded.

To date, September 1934, her condition continues about the same. She has gained no more weight. There is still an excessive urinary flow with much urgency at times. The menstrual periods are irregular. An osteoma developed along the crest of the left ilium which was a little tender to pressure. The blood calcium is 10.78 mg per cent. The heart has remained entirely stable. The pulse rate has never been above 90 since the denervation of the adrenal glands, and the rate is usually 72 to 78. The systolic murmur at the apex is now barely audible. There has never been any recurrence of the sense of palpitation, flushing, inward nervousness or cold extremities, and there has been no undue fatigability in spite of the loss of weight. The patient herself is most enthusiastic about the results of the operation.

COMMENT

In my experience, neurocirculatory asthenia has been rather difficult to control with medical measures. Digitalis has little or no effect in slowing the heart rate and no effect on the other symptoms. Sedatives such as bromides and barbiturates have little effect, and drugs which act on the sympathetic nervous system, such as quinine and ephedrin and ephedramine, have been of but questionable value. In fact, the only thing that has really helped has been about one or two years of intensive rest and convalescent treatment, and that is a form of therapy that is seldom practicable. The fact that a thyroidectomy was performed on this patient in 1921 and failed to cure her symptoms indicates once again that the symptoms of neurocirculatory asthenia are not relieved by thyroidectomy.

It is very gratifying in this case to find a complete cure of all the symptoms of neurocirculatory asthenia by the adrenal denervation, although there is evidence of a disturbance of the pituitary gland following the operation. The fact that there was an increased urinary output with a negative water balance which appeared after the operation along with irregular menses and later amenorrhea when both of these factors had been very stable prior to the operation is presumptive evidence, at least, of some hypofunction of both the anterior and posterior lobes of the pituitary gland.

But despite these complications, the patient's condition has been very much better generally, and the abnormality of the circulation has been entirely controlled since the operation.

PAROXYSMAL VENTRICULAR TACHYCARDIA, REPORT OF A CASE ILLUSTRATING ALL THE ACCEPTED DIAGNOSTIC CRITERIA¹

By AARON E. PARSONNET, M.D., C.M., F.A.C.P., *Newark, New Jersey*

ALTHOUGH there is a growing tendency among recent authors to minimize the rarity of paroxysmal ventricular tachycardia, nevertheless, when all the accepted criteria warranting such a diagnosis are made requisite, this type of abnormal cardiac rhythm looms rarer than ever.

The literature, starting with the work of Lewis,¹ has been materially enriched by contributions devoted to the study of paroxysmal tachycardias, some of which

* Received for publication September 10, 1935.

are unquestionably of the ventricular type. However, after careful scrutiny of the available material, a large percentage of the reported cases falls by the wayside as either unproved, doubtful as to point of origin, or totally worthless for statistical data because of lack of electrocardiographic corroboration. In two exhaustive studies made by Gilchrist² and Strauss³ the former accepts practi-

FIG 1 Tracing taken on May 10, 1932, showing the typical paroxysms of ventricular tachycardia. The variations in the length of the interventricular intervals may be distinctly observed.

cally all reported cases as true ventricular paroxysms while the latter, on the other hand, disposes of the majority of the 65 instances recorded up to 1930, as distinctly doubtful. There is a definite reason for such marked diversity of opinion among careful investigators: electrocardiographic methods of examination are still quite recent and poor tracings and standardizations were the rule up to but a very few years ago. With the practically perfect modern instruments and, of still greater importance, the improved technic and resultant rapid handling

of suspected patients, a paroxysm will rarely escape the observer and a good permanent record will be secured

The criteria warranting the diagnosis of paroxysmal ventricular tachycardia as outlined by Robinson and Herrmann,⁴ must be fully met and are as follows

1 The electrocardiographic tracings must definitely establish the fact that the cardiac impulses responsible for the rapid ventricular rate are of distinct ventricular origin

2 The ventricular complexes must be both preceded and followed by auricular complexes of slower rate

FIG 2 Schematic representation of the above tracing to more clearly note the characteristics of the paroxysms

3 The ventricular complexes must be abnormal in form and, should there be any isolated extrasystoles preceding or following the paroxysm, these must resemble in type the ones seen during the attack of tachycardia

In this connection, Robinson and Herrmann⁴ point out that the abnormal ventricular complexes alone cannot serve as proof of ventricular origin, for their bizarre form may be produced by intraventricular conduction disturbances. If, however, at the termination of the paroxysm no such disturbed conduction is exhibited, the unusual form of the complexes will serve further to substantiate their ventricular origin. Robinson⁵ also brought out the fact that, when the cardiac rate is very fast, conduction disturbances may often be overlooked. The

diagnosis of paroxysmal ventricular tachycardia can be made still more certain when, as Strong and Levine⁶ pointed out the rapid succession of ventricular complexes discloses a slight but nevertheless a definite irregularity of time spacing not met with in any of the other forms of paroxysmal tachycardia

It would be useless repetition and distinctly burdensome to give a detailed review of the literature, this has been very ably done by Strauss³ It is interest-

FIG 3 Electrocardiogram obtained before the onset of the paroxysm

ing to note, however, that as late as 1921, the entire number of published cases comprised 16, of which only six could be considered authentic. The writer's experience has been similar for, although over 90 cases were carefully examined in the available literature, the data in a large percentage were found unconvincing

It is not amiss, therefore, to present the following case of paroxysmal ventricular tachycardia exhibiting all the essential electrocardiographic features of this still rather rare arrhythmia

CASE REPORT

History F C, male, aged 63, a native of the United States, receiving clerk by occupation, was seen in consultation on May 10, 1932. His chief complaints at the time were dyspnea upon exertion, precordial discomfort and occasional attacks of palpitation. His family history was unimportant, his parents having died of old age and one brother and two sisters during infancy. His previous history was un-

FIG 4 Electrocardiogram taken after the paroxysm subsided. Note the isolated extra-systoles in each lead and compare their form with those in figure 5.

eventful, except for the usual diseases of childhood and a minor surgical operation for ischiorectal abscess at twenty-five. He had been married 35 years, and had six children all living and well. His wife always enjoyed good health and gave no history of miscarriages or stillbirths. He was always temperate in his habits, using no tobacco or alcohol and drinking tea and coffee moderately. His exercise consisted chiefly in walking to and from work. He always enjoyed a good appetite, was a hearty eater, but habitually was a very poor sleeper.

Present Illness Although dyspnea and palpitation were symptoms familiar to him for the last year or two, he was quite sure that these were very much aggravated

since the beginning of April 1931, when in the course of his work he met with an accident. A heavy bale of wrapping paper struck him, knocking him down and fracturing his right clavicle and arm, he also received a crushing blow over the left chest, but no ribs were broken. Following this occurrence he became very short of breath even upon the slightest exertion, and the dyspnea would invariably be accom-

FIG 5 Redrawn section of the electrocardiogram (figure 1), isolating one ventricular complex from each lead and comparing it with the corresponding ectopic beat in figure 4. Note the striking structural similarity.

panied by marked precordial pain and palpitation. At times, while walking, he would stop short, being conscious of a sudden beginning and termination of rapid heart action.

Physical Examination The patient was 5 feet, 7 inches tall, and weighed 170 pounds. He appeared chronically ill, very dyspneic, and slow and deliberate in his movements. His skin was free from eruptions, dry, and had a leathery feel; his lips and nail-beds were moderately cyanosed. Oral examination showed moderate dental sepsis, with many teeth missing; the tongue was thickly coated. The naso-

pharynx was normal. The sinuses transilluminated well and the larynx was freely movable. There was no thyroid enlargement. The eyes reacted to light and to accommodation; the pupils were regular, both palpebral fissures equal. The conjunctivae were clear. A well-marked arcus senilis was present. The ophthalmoscopic examination revealed increased tortuosity of the retinal vessels.

The chest was well formed and disclosed no abnormal prominences or depressions, but scattered moist rales were heard posteriorly in both bases.

The heart was enormously enlarged to percussion in all its diameters and the aorta markedly widened. The heart sounds were muffled and toneless and the regular rhythm was frequently interrupted by extrasystoles, isolated and in showers. These were detected with difficulty at the radial artery. There was a marked pulse deficit. Under a moderate spirometric exercise test the patient became cyanotic and very dyspneic, showing a very poor myocardial reserve. An occasional systolic blow was heard at the apex which was also elicited over the aortic area. Repeated blood pressure readings averaged 140 systolic and 40 diastolic.

The abdomen was prominent, no masses and no ascites were noted. The liver was enlarged and tender to pressure, the lower margin extending four fingers below the costal margin. The spleen was not palpable.

FIG 6 A tracing of a typical proximal auricular tachycardia inserted for comparison. Note the practically clock-like regularity of the interventricular time intervals here as compared with the variations in the interventricular intervals as seen in figure 1.

The genito-urinary tract, with the exception of a moderately enlarged prostate, disclosed no abnormalities.

Fluoroscopic examination revealed a markedly enlarged cardiac shadow, aortic in configuration, a very much widened aorta and an accentuated aortic knob. The transverse diameter of the chest measured 29.7 cm, with a maximum transverse cardiac diameter of 18.8 cm. The lung fields were clear. The diaphragmatic excursions were limited.

Laboratory Data The urine showed a 1 plus albumin test, a few small granular casts and an occasional pus cell; many cylindroids were noted. The blood count showed a hemoglobin of 82 per cent with 4,400,000 red blood cells, and 9,600 white blood cells. The differential count showed 59 polymorphonuclears, 37 lymphocytes and 4 eosinophiles. The blood chemical tests showed a urea nitrogen of 16.8, creatinine 1.5, and sugar, 95 mg per hundred cubic centimeters. The Wassermann and Kahn tests were negative.

The electrocardiograms taken on May 10, 1932 (figures 1 and 2) showed the following: There were no gross errors of conduction. The P-R intervals were 0.20 sec, the QRS complexes were upright and of high voltage in Leads I and II, and inverted in Lead III, showing a left axial rotation. The T-waves were dominantly upright in Leads I and II, and inverted in Lead III. They exhibited a low take-off in Lead I. The P-waves were upright in Leads I and II, and inverted in Lead III. The dominant rhythm is interrupted in every lead by showers of ventricular extrasystoles reaching a rate of 210 beats per minute. All the ectopic beats originate from

a single ventricular focus of irritability (figures 4 and 5) The auriculoventricular rate before the onset of the paroxysm is 90 beats per minute (Figure 3)

The patient is now 66 years old and has had several severe attacks of coronary occlusion, the paroxysms of ventricular tachycardia still continue at irregular intervals

SUMMARY

A case of undoubted paroxysmal ventricular tachycardia is reported in which all the essential criteria warranting such a diagnosis are exhibited An exhaustive review of most of the available literature established the rarity of cases of this condition properly authenticated by satisfactory electrocardiographic proof Such proof, however, is here presented as unmistakable evidence for the above diagnosis

EDITORIALS

THE DETROIT AND ANN ARBOR SESSIONS

THE return of the College, after ten years, to the city of Detroit gave to many of the older members an opportunity both to evaluate the progress of the College in this period of time and to appreciate the many alterations and advances in the medical institutions of Detroit and Ann Arbor. Changes have taken place, a normal healthy development has occurred. The College brought to this meeting a larger group of men better able to enjoy the richer intellectual fare provided for them.

In the minds of all was the memory of the man to whom the College owes so much, Dr Charles G Jennings. Both in the development of the policies of the general body of the College and in arousing the interest of the medical men of Michigan in the value of the College, Dr Jennings played an important part. He it was who transmitted to the Regents the invitations to the College from the Medical Schools, the Hospitals and the Medical Societies of Detroit and Ann Arbor, to hold the Sessions of 1936 in Michigan. The acceptance was based in no small part upon his agreement to act as General Chairman. The success of this meeting constitutes a tribute to him since much of the labor was his and since those who took up the burden when he dropped it were his friends and carried out the work in the spirit of his wishes.

Perhaps at no meeting has there been more satisfaction among the Fellows both with the high quality of the General Sessions and with the interest and variety of the program of clinical meetings. The gratitude of the College is due to all who took part in the laborious task of arranging this highly successful meeting.

PNEUMOCOCCUS TYPE III PNEUMONIA

THE differentiation of the pneumococci into biological types led naturally to the hope that more intensive study of the clinical aspects of lobar pneumonia would disclose characteristic features which would be distinctive for the pneumonia caused by each type of the pneumococcus. This hope has as yet been only partially fulfilled, but a recent study by Cecil, Plummer and McCall¹ of 500 cases of Type III pneumonia adds further data in confirmation of earlier work that established important clinical facts bearing on infection with this organism.

The analysis of the incidence of Type III infections has shown again that though in the total of all pneumococcus pneumonias only about one in eight is due to Type III infection, in pneumonias occurring after 60 years of age Type III pneumococci are the commonest etiologic agent. In this age group the authors found in their recent study 32.8 per cent of Type III.

¹ CEIL, R. L., PLUMMER, N., and MCCALL, M. *Pneumococcus Type III pneumonia*, *Am Jr Med Sci*, 1936, vol. 305-319.

infections In all cases over 50 years the incidence of Type III infections was 24.2 per cent, while in cases under 50 years it was only 9.4 per cent Since these figures accord well with those found in earlier series published by Cecil, Baldwin and Larsen² and by Blake³ it may be considered clearly demonstrated that Type III pneumonia is a relatively rare variety before 50 but becomes the commonest type in the elderly

The death rate in the 500 cases of Type III pneumonia analyzed was 42.2 per cent This is in very close agreement with the figures derived from other large series It seems, however, that this high death rate is not necessarily due entirely to the excessive virulence of the organism The death rate of all types of pneumonia increases with each decade after maturity Since Type III pneumonias are common among the aged, it is evident that a part of the high death rate may be due to the lessened resistance of those attacked In the Bellevue series Cecil, Plummer and McCall have found that the death rate for Type III cases under 40 is not significantly higher than that of Type I or Type II Approximately 40 per cent of all the Type III cases, however, were over 50 years of age, whereas only 18.4 per cent of the Type I cases were over 50 and only 31.7 per cent of the Type II cases That the age incidence is, therefore, a factor in determining a part of the high mortality of Type III infections seems clear

Another factor apparently is the tendency of Type III infections to attack those already debilitated by chronic disease In the present series the incidence of systemic diseases, especially alcoholism and degenerative cardiovascular diseases, was 49.6 per cent Blake found that even in the earlier age periods this same tendency could be observed Comparable figures given for series of Type I and Type II cases show that systemic disease occurred in only 20.4 and 33 per cent respectively of these infections

These considerations of the factors bearing on the virulence of the Type III pneumococcus seem of particular interest The fact that this organism, unlike the Type I and II pneumococci, is not infrequently found as an apparently harmless saprophyte in the mouths of healthy individuals has always raised the question as to what determined its behavior in the cases in which it causes a highly fatal infection

To this fundamental question no answer has been given, but when a more complete understanding is attained the explanation must include the behavior of this organism in relation to age and to chronic disease

BOOK REVIEWS

Laboratory Methods of the United States Army Edited by MAJOR JAMES S SIMMONS and MAJOR CLYDE J GINTROW (Associate editor) Fourth edition Lea and Febiger, Philadelphia 1935 1091 pages Price, \$6.50

This new edition of the Army Manual has been largely rewritten and considerably extended in scope. Twenty contributors are listed, chiefly members of the Medical Corps on the staff of the U. S. Army Medical School.

The book is primarily a laboratory manual. It covers in a severely practical way the usual field of medical bacteriology, serology, protozoology and clinical pathology, including quantitative chemical analyses of the blood and urine. There are also brief sections on mycology, on the helminths and on the more important mosquitoes and other arthropod vectors, with tables and keys to facilitate identification. The individual parasites are not described, however. In addition there are sections on the filtrable viruses, chemical and bacteriological examination of water, milk, foods and beverages, toxicological procedures, autopsy technique and preparation of tissue sections, special methods applicable to veterinary medicine, and statistical methods.

The technique of the various laboratory examinations is given in detail, and the underlying principles are clearly explained, so that the procedures can be followed by technicians with limited experience. As a rule the authors have selected a single analytical method for each determination with occasionally an alternative procedure. In most instances the selections seem wisely made. Relatively less attention is paid to the clinical significance of the tests except in a few instances. Thus, tests of liver function and of kidney function are discussed at considerable length.

In general the subjects are adequately covered, and the work is reasonably well balanced. As is usually the case in books which are the product of a number of contributors, some subjects seem unduly stressed at the expense of others. The reviewer regrets, for example, that only 18 pages were allotted to hematology, less than half the space devoted to tests of liver function. He was also unable to find a description of the glucose tolerance test.

On the whole the book is well written and accurate and contains a great deal of carefully selected, useful information. It should be of great assistance to those who are engaged in the actual performance of these procedures. P. W. C.

The Practitioner's Library of Medicine and Surgery Supervising Editor, GEORGE BLUMER, M. A. (Yale), M. D., F. A. C. P. David P. Smith Clinical Professor of Medicine, Yale University School of Medicine, Consulting Physician to the New Haven Hospital. Volume IX *Neurology and Psychiatry* Associate Editors, JAMES C. FOX, JR., B. A., M. D., Associate Professor of Neurology, Yale University School of Medicine, and CLEMENTS C. FRY, B. S., M. D., Associate Professor of Psychiatry and Mental Hygiene, Yale University School of Medicine. xlviii + 1234 pages, 193 illustrations. D. Appleton-Century Company, Inc., New York. 1936. Price, \$10.00 a volume.

In the preface to this ninth volume, *Neurology and Psychiatry*, of *The Practitioner's Library of Medicine and Surgery*, attention is very properly called to the fact that the ultimate welfare of the patient with a "nervous" disorder often depends upon the alertness and insight of the practitioner whom he first consults. To learn to appreciate the patient's personality make-up, and to recognize organic disease of the nervous system in its clinically incipient stage are the responsibilities of the physician toward this group of patients. Thirty-nine authors have contributed the forty-one chapters of this book. After sections in which the general principles of behavior, psychopathic personalities and their manifestations, and special methods of examina-

tion are considered, the individual affections of the nervous system are treated according to a grouping based upon etiological factors so far as is possible. This method brings together conditions in respect to which differential diagnosis is required and directs attention at once to such causal agencies as may be avoided or alleviated. Thus entire sections of from one to six chapters each are devoted to disease due to infection, to intoxication, to alimentary deficiency and to trauma.

It is quite impossible to attempt a critical evaluation of the individual sections of this book. In a general way it is evident that the editors have secured a degree of uniformity in style and a balance in treatment which is unusual in a work to which there have been so many contributors. Brief historical notes give added interest to many sections and well chosen illustrations have been freely used. To those practitioners who think that neurology and psychiatry are abstruse specialties, of but little application in their daily routine this volume can be enthusiastically recommended as readable, entertaining, informative and stimulating. It is a highly successful addition to *The Practitioner's Library*. C V W

Essentials of Psychopathology. By GEORGE W. HENRY, M.D., Associate Professor of Psychiatry, Cornell University Medical School. ix + 312 pages. William Wood & Company, Baltimore. 1935. Price, \$4.00.

As the author says, "the study of psychopathology includes such a wide range of topics that it is difficult to select those most pertinent" to the understanding of the nature and causes of personality disorder. He has done well in his selection and in 12 chapters has concisely surveyed the subject. No matter how biased the reader may be, he will find a logical presentation of the factors in the evolution of personality. Sufficient case material is included to clarify his discussion. This book is not as verbose as the usual psychiatric textbook, although the author states that he has written it primarily for medical students and members of the medical profession.

Henry brings out the fact that "in spite of careful and extensive study of functional illness, no pathology of the brain has been disclosed. Furthermore the clinical manifestations of organic psychoses are little more than a caricature of the phenomena observed in functional psychoses. The sequence of emotional stresses which is so important in the evolution of personality disorders is usually irrelevant in organic illness. Just as mental illness is peculiar to human beings, so the associated phenomena would be possible only through the activity of a highly developed cerebral cortex."

The author proves the point that "with failure to take into consideration the psychogenic aspects of illness, not only do physicians make serious errors in diagnosis but their numerous examinations and their discussions at the bedside together with ill-advised medical and surgical treatment may accentuate the illness itself. Even when the physician is alert to these aspects he is inclined to divide the patients into two classes according to whether their illnesses are functional or organic. Such classification is necessarily inaccurate because there are psychogenic elements in all forms of illness, so that in order to understand and to deal effectively with any illness the physician must determine to what extent and under what circumstances psychogenic elements are present." On the other hand "no form of personality disorder offers immunity to physical illness."

In the X and XI chapters the author discusses psychiatric case records and methods of examination. Every physician should read these chapters in order to get some idea of the painstaking effort necessary to proper understanding of human nature. "Snap diagnosis" has no place in scientific medicine.

This is not a book of diagnosis, and the reader will not find listed the clinical entities or any of the various reaction types which occupy the attention of the psychiatrist, but he will find a most readable volume that may well supplement any textbook in medicine or surgery.

AWARD OF THE JOHN PHILLIPS MEMORIAL MEDAL FOR 1936

DETROIT, MICHIGAN, MARCH 4, 1936

"After careful consideration by the Committee on Awards and upon its recommendation, the Board of Regents of the American College of Physicians has awarded the John Phillips Memorial Medal for 1936 to Dr Eugene Markley Landis

"Dr Landis exemplifies in his training and career and achievements the characteristics which this College wishes to encourage in American medicine and for the honor of which the award of this medal was established

"Dr Landis, though young in years, is already old in his experience in the special field of medical research which he has chosen. His contributions to scientific medicine have been numerous and important, and he holds a position of honor among his colleagues which has been recently recognized by his appointment as Assistant Professor in Medicine in the University of Pennsylvania

"The important contribution of Dr Landis has been in the field of capillary physiology and of edema. From this his interest has been extended to disturbances of the peripheral circulation, in which field he has made valuable contributions. He has devised new methods for testing these disturbances and for their treatment by a very original device of alternate suction and pressure. More recently he has been active in the study of renal disease in association with Professor Richards

"It is on the basis of these outstanding achievements that the award of the medal has been made to Dr Landis, and I have the honor and the privilege, on behalf of the Board of Regents, to bestow upon you, Dr Eugene Markley Landis, the John Phillips Memorial Medal for 1936"

Presentation address by Dr James Alex Miller, President of the American College of Physicians at the Annual Convocation

COLLEGE NEWS NOTES

The following Fellows of the College have become Life Members, making a total of 61 to date

Dr Anna Weld, Rockford, Ill
Dr Estes Nichols, Portland, Maine
Dr William H Watters, Miami, Fla

GIFTS TO THE COLLEGE LIBRARY

Dr J W Torbett (Fellow), Marlin, Texas—one book, "Pastime Poems of a Busy Doctor" Dr Torbett's book is autographed "To the Doctors of the American College of Physicians"

Dr William R Brooksher (Fellow), Fort Smith, Ark—one reprint
Dr Gerald M Chne (Fellow), Bloomington, Ill—one reprint
Dr Archibald L Hoyne (Fellow), Chicago, Ill—two reprints
Dr Manfred Kraemer (Fellow), Newark, N J—seven reprints
Dr William LeFevre (Fellow), Muskegon, Mich—one reprint
Dr Alfred J Scott, Jr (Fellow), Los Angeles, Calif—one reprint
Dr Sidney A Slater (Fellow), Worthington, Minn—two reprints
Dr Ramon M Suarez (Fellow), Santurce, P R—two reprints
Dr John W Williams (Fellow), Cambridge, Mass—eighteen reprints
Dr Robert B Wood (Fellow), Knoxville, Tenn—one reprint
Dr Jacob Greenstein (Associate), Providence, R I—one reprint

Dr Herbert T Kelly (Fellow), Philadelphia, Pa, was guest speaker, February 5, at the meeting of the Luzerne County Medical Society at Wilkes-Barre, Pa, his subject being "The Early Diagnosis and Treatment of Diabetes"

Dr Robert B Radl (Fellow), formerly Physician, Students' Health Service, University of Minnesota, and Assistant Professor in the Department of Preventive Medicine and Public Health, University of Minnesota Medical School, is now associated with the Quain and Ramstad Clinic at Bismarck, N D

Dr John Russell Twiss (Fellow), New York City, Associate in Medicine, New York Post-Graduate Medical School and Hospital, Columbia University, has recently become Assistant Attending Physician, Gouverneur Hospital

Dr William C Voorsanger (Fellow) has been appointed to the Health Advisory Board of the City and County of San Francisco

Dr Raymond W Swinnev (Fellow) is chief of the medical staff of the Long Beach Community Hospital and has recently been elected Secretary of the Harbor Branch of the Los Angeles County Medical Society

Under the Governorship of Dr L E Viko, the Utah members of the American College of Physicians held a sectional meeting at Salt Lake City during the latter part of January

Under the Governorship of Dr Adolph Sachs, members of the American College of Physicians held a sectional meeting for the State of Nebraska on January 30, 1936, at Omaha Dr Augustus Pohlman, Professor of Anatomy at Creighton University Medical College, addressed the group on "The Physiology of the Lymphatic System" Forty members were present, various committees were appointed and a plan drawn up for meetings each year, alternating between Omaha and Lincoln

Dr Albert A Raymond has resigned from the Rockefeller Institute of Medical Research with which he had been connected for the past nine years to accept the appointment as Director of the Research Laboratories of G D Searle & Co, Chicago

Dr William D Weis (Fellow), Crown Point, Ind, is Health Commissioner of Lake County Lake County is the first and only County in the State of Indiana having an all-time Health Department personnel consisting of the Health Commissioner, Sanitary Inspector, four nurses and a clerk

The Thirty-Second Annual Congress on Medical Education, Medical Licensure and Hospitals was held at Chicago, February 17 and 18, 1936 Fellows of the College who contributed to the program appear below

Dr Walter L Bierring, Des Moines, Iowa—"Consistency versus Chaos in Medical Education and Licensure"

Dr James S McLester, Birmingham, Ala—"The Personal Characteristics of the Teacher"

Dr Nathan B Van Etten, New York, N Y—"What Is the Social Objective of the Young Physician?"

Dr William D Cutter, Chicago, Ill—"The Federation and the Survey of Medical Schools"

Dr Harold Rypins, Albany, N Y—"Final Objective—The Federation of State Medical Boards"

Dr Howard T Karsner, Cleveland, Ohio—"The Laboratory of Pathology in the Small Hospital"

Dr W McKim Marriott, St Louis, Mo—"Newer Points of View Concerning the Use of the Outpatient Department in Medical Education"

Dr Arthur C Morgan, Philadelphia, Pa—"Aggressive versus Passive Attitudes of State Board Members"

Other Fellows of the College who participated in the official discussions or as presiding officers included Dr Merritte W Ireland, Washington, D C, Dr Waller S Leathers, Nashville, Tenn, Dr Roscoe L Sensenich, South Bend, Ind, Dr Wilburt C Davison, Durham, N C, Dr John Wyckoff, New York, N Y, and Dr Wilbard C Rappleye, New York, N Y

Drs Anthony Bassler (Fellow), Max Einhorn (Fellow) and Samuel Weiss (Fellow) have been selected as the three American physicians who have been named

honorary members of the Belgian Gastroenterological Society All three are also Fellows of the National Society for the Advancement of Gastroenterology

Dr Anthony Bassler (Fellow) has been elected President of the National Society for the Advancement of Gastroenterology, President of the American Committee and United States Delegate to the International Society of Gastroenterology and Vice-Chairman of the Gastroenterological Section of the Pan American Congress

Dr Joseph H Barach (Fellow), Pittsburgh, Pa, has been elected a member of The Society of the Sigma Xi

OBITUARIES

DR JOHN LEONARD ECKEL

From the Encyclopedia of American Biography we learn that our much beloved confrere, Dr John Leonard Eckel, who died November 26, 1935, was born in Perrysburg, Ohio, April 28, 1880. He graduated in medicine at the School of Medicine, University of Buffalo, in 1907. He interned at the East Manhattan State Hospital, New York City, and was Junior Assistant Physician there in 1908-09. He held the same post at the Buffalo State Hospital, 1909-10, and was senior assistant physician at the same hospital, 1910-11. September 1911, he went to the University of Berlin and worked in nervous and mental diseases for two semesters under Professors Oppenheim, Ziehen and Jacobson. He also worked in the University of Munich under Professors Alzheimer and Kraepelin. He spent one semester at the University of London, Queen's Square Hospital, for nervous and mental diseases under Professors Gordon Holmes, S. A. K. Wilson, Farquhar, Buzzard, Purves Stewart and Frederick Batten. Returning to Buffalo in 1913, he began a practice limited to nervous and mental diseases and was soon put on the roster of the Medical School of the University of Buffalo. He was Associate Professor of Neurology and Assistant Professor of Psychiatry.

Dr Eckel went to Vienna for further scientific research and clinical work under Professor Wagner von Jauregg and his assistants, Pappenheim and Schilder. His research work was done with Professor Otto Marburg, Director of the Neuropathological Laboratory. It was there Dr Eckel's research work "Encephalitis Acutissima" was published in the "Jahrbuch" in January 1926. This was an outstanding bit of work which was widely quoted, referred to and favorably mentioned in European medical journals. He did much research work with Dr N. W. Winkelman of the University of Pennsylvania and Temple University, Philadelphia, going to Philadelphia every month for over 15 years. Several of the most valuable articles he wrote were in collaboration with Dr Winkelman.

Dr Eckel was attending and consulting neurologist and psychiatrist to the Buffalo General Hospital, Millard Fillmore Hospital, Memorial Hospital, Our Lady of Victory Hospital, Buffalo City Hospital, Sister's Hospital, Providence Retreat, Crippled Children's Guild, Emergency Hospital and J. N. Adam Memorial Hospital at Perrysburg, N. Y.

He was a member of the American College of Physicians, The Buffalo Academy of Medicine, Erie County and New York State Medical Societies, American Medical Association, American Psychiatric Association, American Neurological Association, American Association for Research in Nervous and Mental Diseases, New York Neurological Society, Philadelphia Neurological Society, Central Neuro-Psychiatric Association, Buffalo

Neuro-Psychiatric Society, Pan-American Medical Association and the American Association for the Advancement of Science and held important offices in many of these organizations

Dr Eckel was asked to read papers at the following meetings the British and American Neurological Societies, London, July 28, 1927, the First International Congress on Neurology in Berne, Switzerland, September 3, 1931, the Pan-American Medical Congress in Dallas, Texas May, 1933, the Pan-American Floating Congress, March, 1934, the Second International Congress on Neurology in London, August 1, 1935, etc

During the World War, Dr Eckel held the commission of Captain in the U S Army

He was a member of the Saturn Club, the University Club, the Buffalo Club, the Torch Club and many other social and fraternal organizations

John Leonard Eckel had personal charm of manner which won many friends He was sound in his work and practice and thorough in his clinical approach, possessed of a sunny nature with a winning smile and presence, comforting to the sick, yet, withal, inspiring confidence and trust

His death was almost a tragedy He apparently did not realize he was ill but had precordial and epigastric pain a few days before his sudden death He went, however, to see some of his patients and while sitting beside one of them while two nurses stood by, according to the account given in the *Courier-Express*, "he straightened in his chair, sighed and died"

ALLEN A JONES, M D , F A C P ,
Governor for Western New York

DR HENRY FINLAY HYNDMAN

Dr Henry Finlay Hyndman (Associate), Wichita, Kansas, died on October 31, 1935, of diabetes mellitus, aged, 49 years

Dr Hyndman was born in Adrian, Illinois, May 4, 1886 He received the degree of Bachelor of Arts from the University of Kansas, in 1908, and the degree of Doctor of Medicine from the Medical School of that institution in 1910

Dr Hyndman devoted his practice to internal medicine but was especially interested in diabetes He was a member of the staff of St Luke's Hospital, Wellington, Kansas, 1911-18, member of staff, Wichita Hospital, 1918 to date, chief of service and member of Executive Council of the staff of Sedgwick County Charity Hospital of Wichita, from 1933 to date, and a member of the medical service and President of Staff of Wesley Hospital, Wichita, from 1929 to date He was a member, also, of the Sedgwick County Medical Society, Kansas State Medical Society, Nu Sigma Nu Fraternity, a Fellow of the American Medical Association, and had been an Associate of the American College of Physicians since December 16, 1934

"Dr Hyndman stood for and practiced the highest principles in his profession. He loved his work and was unwavering in his endeavor to live up to the professional code of ethics. He was never heard to speak disparagingly of any colleague's work or character. Basically he was one of that group of disappearing physicians—the family doctor. Of recent years, however, he devoted most of his time to the care of diabetics and was one of the foremost men in this type of work in Kansas. Our Society has lost an enthusiastic and progressive member and we all have lost a dear friend, and a counsellor"—Medical Bulletin of The Sedgwick County Medical Society

DR WILLIAM KRAUSS

Dr William Krauss (Fellow), Meridian, Miss., died December 21, 1935, in the Gartly-Ramsay Hospital, Memphis, of carcinosis originating in x-ray burns of the hand, aged, 74 years.

Dr Krauss was born in Bavaria. He graduated from the Memphis College of Pharmacy in 1883. He then attended the Memphis Hospital Medical College, graduating in 1889. He pursued postgraduate study in histology, pathology and bacteriology at the University of Kiel and at the University of Wurzburg. He was successively Assistant in Anatomy, Instructor in Chemistry, Histology, Pathology and Bacteriology at the Memphis Hospital Medical College between 1890 and 1903. He became Dean and Professor of Pathology in the Medical Department of the University of Mississippi, 1909-10, after having served as Professor of Pathology and Tropical Medicine in the College of Physicians and Surgeons Memphis, 1906-09. From 1912 to 1929, he was Professor of Tropical Medicine at the University of Tennessee College of Medicine. He was at one time Secretary of the Board of Health of Memphis, also, acting Assistant Surgeon in the U. S. Public Health and Marine Hospital Service, serving as diagnostician during the yellow fever epidemic in 1897-98 and in 1905. At one time he was Director of Laboratories, Memphis City Health Department, and just previous to his death had been with the Stingily Laboratories, Meridian, Miss., in the capacity of Director of the x-ray department and of the laboratories proper.

Dr Krauss was a past President of the Memphis and Shelby County Medical Society, a past President of the West Tennessee Medical and Surgical Association, a member of the Mississippi State Medical Society, Southern Medical Association and the American Medical Association.

At various times he served on the staffs of the Memphis General, Baptist and St. Joseph's Hospitals, all of Memphis. He was a former Chairman of the National Malaria Commission and Chairman of the Tennessee Pellagra Commission. Dr Krauss became a Fellow of the American College of Physicians during 1919.

DR GEORGE WASHINGTON McCASKEY

Dr George Washington McCaskey (Fellow), Fort Wayne, Ind., died December 30, 1935, of cerebral hemorrhage and cerebral arteriosclerosis, aged, 82 years

Dr McCaskey was born at Delta, Ohio, graduated from the Jefferson Medical College of Philadelphia in 1877 and began practice in Fort Wayne, Ind., in 1882. He became an outstanding diagnostician and was nationally known as an authority on diseases of the stomach. For a number of years he served as professor of the theory and practice of medicine in the old Fort Wayne Medical College. He was professor emeritus of medicine at the Indiana University School of Medicine in Indianapolis.

Dr McCaskey was a member and past president of the Indiana State Medical Association, a member and past president of the northern Tri-State Medical Association, a member of the American Medical Association, the American Gastro-Enterological Association and had been a Fellow of the American College of Physicians since June 5, 1917. He was the author of more than one hundred publications.

DR STEPHEN R PIETROWICZ

Stephen R. Pietrowicz, a Fellow of the College since 1920, died January 12, 1936. Dr. Pietrowicz was born in Posen, Poland, August 23, 1873. He attended St. Mary Magdalene Gymnazium, Posen, Poland. In his young manhood he came to America where he continued his education at St. Stanislaus College, Chicago, and at the College of Physicians and Surgeons of Chicago, School of Medicine, University of Illinois, from which he received his medical degree in 1898.

Since that time he was engaged in practice in Chicago, for many years devoting special attention to internal medicine. He was attending physician at St. Mary's of Nazareth Hospital in Chicago from 1900 to 1908, physician-in-chief of the same hospital from 1908 to 1925, and president of the staff and senior attending physician from 1925 to the time of his death.

He served as attending physician at Cook County Hospital from 1911 to 1913. He was superintendent of the Chicago State Hospital in 1912. From 1911 to 1917 he was senior professor of medicine at the Chicago College of Medicine and Surgery. From 1918 to 1920 associate in medicine, University of Illinois. Thereafter, until the time of his death he was clinical professor of medicine, Loyola University School of Medicine.

He was a member of the school board of Chicago at one time. He held membership in the Society of Internal Medicine of Chicago, the Institute of Medicine, Chicago, the Chicago Medical Society, Illinois Medical Society, American Medical Association, Chicago Pathological Society, Polish Medical Society, Chicago Tuberculosis Institute.

Through many years Dr Pietrowicz carried on a very busy and extensive practice. He gave much of his time to his work in the hospital and medical school. His interest in St. Mary's of Nazareth Hospital was especially great and he rendered a service which will long be remembered. Deeply interested in his life work, he gave himself without stint to those who came under his care.

JAMES G. CARR, M.D., F.A.C.P.
Governor for Northern Illinois

DR. CHARLES CRAWFORD HINTON

Dr. Charles Crawford Hinton (Fellow), Macon, Georgia, died suddenly of coronary artery disease on February 25, 1936, aged 47.

Dr. Hinton was born at Milledgeville, Georgia, October 1, 1888. He attended the public schools of Bibb County and entered Emory University, now at Atlanta but then at Oxford, Georgia, graduating with the degree of B.Ph. in 1909. He thereafter entered the medical department of Johns Hopkins University School of Medicine, graduating in 1913. His internship was spent in a Baltimore hospital, whereupon he became Assistant in Medicine and Chief of the Out-Patient Department Clinics of Emory University. In 1916 he became Associate in Medicine at Emory University, remaining until 1917. From 1919 until the time of his death, he was Laboratory Consultant to the U. S. Veterans Administration at Macon, and from 1920 until the time of his death, he was Internist to the Middle Georgia Sanatorium. He was a former president of the Macon Medical Society of Bibb County, a member of the Southern Medical Association, the American Medical Association and the Clinical Society of Middle Georgia Sanatorium. He had been a Fellow of the American College of Physicians since 1929.

ANNALS OF INTERNAL MEDICINE

VOLUME 9

APRIL, 1936

NUMBER 10

THE CHANGING ORDER IN MEDICINE ~

By JAMES ALEXANDER MILLER, A M , M D , F A C P , *New York, N Y*

I WOULD be very neglectful of my opportunity and very untrue to my deep feelings if I failed upon this occasion to record my great appreciation of the progress the American College of Physicians has made and is making in the rôle of leadership in the field of internal medicine, and also my very deep and heartfelt appreciation of the privilege and honor which has been conferred upon me in my selection to preside over the activities of the College during the past year

College Matters This year has been fruitful in accomplishments The affairs of the College have continued to prosper, and this is due in no small measure to the faithful devotion of the Board of Regents and Governors and particularly to the extraordinary faithfulness and ability of our executive staff under the leadership of Mr Loveland

Our main function, that of postgraduate education, was notably furthered at our Philadelphia meeting, and this meeting which we are holding in Detroit is also a notable landmark in our progress We have met here under a cloud of sorrow caused by the sudden death of our beloved associate Dr Charles G Jennings who, before his untimely end, had already organized the clinical program which we have been enjoying, and whose devotion to the highest ideals of the College has been notable during many years of service upon our Board of Regents His loss is irreparable but the memory of his life will always remain an inspiration to all of us who have been associated with him

In connection with our educational activities we are all increasingly aware of the important part which our journal, the Annals of Internal Medicine, continues to play in this field The Annals has continued to grow both from the standpoint of the high character of the scientific contributions to medical literature which it presents and also in the support from subscribers and advertisers which is founded upon a growing appreciation of its value We owe this in no small part to the able and skillful leadership of its editor

* Presidential Address, delivered at the Convocation Exercises of the American College of Physicians, Twentieth Annual Session, Detroit, March 4, 1936

The general financial condition of the College is extremely satisfactory and has been ably directed by our Finance Committee and our treasurer

There are two developments in the affairs of the College which have occurred during the past year, to which it seems timely to call special attention. The first of these is the serious consideration upon the part of our Officers and Regents of the desirability and possibility of acquiring a permanent home for our College. There are many reasons why this seems desirable, and if feasible it will add dignity and assurance of permanency to our organization. That this plan can be even considered is due fundamentally to the soundness of our financial position, and it is not unlikely that in the near future the ownership of our own home may be an assured fact.

The second notable development is the direct outcome of a policy strongly urged by my predecessor in the office of President of the College, Dr. Jonathan C. Meakins. I refer to the leading part which we have taken in the formation of a National Board for the qualification of internists.

A number of the Board of Regents, under the leadership of Dr. Meakins, for several years have been impressed with the need of better standardization for qualifications leading to the designation of experts in the field of internal medicine, and have felt that our College should take the initiative in meeting the problems raised by this need. Consequently, by vote of the Board of Regents and with the approval of the proper authorities of the American Medical Association, a joint Board of Medical Examiners has been organized for this purpose, under the combined auspices of our College and the Section on Medicine of the American Medical Association. This Board is expected to function effectively in the near future, and by establishing suitable criteria for the qualifications necessary for the designation of specialists in the field of internal medicine will do much to raise the standards of our practice, to develop a more adequate recognition of the special field of medicine, and incidentally will, we believe, do much to improve the standards of qualification for membership in the College of Physicians. We are all very much indebted to the very efficient and arduous labors of the special joint Committee which has been struggling with the many ramifications of this plan during the past year under the chairmanship of Dr. Walter L. Bierring.

More General Problems. While of course we have met here on this occasion under the auspices of and directly in the interest of the American College of Physicians, I am not unmindful of the fact that we of the College are merely one representative part of that larger and more important group, namely, the physicians of America. Consequently, I propose upon this occasion to address you upon some of the problems in modern medicine which seem to me to be of importance to the medical profession as a whole, and in the solution of which we of the College ought to play an active rôle.

It is, of course, obvious to all of us that we are living in a period of change, difficult but extremely interesting and affecting all the relationships of our social order, including that of the practice of medicine.

In the midst of the troubled and even anxious thoughts which the unrest about us may create there is some comfort in the recollection that this is not the first period in history in which civilization as a whole and medicine in particular have gone through similar experiences of change, sometimes approaching revolution but always leading eventually to progress. The period in the world's history when civilization as a whole and medicine as a part of that civilization remained stagnant, nearly dead, was that long thousand years known as the Middle Ages. There was no thought of change during that period, no stimulus of new or revolutionary thought, and in medicine the dogmatic dictums of Galen reigned supreme and unchallenged, and medical thought was like a flickering candle barely kept alight in the recesses of the monasteries. The sixteenth century and the Renaissance brought changes, rapid and frequently revolutionary, in all fields of social endeavor, and medicine shared in this reawakening, largely under the influence of more exact knowledge founded on the study of pathological material through autopsy. But in the light of our modern knowledge even this progress was very halting and imperfect. It was not until the early part of the nineteenth century, following the French Revolution and the Napoleonic era, that very great and important contributions to the knowledge of disease were made under the influence of such leaders as Bayle, Laennec and Louis in France, and in the field of pathology particularly by Virchow in Germany. But the really revolutionary period came in the latter part of that century, with the development of our knowledge of the role of bacterial infection in many diseases, with the names of Pasteur and Koch standing out preeminently as leaders in this new field. It is since those days of 1870 to 1880 that the greater part of the fabric of modern medicine has been created, founded upon the increasing knowledge gathered by unceasing laboratory and clinical research, in such astonishing fashion as to be really bewildering albeit inspiring to those of us who have been privileged to live during this epoch.

But our intense interest in all of these developments has required a devotion of time and concentration of effort, which has quite naturally tended to make our profession individualistic in its approach toward medical problems and often oblivious to other important elements in our social fabric because of the very fascination as well as absorbing interest of the new knowledge which has so rapidly and constantly been developed in our own chosen field.

It is not to be wondered at, therefore, that in our habits of mind as well as in our practice we have tended to become individualists.

But during these latter years the practical application of our growing medical knowledge has become increasingly evident to the world at large, and the same principles which guide us in the treatment of our individual patients are recognized to have great significance to the community as a whole. So that one of the most important changes that have occurred is the realization that society as a whole is interested in these problems quite

as much as is the physician, and that the practical solution of them is perhaps even more the concern of the community than of the physician himself. No longer, therefore, is the physician a man apart, a sort of high-priest of mystery giving out his solemn pronouncements dogmatically, unconcerned with explanation of the reasons why, but rather an enlightened and interested public expects and demands a reasonable understanding of what is going on, and also an extension of our activities far beyond the intimate personal relationships between the individual patient and his physician, to those broader fields which we designate as preventive and social medicine.

Thus, the physician, whether he will or no, has been brought out of his cloistered existence into the field of active participation in community movements of great significance, in which he must play a part as leader, educator and guide or else stand adjudged unworthy at the bar of an exacting public opinion.

This changed relationship has brought us face to face with many problems which previous generations have not considered medical at all but which are pressing upon us for solution. It is of some of these that I will briefly speak to you on this occasion.

Changes Due to the Increase of Medical Knowledge Before, however, we consider these outside relationships it is apparent that many changes in medical practice are due to the rapid development of our knowledge in many directions. Some of these may be briefly summarized.

One of these, of great significance, has been emphasized in Professor Cannon's address to us this evening, that is, the development of the physiological approach to many problems, as distinct from the strictly pathological approach which has been the main basis of medical science up to recent years. It appears to be evident that a closer study and appreciation of functional disturbances during life are to take a much larger share in our medical thinking in many fields. This field of study is difficult, and in it we have only made a beginning, but it offers opportunities for further progress which may have great importance and significance.

Then, we note the great progress in our knowledge of chemistry as applied to biology and to medicine. Processes which we have been accustomed to consider as morphological, now appear to have their ultimate basis in microscopic chemistry. Not only in the diseases of metabolism but also in the infectious diseases, where the chemical constituents of pathogenic bacteria together with the character of the tissue reactions which they cause are now being studied, chemistry is becoming increasingly important.

Of course, in the field of the hormones and the vitamins we have seen a rapid development of our knowledge, due to chemical research.

In general, our conceptions of the physical structure of living matter, the chemical changes which accompany vital activities, and our increasing knowledge of chemical substances which may control such activities, are the result of modern research. These researches have also led to a marked advance in the development of pharmaceutical preparations and to definite improvement of numerous therapeutic agents placed at our disposal.

Then we have the fascinating new field of knowledge opened up by the discovery that ultramicroscopic viruses are the causes of some of the important infectious diseases the etiology of which has heretofore baffled us during the bacteriological era. These researches open up new fields of knowledge and give promise of better control and treatment of these diseases.

One of our great problems is to keep abreast of all this new knowledge, so that we and our patients may receive the maximum benefit from it. We must continue to be students as well as practitioners, and there is always real danger that our practice may lag behind the advance of medical knowledge.

Changes Due to the Application of the New Knowledge It is here that we move out from our narrower, strictly professional sphere into our contacts with the community.

Specialism One of the first of these changes has been due to the very amount of new knowledge which has made it impracticable, even impossible, for any one mind to grasp all of the ramifications of this new knowledge and to make the best use of it.

It is this fact, I think, rather than any economic motives, that has led to the development of specialism in medicine.

No one who has grown up in the medical profession can fail to have the highest respect and the deepest affection for those representatives of our profession who have carried on against the greatest difficulties with courage and devotion and who have been not only the physician but also the wise counselor and friend of the families entrusted to their care. All honor always to the general practitioner!

It is obvious, however, to them as well as to the rest of us, that if the highest attainment of skill and knowledge is to be at the disposal of the community, many of us must devote our special attention to certain specific lines of study and of practice. In losing some of the personal touch of the family physician there has nevertheless been great gain in the development of better diagnosis and treatment. How to hold the advantages of each of these groups and to have them go on together to their mutual advantages and particularly to the advantage of our patients, is one of our modern problems.

I feel that we are taking an important step forward toward the solution of this problem in the plans which have been formulated for the application of standards by which specialists in internal medicine may be recognized, and it is particularly to be noted that in this plan special emphasis is placed upon the essential importance of an adequate preliminary training in general medicine as the foundation of any specialty.

The defects in the practice of the specialties would appear to revolve mainly around the temptations to their abuse through false or misleading claims of special proficiency, through the multiplication of unessential and costly procedures or through inequitable professional charges, in a word they are due to the commercialization of the public demand for expert serv-

as much as is the physician, and that the practical solution of them is perhaps even more the concern of the community than of the physician himself. No longer, therefore, is the physician a man apart, a sort of high-priest of mystery giving out his solemn pronouncements dogmatically, unconcerned with explanation of the reasons why, but rather an enlightened and interested public expects and demands a reasonable understanding of what is going on, and also an extension of our activities far beyond the intimate personal relationships between the individual patient and his physician, to those broader fields which we designate as preventive and social medicine.

Thus, the physician, whether he will or no, has been brought out of his cloistered existence into the field of active participation in community movements of great significance, in which he must play a part as leader, educator and guide or else stand adjudged unworthy at the bar of an exacting public opinion.

This changed relationship has brought us face to face with many problems which previous generations have not considered medical at all but which are pressing upon us for solution. It is of some of these that I will briefly speak to you on this occasion.

Changes Due to the Increase of Medical Knowledge Before, however, we consider these outside relationships it is apparent that many changes in medical practice are due to the rapid development of our knowledge in many directions. Some of these may be briefly summarized.

One of these, of great significance, has been emphasized in Professor Cannon's address to us this evening, that is, the development of the physiological approach to many problems, as distinct from the strictly pathological approach which has been the main basis of medical science up to recent years. It appears to be evident that a closer study and appreciation of functional disturbances during life are to take a much larger share in our medical thinking in many fields. This field of study is difficult, and in it we have only made a beginning, but it offers opportunities for further progress which may have great importance and significance.

Then, we note the great progress in our knowledge of chemistry as applied to biology and to medicine. Processes which we have been accustomed to consider as morphological, now appear to have their ultimate basis in microscopic chemistry. Not only in the diseases of metabolism but also in the infectious diseases, where the chemical constituents of pathogenic bacteria together with the character of the tissue reactions which they cause are now being studied, chemistry is becoming increasingly important.

Of course, in the field of the hormones and the vitamins we have seen a rapid development of our knowledge, due to chemical research.

In general, our conceptions of the physical structure of living matter, the chemical changes which accompany vital activities, and our increasing knowledge of chemical substances which may control such activities, are the result of modern research. These researches have also led to a marked advance in the development of pharmaceutical preparations and to definite improvement of numerous therapeutic agents placed at our disposal.

Then we have the fascinating new field of knowledge opened up by the discovery that ultramicroscopic viruses are the causes of some of the important infectious diseases the etiology of which has heretofore baffled us during the bacteriological era. These researches open up new fields of knowledge and give promise of better control and treatment of these diseases.

One of our great problems is to keep abreast of all this new knowledge, so that we and our patients may receive the maximum benefit from it. We must continue to be students as well as practitioners, and there is always real danger that our practice may lag behind the advance of medical knowledge.

Changes Due to the Application of the New Knowledge It is here that we move out from our narrower, strictly professional sphere into our contacts with the community.

Specialism One of the first of these changes has been due to the very amount of new knowledge which has made it impracticable, even impossible, for any one mind to grasp all of the ramifications of this new knowledge and to make the best use of it.

It is this fact, I think, rather than any economic motives, that has led to the development of specialism in medicine.

No one who has grown up in the medical profession can fail to have the highest respect and the deepest affection for those representatives of our profession who have carried on against the greatest difficulties with courage and devotion and who have been not only the physician but also the wise counselor and friend of the families entrusted to their care. All honor always to the general practitioner!

It is obvious, however, to them as well as to the rest of us, that if the highest attainment of skill and knowledge is to be at the disposal of the community, many of us must devote our special attention to certain specific lines of study and of practice. In losing some of the personal touch of the family physician there has nevertheless been great gain in the development of better diagnosis and treatment. How to hold the advantages of each of these groups and to have them go on together to their mutual advantages and particularly to the advantage of our patients, is one of our modern problems.

I feel that we are taking an important step forward toward the solution of this problem in the plans which have been formulated for the application of standards by which specialists in internal medicine may be recognized, and it is particularly to be noted that in this plan special emphasis is placed upon the essential importance of an adequate preliminary training in general medicine, as the foundation of any specialty.

The defects in the practice of the specialties would appear to revolve mainly around the temptations to their abuse through false or misleading claims of special proficiency, through the multiplication of unessential and costly procedures, or through inequitable professional charges, in a word they are due to the commercialization of the public demand for expert serv-

ice Surely, we as a profession should be able to control and to remedy these evils

Preventive Medicine Perhaps the greatest change which our new knowledge has brought to us is the widening of our sphere of responsibility from the care of the individual patient to that of the community of which this patient is a part This is particularly true, of course, in the field of infectious diseases where the protection of others is quite as important as the cure of the individual patient There are, however, applications of this principle other than that of preventing the spread of infection

Thus we have the developing field of responsibility for large groups of individuals who are not apparently ill Great progress has been made in the survey of such groups through the operation of medical services for industry, for life insurance and for schools, and also through the movement to educate individuals to the importance and advantage of periodic health examinations at the hands of their own physicians

The results of such surveys have already uncovered a large number of unsuspected cases of disease in incipient and remedial stages But this progress has largely been due to the operation of organized groups associated either with governmental or with industrial agencies The individual practising physician has taken too little share in this movement, due largely to faulty training which centers our interest upon obvious disease and has failed to develop a technic and interest in the recognition of slight deviations from the normal which have not yet led to symptoms or complaints on the part of the patient Not only has the bulk of the population not been educated to the point where the average man would consult a physician for a regular check-up once or twice a year, just as he would his dentist, but also the few who do often have their enthusiasm dampened by the lack of interested response on the part of the physicians whom they may consult This whole field demands a different outlook both in our medical education and in our medical practice

Then we have the whole field of prophylactic and preventive inoculations, best exemplified by their use in smallpox and diphtheria but also applicable to other diseases There is also the large field of remedial physical defects found especially in childhood, such as defective teeth, tonsils, adenoids, eyesight, faulty nutrition and the like These conditions in themselves do not constitute disease but are the underlying and predisposing causes of many diseases

We have left this field of service very largely to our public-health and school authorities, excepting in so far as the pediatricians take part in it As a group the pediatricians may be fairly characterized as the best exponents in our profession today of the highest type of general practice combined with an appreciation of the responsibility for preventive medicine But we should not leave this field entirely to our public-health authorities and to our pediatricians

Very recently a new potential force of great significance has been added

to the public-health movement. I refer to the provisions of the Federal Economic Security Act which will make available nearly twenty million dollars a year to be expended through the Public Health Service and the Children's Bureau.

Serious problems are here involved. In what directions are these funds to be expended, how will their administration be affected by political considerations, what properly trained personnel is available, and how will these new activities be related to those of the medical profession?

These great appropriations signify enormous possibilities for improving the health of the nation, but they also constitute a new opportunity and a challenge to the medical profession.

In the first place, in these days of professional insecurity an attractive field of service is opened up to many physicians. I must confess that were I at the present time in the stage of my medical career which I was passing through when five or ten years out of the hospital, this prospect for public-health service would have a great appeal to me. I hope that there will be many of our younger best trained physicians who may become enlisted in this public-health service.

In the second place, however, we must realize that this new development will greatly strengthen the organization of our health authorities and might easily lead to an increase of the amount of public or state medicine. Dr. Thomas Parran, Jr., the Commissioner of Health of the State of New York who undoubtedly will have a considerable influence in the formation of these new policies, hopes that it will "liberalize present medical practice, coordinating it with public-health and medical services." He would propose "to assist the private physician by providing for him laboratory, hospital, nursing and other facilities for the treatment of his cases, and at the same time relieve part of the load of catastrophic illness from the low-income group."

In this or some similar manner we as physicians must cooperate in this movement or face the possibility of the slow advance of State medicine.

What a wonderful power we, as a body, could exert in this field if we each individually constituted ourselves health officers for the families under our care, detecting and correcting defects, following up sources of infection in syphilis, in diphtheria and other infectious diseases, checking the contacts in our cases of tuberculosis, and in general in every way cooperating closely with our health officials in their efforts to prevent disease! This is the challenge of preventive medicine to us. We must either take our proper place in this field or we will surely be pushed aside.

Mental and Emotional Problems. There is another field perhaps even less well understood and possibly more important than those we have been considering. I refer to those influences of our modern life which affect the behavior and the mental, nervous and ethical reactions of individuals.

There can be no doubt that the tremendous incidence of various forms of insanity, of mental deficiency as well as of functional nervous disorders

is susceptible of decrease by preventive measures, and for the prevention of these conditions the medical profession must take considerable responsibility.

The role of syphilis in the causation of many forms of mental and nervous disease is known. But even here we are doing comparatively little to apply well established principles of treatment. When we come to other disorders of which the causes are less definite, as for example, faulty inheritance, faults of early childhood environment or education, or the pressure of modern social, business and industrial life how little are we, as advisers, doing to influence either the environment in which we all live or the individual habits of the patients under our care!

Perhaps the lack of intimate personal contact which we have lost in the passing of the family physician is a factor in the situation. But whatever may be the explanation, is it not true that we, as physicians, under the influence of our passion for modern and exact science have lost sight of those more intangible and less demonstrable factors which we call the nervous and the psychic? Not only in the prevention of actual nervous or mental disorders is this factor important but also in the treatment of our patients suffering from any disease, particularly the chronic disorders. A better recognition of the importance of their mental processes would appear to be demanded which would bring us back to a fundamental appreciation of our patients as individuals rather than as cases of disease, and to an understanding of their personalities and the influences under which those personalities have developed and are manifested. Is it not at least partly true that the extraordinary development of cults of faith and mental healing in this country, estimated to affect approximately ten millions of our people directly or indirectly, may be attributed to a lack of interest in and appreciation of these factors by the practising medical profession? Personally I have a very strong feeling that as a whole we of the profession are constantly losing magnificent opportunities not only to help our patients get well but also to control and develop their characters and personalities as evidenced by their nervous and emotional as well as their intellectual responses. In other words, have we not been affected too much by materialistic and scientific progress and failed too often to appreciate the importance of the individual as a whole, which would include all of these psychic, emotional and ethical values in his life as well as the physical?

Biological Aspects Our consideration of certain aspects of preventive medicine has emphasized particularly the prevention of disease and the saving of human life. As far as the general population is concerned this means that we have been attempting to diminish subtractions only. But what about the additions? I refer to the control of increase of population. Have we physicians any responsibility for this?

This is perhaps a somewhat new slant on community responsibility to most of us. The problem, however, is with us. In certain centers the pressure of overcrowding and overpopulation is acute, and in times of economic depression the effect not only upon comfort and happiness but

also upon health and life itself is very real. Students of biology are becoming very much interested in this problem. It is, of course, a part of the general field of eugenics which is concerned not only with the quantity but also with the quality of the population.

At the present time, where this problem concretely confronts the physician is in the question of limitation of births, as involved in contraception and in the interruption of pregnancy. It is not my purpose to deal exhaustively with this highly disputatious subject. But I simply wish to lay before each of you some thoughts for your individual consideration.

Many of us certainly cannot accept the doctrine which sacrifices the threatened life of the mother for the potential existence of the infant. But I wish to raise in your minds the searching individual question whether our modern tendency to exercise our opportunities for advice concerning contraception and the interruption of pregnancy has not been gradually and increasingly influenced by personal and economic considerations, whether, in other words, we are not becoming gradually calloused to a lack of appreciation of the value of human life as such, and whether, particularly in our large cities under the pressure of economic conditions, we are not imperceptibly laying ourselves open to the criticism from certain religious quarters that we are unjustifiably and unethically interfering with natural processes?

I further wish to raise the question in your minds as to whether our approval of contraception in general has not imperceptibly led to a change in our attitude toward the ethics of the other problem, that of early abortion, and as to whether this, if true, is not having its influence upon our conception of the sanctity of human life in itself and consequently upon our attitude toward family life in general as the basis of our society? In other words, are not some of our critics at least somewhat in the right in suggesting that tendencies in this direction might lead us ultimately in the direction already followed in Soviet Russia?

Another aspect of this same problem is raised by the recent discussion concerning the ethics of euthanasia. I think that there is little doubt that we are all pretty much in agreement on this subject, but I again raise the question as to whether the support of euthanasia in some quarters and the interest which the public discussion of it has aroused are not again indications that there is an imperceptibly changing point of view toward the sanctity of human life?

Social and Economic Problems of Organized Medicine Perhaps the greatest recent changes of all in our medical relations have been those which involve the social and economic order. According to the recent trend these relationships also involve important political ramifications, so that we find ourselves as a profession brought face to face with many problems which have not particularly concerned our forefathers in medicine. Important questions of serious moment have been raised, and we cannot escape some consideration of them, much as we might prefer to devote our time and energies to more strictly medical problems.

The recent widespread interest in these problems was probably crystallized about the reports of the Committee on the Costs of Medical Care. After several years of very extensive study this Committee brought out reports which, while they contained many data of interest and value, led to a division of interpretation among the members of the Committee itself and have precipitated a widespread and sometimes acrimonious discussion among the medical profession and the community at large.

I think that any fair-minded person who has studied these reports will appreciate that they reveal conditions heretofore incompletely recognized and understood, which demand serious consideration and, if possible, remedy. The most important of these perhaps are those which relate to the unequal distribution of the burden of sickness, the unequal and often inadequate compensation to physicians, the unequal and inadequate provision of medical services in many communities, and the disproportionate cost of notoriously ineffective instruments of treatment such as proprietary and patent medicines as compared with the cost of adequate medical and hospital service.

All of us who practice medicine are well aware that long illness is a great burden, often a crushing one, upon our patients, and we have long been accustomed to adjust our own services and their cost to existing circumstances. All fair laymen recognize the fact that, as a profession, our aim and ideal has been the provision of services rather than insistence upon adequate financial compensation. That there are exceptions to this rule also, we of course all well know. But in our hearts we are assured that we cannot in fairness allow the motives of our profession as a whole to be impeached.

The consciousness of this fact should not lead us, however, to contend that because in general we know that our motives have been generous and fair, consequently all is well and no changes are desirable or necessary. It is very probably true that with the improvement in general social conditions in the United States there has also been an accompanying improvement in the character of medical service, and very likely, as has been claimed, no country in the world enjoys better medical service than ours.

But this is far from sufficient. The very progress that we have made is an incentive and challenge to further improvement, and it would appear from recent studies and analyses of the situation as it affects medical practice in this country that the need for such improvement does exist, and we are all individually conscious of that fact. Consequently it would appear to be a great mistake for us as a profession, either individually or as an organized body, to resist as unnecessary and unfair the demands for a study of this situation and for the application of appropriate remedies when and if they are found necessary. It is very gratifying to know that the recent trend in organized medicine is away from a general denial of such need and is turning toward a more rational study of the situation and a willingness to cooperate in making reasonable changes.

Quite properly however, we as a profession insist that the problems of medical care are better understood by the medical profession than by other groups. Without in any way denying that the community as a whole, the members of which, when sick, constitute the patients under our care, is directly and primarily interested in these problems, nevertheless we feel that by our experience and training we are the ones best qualified to understand the various ramifications of this problem and to take the leadership in applying effective remedies. This can only be done, however, if, as individuals and as a body, we approach this problem with the same open mind and scientific spirit with which we would approach a more strictly medical problem.

Already considerable progress is being made in this direction. In the past few years a very large number of experimental activities looking toward a more equitable distribution of the cost of illness and remuneration of physicians have been instituted under medical auspices. The results of these experiments are varied and as yet inconclusive, but it is evident that progress is being made. It appears that quite independently of the financial and economic factors involved, our chief concern as physicians should be that high standards of professional service be maintained and that any proposed change should improve rather than impair these standards.

The immediate burning question, about which considerable discussion and debate have already occurred, is that of health insurance. This method of meeting the problem has been generally adopted in the countries of Europe. Studies of the operation of these systems have led to conflicting reports as to their results. But from the discussion, I think, has come a realization that there are many defects in existing health insurance systems and that, taken all in all, with the conditions as they exist in the United States the adoption of compulsory health insurance, as organized in England and Germany or even in Denmark where it has been most successful, would be an unwise experiment for this country. It is, therefore, I think, a matter on which we are to be congratulated that plans to include health insurance in the National Economic Security Bill were laid aside by the present Federal Administration. This result was due very largely to the arguments raised by members of our profession, and in so far as this change in the proposed plan was due to medical opposition, it places upon the organized profession an increased obligation to make every effort to solve the problems involved by other means which may give the good results sought by compulsory health insurance, without incurring the objections and dangers which it entails.

It is estimated that there are at least sixty types of experiments now going on in various communities of this country along these lines at the present time. Some of them are already obvious failures, others are apparently fairly successful. All of them appear to have some defects. Under a broad-minded leadership our profession should be in a position to analyze

and assess the value of these experiments. Such a study will take time and money as well as special ability. In view of the great service it might be to the cause of public health and general welfare in which the Foundations are interested I very much hope that they may join with organized medicine in a cooperative analysis of these important experiments. Such enlistment in a common cause might also serve to bring closer contact between the great health Foundations and the organized medical profession. In recent years there has been an unfortunate tendency for them to be arraigned in opposite camps. Now, it so happens that I know the leaders of these social groups very well. They are a fine lot, quite as fine in their way as we are in ours, and, I may add, they also have similar failings as well as similar virtues, in other words they, too, are human.

The interests of these Foundations and of the medical profession are in the long run the same, and they can only be best served if the representatives of each work shoulder to shoulder to solve these important problems, without any self-seeking motives and particularly without bitterness and jealousy. Evidence that this most desirable state of affairs is gradually coming about is now appearing, and I feel more confident than at any other time during the past few years that wise and equitable solution of this problem will eventually be evolved.

Medical Personnel One phase of the problem, for which the medical profession is largely if not exclusively responsible, is the question of the amount and caliber of medical service which is available. As to quantity, this goes back to the number of physicians, and in these days when the path of least resistance leads the youth of our country to further study rather than an attempt to get a job, our medical schools are flooded with applications, the number of graduates in medicine has increased and the saturation point of numbers has already been reached in many of our communities.

Judging by the low average rate of income of physicians and the struggle of the younger members of the profession in our large cities, one suspects that either there are too many physicians or else that their distribution is faulty. That the latter is true in many communities of our country has been demonstrated. It would therefore appear to be our first responsibility to take the lead in supplying better distribution of service where needed, and then, on the other hand, to bring pressure to bear upon our medical schools to restrict the number of graduates to the need, while at the same time improving their quality, by which we mean higher standards of ethics and ideals quite as much as improved intellectual proficiency and professional training.

The representatives of our best medical schools are well aware of these problems and are giving serious thought to the responsibilities which devolve upon them. It is not too much to hope that they will be able to meet this phase of the situation adequately.

Hospital and Dispensary Abuse Another burning question in our large

cities is what has been termed hospital and dispensary abuse, by which we mean that these institutions which owe their efficiency mainly to our voluntary and unremunerated medical service, are patronized by many who economically are in a position to pay for private medical service, thus putting the physicians in a position of serving in the hospitals and dispensaries against their own economic interests

Quite properly the representatives of organized medicine are insisting that safeguards against this abuse be thrown about the hospitals and dispensaries, and progress is being made in this direction. They are, however, making other recommendations of more dubious propriety, in my opinion. I refer particularly to the suggestion that all physicians in hospitals and dispensaries should be paid for the medical services rendered. If this were done, we would in the first place put an overwhelming increased financial load upon the administrative expense of these institutions. In the second place we would be demanding as physicians compensation for services which it has always been our pride and boast that we have given freely. A great deal of the criticism of the medical profession of recent years has been counteracted by the appreciation of the high-minded, generous contribution of service to the sick poor which we have always made. It would appear to be a great pity to take away this privilege as well as strategic advantage from our profession. Moreover, all of us in this body appreciate the fact that our postgraduate education depends upon our hospital practice and that we are only too happy to do this work because of the opportunities for improving our medical competency and the joy that we have in the acquisition of new knowledge.

Another phase of the subject which we cannot afford to overlook is that the placing of all of the staff of our State and municipal hospitals upon a salary would tend to make these positions more political and create a real danger that in this very plan so strongly recommended in some medical quarters we would be taking the first step toward that anathema of organized medicine, namely, State medicine.

That there exist, however, many instances in which hospital or dispensary practice infringes on the rights and privileges of individual physicians, there appears to be little doubt. Changes in the existing order may be desirable, but we, as physicians, are interested both in the institutions and in the individuals, and we should make sure that any such changes are mutually fair and beneficial to both parties.

Socialized or State Medicine This leads us finally to the consideration of socialized or State medicine as a present-day problem in medical economics.

In the first place, I think, we must recognize the fact that we already have a considerable amount of State medicine in this country, with the apparent approval of the medical profession. We see it in the State care of the insane, of the mentally defective and of the tuberculous, we see it in the Army and Navy medical service, we see it in many of the activities in the

field of preventive medicine under the control of the public departments of health, and I have already discussed the possibility of its extension under the Social Security Act

During the depression we have also seen a very insidious extension of State supervision of medical service in the administration of medical care for those on home relief. In some communities this is very wisely and properly administered with the cooperation of organized medicine through the county societies. But medical safeguards are often objectionable to administrative authorities, and there are not a few who are in favor of paying straight salaries for physicians engaged by the State for this medical service. Properly organized, controlled and supervised, this very need for home medical relief which our present economic distress has brought out can be utilized for the improvement of medical service from both the curative and the preventive aspects. In some communities this is being done, high standards of medical practice have been set up and insisted upon to the mutual advantage of the sick poor and of the physician. Where medical control of this service, however, is replaced by purely administrative or political control, the danger is great that medical standards will be lowered and the opportunities for progress not only lost, but actual deterioration of the present standards of service may result. This is of course exactly what we fear in what is called State medicine, and the fears are well-grounded.

Not only have we seen tendencies leading toward a mechanical and superficial character of medical service in medical home relief under State auspices but also in the operation of the workmen's compensation laws in many States we have had a very instructive illustration of the demoralization of standards which is always likely under a system of medical service under political control. Some of these workmen's compensation evils are being corrected in some communities, but only when active and wide-awake members of the medical profession have been alive to the situation and have taken an active part in remedying the abuses and eliminating faulty methods.

Not the least important responsibility of the medical profession in this field of economics is the insistence upon high ethical standards as distinct from merely high standards of medical proficiency. We are all of us aware of the insidious infiltration of our standards of professional probity which has been brought out under the stress of the economic depression. There has recently been published a sordid story of the practice of medicine at its worst. The author of this book evidently speaks from first-hand knowledge, and the allegations made are sufficiently plausible to bear the stamp of actual experience leading us through many sordid details into the haven of socialized State medicine as the remedy. This would appear to be an extraordinary deduction, but at the same time this line of argument probably represents the opinion of a considerable number of people both within and without our profession, and consequently cannot be entirely disregarded.

In the first place it is obvious that the experience of this physician was

very unfortunate and represents a very small fraction of the profession. We would like to know a little more of the professional company which the author kept before he became a convert to the doctrine of State medicine, and would particularly like to know whether there are no ways and means available of correcting these abuses by bringing those guilty of them out into the open on charges of unprofessional conduct. I am convinced that if we could simply expose these instances of unethical conduct they would quickly defeat themselves, but we as a profession have been perhaps too complacent in regard to them and too negligent of active efforts to eradicate them. On the other hand, if the undesirable elements of our profession are not eliminated, a system of State medicine would be apt to find these very individuals in control of such a system and much more powerful and dangerous than they are at present. We need to clean house of these elements and at the same time to control the situation at the source, namely, in a more rigid selection of those admitted to our medical schools and to medical practice.

CONCLUSIONS

I feel that we have wandered considerably afield in our discussion of the changing order in medicine.

The main thought which I have wished to emphasize is that there exists a pressing necessity for the medical profession to adapt itself to modern changing conditions.

We ourselves are mainly responsible for putting our house in order, and if it is in order we need have no fear that it will be sold over our heads either to irregular cults, to socialism, to the State, or to anyone else.

Our chief objective must always be to develop the art and science of medicine. But without sacrificing this main objective we must widen our interests to include those of the community as a whole. As we move out of our cloistered life of concentrated interest in our own special and fascinating job into the larger field of more general human interests we have the opportunity for a greater service which will be less individualistic and more social-minded. Thus will our horizon be immeasurably widened and we ourselves may at the same time become better physicians and better citizens.

God forbid that we should wrap ourselves about in the cloak of self-satisfaction, content with our own immediate objectives and past achievements, or that, on the other hand, we should assume an attitude of aggressive trade unionism, intolerant of criticism, resistant to change and insistent upon our own special privileges and interests to the exclusion of those of others!

As individuals and as a profession we need to take thought of these matters and then move on to meet the challenge in a manner worthy of the fundamental principles and the high ideals upon which our profession is founded.

Without presuming to present any specific program of action the prin-

ciples upon which such action should be based might be formulated as follows

1 A strict adherence to Truth both as we now know it and as it may be developed in the future by continued persistent research into the as yet hidden secrets of Nature

2 An absolute ethical Honesty Honesty in our thinking as well as in our professional conduct

3 A devotion to the spirit of Service Service not merely to those individuals entrusted to our care but to the whole community

May we ever be able truthfully to claim for our profession that our inspiration is the opportunity for service, not the hope of reward!

LYMPHOPOIESIS, LYMPHATIC HYPERPLASIA, AND LYMPEMIA FUNDAMENTAL OBSERVATIONS CONCERNING THE PATHOLOGIC PHYSIOLOGY AND INTERRELATIONSHIPS OF LYMPHATIC LEUKEMIA, LEUKOSARCOMA AND LYMPHOSARCOMA^{*}

Discussion
Conclusions

It is doubtful whether there is any group of diseases about which there is more controversy over the clinical classification pathogenesis and morbid physiology, than those which primarily involve the lymphatic tissues. As contrasted with those dyscrasias which have their origin in the sister blood forming tissue, the bone marrow, the greater difficulty in the interpretation of morbid processes in the lymphadenopathies is quite manifest. Thus, while the division of the diseases affecting the bone marrow into various categories is unanimously agreed upon and the principal features of their pathologic-physiology are accepted with little dissension, the mechanism and meaning of pathologic alteration in the lymphatic tissues remain today almost as obscure and chaotic as for the past fifty years. Witness, for example, the popular use of the terms lymphoblastoma and lymphoma, designed to encompass most of the non-infectious lymphadenopathies. The continuance of the use of such vague general terms is an admission of the confusion that prevails in this field.

The reasons for the difficulties that have continued to beset workers in this field are not difficult to find. They are largely, if not entirely, the obstacles that attend the interpretation of the histogenesis of the lymphocyte. No completely satisfactory concept of the identity, life history, and specific functional potentialities of the lymphocyte has yet been accepted. The fundamental cytological studies of Sabin and her associates have gone farthest perhaps toward establishing this cell in its proper relationship to the other cells of the blood forming tissues,¹ and are basic to any interpretation of the rôle of this cell in the lymphatic dyscrasias.

^{*} Read in part May 1, 1935 at the 19th Annual Meeting of the American College of Physicians, Philadelphia, Pa., under the title "The Fundamental Mechanism in the Production of Chronic Lymphatic Leukemia."

From the Department of Medical and Surgical Research, Ohio State University, Columbus, Ohio

The problem of chronic lymphatic leukemia is essentially the problem of the pathologic-physiology of lymphopoiesis. Any rational attempt to trace the course of events in which the lymphocyte plays the dominant rôle must take into consideration the well established facts relating to the known pathologic alterations in which this cell type is the chief reacting unit, and also must be consistent with the physiologic conditions under which this cell reproduces itself. Further, it is clear that the unsatisfactory state of our understanding of both the physiology and the pathology of lymphopoiesis directly reflects the uncertainty and conflicting opinions that prevail with regard to the lymphemic states. Admitting, then, that any discussion concerning the mechanism of chronic lymphatic leukemia is hampered by our incomplete knowledge of this subject, it is desirable, nevertheless, if only for the purpose of stimulating new lines of thought and research, to review critically the available facts and to add certain original data bearing upon the problem. Such an analysis has formed the basis for the present concept which suggests a rational explanation of this enigma on the basis of our present state of knowledge.

THE PHYSIOLOGY OF LYMPHOPOIESIS

Reference to chart 1 shows schematically the course of events in the evolution of the lymphocyte from the mesenchymal rest, the non-phagocytic reticulum cell, through the phases of maturation to the definitive small round cell readily identified wherever found as the lymphocyte. While it is believed that all of the primitive cells (including the reticulum cells) are totipotent, yet because of the environmental conditions, the conditioning stimuli received, or both, these precursors mature only in the direction of lymphoblasts in lymph nodes and spleen and in a few other locations. All cells below level 2 are fully differentiated units and appear to have lost their power to reproduce cells other than lymphocytes. As indicated by the chart, lymphopoiesis is usually effected by progressive stages of maturation and division (chiefly mitotic) through the successive levels 1, 2, and 3, the latter level being most active (quantitatively) under physiologic and certain pathologic conditions. However, lymphopoiesis may also be effected to an important degree by a rapid division of cells in level 4 (chiefly amitotic). The qualitative characteristics of these cell types have been described previously in detail - ³

The significance of the histologic structure of the lymph nodes in which these changes take place has long been a subject of controversy. The pioneer hypothesis of Flemming⁴ which emphasized the significance of the so-called germinal center, though contested by Marchand,⁵ Hellmann,⁶ Heilmann,⁷ Latta,⁸ Heiberg,⁹ Pol,¹⁰ and many others, has been vigorously supported by the work of Aschoff,¹¹ Groll and Krampf,¹² Maximow,¹³ et al. At present the prevailing opinion supports Flemming's original concept of the import of the secondary nodule. Original work in this laboratory has indicated

LYMPHOPOIESIS

CHART 1 A graphic representation of physiologic and pathologic lymphopoiesis. The cells, in their relationships to normal physiologic lymphocyte production, are shown by connecting them with solid lines. The non-phagocytic reticulum cell gives rise on the one hand to daughter reticulum cells and on the other, by maturative phases, to primitive round cells and thence to lymphoblastic units. Further division and maturation of the latter elements result in the production of the mature cells of the peripheral zone, which not only encircle the germinal centers but also are diffusely distributed throughout the lymph node. Normally most of the proliferation occurs by concomitant maturation and division. However, in the pathologic states of leukemia and lymphosarcoma, it is suggested that division is accentuated and maturation is limited. Various degrees of maturative arrest result in production of the cells of various levels of immaturity as seen in different cases of these diseases. This is indicated by the horizontal dotted connecting lines indicating proliferation with minimal maturation. It is clear from this chart that, theoretically, pathologic proliferation with maturation arrest may be either neoplastic in nature, or metabolic in the sense that unknown disturbed physiologic factors permit or cause undue proliferation without concomitant maturation.

that intense stimulation of the formation of lymphocytes results in a proliferation of the germinal center tissue which breaks through the limiting zone of small lymphocytes and may eventually almost completely fill the entire node within the capsular borders. As this tissue extends through the node it becomes mixed more and more with cells of level 4, so that its identity becomes less and less clearly defined, until in the completely hyperplastic node the entire content of the structure reveals only a diffuse lymphatic tissue with a thorough mixing of all the various types of lymphocytes. Lymph nodes with small but prominent germinal centers are probably resting structures. This would account for the histologic differences between the peripheral deposits of lymphatic tissue which contribute only slightly to the

mass of circulating lymphocytes and those deposits about the gastrointestinal tract which are continually being stimulated by afferent streams from the gut and which, by their efferent vessels, supply nearly all the blood lymphocytes^{14, 16}

Chart 1 shows that when normal maturation and division both occur, lymphopoiesis is expressed histologically by the prominence and extension of the tissue represented in levels 1, 2, and 3, i.e., by the germinal center tissue of Flemming. It indicates, however, that abnormal proliferation is theoretically also possible by specific multiplication without maturation of the cells at any of the levels shown, since all of these cells have the power to reproduce themselves. It is further evident that neoplastic changes may occur at any of the stated levels and thus provide a third mechanism for the over-production of lymphocytes. Each of these three mechanisms may conceivably give rise to pathologic states characterized by proliferative phenomena. The significance of these potentialities will become clear in the later discussion of certain of these pathologic states.

A study of the blood and tissue changes occurring in infectious mononucleosis serves to emphasize the orderly course of events which occurs when the stimulus to increased production of lymphocytes as provided by this infection is pronounced. Chart 2 records the significant hematologic observations made upon patient H. W. from the time he came under observation (24 hours after the onset of the disease) until the blood findings returned to normal. The lymphocytes, polymorphonuclear leukocytes and monocytes, classified by the supravital technic, are shown in absolute numbers together with the totals for white and red cells. In the lower block are plotted the values in per cent for the young lymphocytes as determined in Wright-Giemsa stained blood films, classification being made according to the principles outlined in an earlier publication². It will be observed from a study of this chart that whenever the total lymphocytes exceed the normal number for an individual in health, the percentage of young types is distinctly above the upper limit of normal (over 10 per cent). It is also clear that as the total number of lymphocytes in the peripheral blood fluctuates, there is a corresponding and parallel fluctuation in the percentage of young forms. This is shown especially well during the repeated observations made on Dec 5, when a study of the blood was made every 15 minutes for three hours. These facts indicate that delivery of increased numbers of lymphocytes to the blood is attended by an increasingly marked shift to the left in this series of cells and bespeak the origin of the cells from a series of maturative phases involving the increased activity of germinal centers, as indicated in chart 1 for levels 3 and 4.

Further evidence for this belief is secured by an examination of the pathological tissue in cases of infectious mononucleosis. A cervical node was obtained Dec 6 by biopsy from a patient, C. W. Z., early in the course of the disease. The photomicrographs (figures 1 and 2 in plate 1) show quite plainly the proliferating germinal center tissue infiltrating the

CHART 2 Blood findings obtained by study of case H W who had infectious mononucleosis. Serial 15 minute counts were made during the period indicated on Dec 5, 1930 and the percentage of young lymphocytes charted to contrast with the fluctuation in total numbers of lymphocytes. The correlation between increase in young cells and increase in total numbers is evidence that lymphopoiesis is physiologic as described on chart 1. Tissues from this case shown on plate 1, figures 3 and 4.

entire gland to such an extent that the greater portion of the node is composed of pre-lymphoblastic units, indicating that the supply of lymphocytes is obtained by increased activity and functioning volume of the germinal center tissue of Flemming. The lymph node from patient H W was removed late in the course of the disease, just prior to the restoration of the lymphocytes to normal levels (chart 2). The microscopic character of the

tissues is now totally different (figures 3 and 4 in plate 1). The sections clearly show that "pure" germinal center tissue is much less obvious, the mixing of the cells in the lymph node is more uniform, and increased numbers of more mature lymphocytes are especially prominent. These observations suggest that lymphocytes are being matured by the process indicated in chart 1. It is also pointed out that during the course of these events the predominating cell in the peripheral blood is the young, but not pathological, lymphocyte, corresponding to cells of the level of chart 1 labeled "large lymphocytes." It is felt that these facts constitute strong supporting data for the theory of Flemming and indicate the essential truth of the course of events in normal physiologic lymphopoiesis shown in chart 1. The importance of these observations will become more apparent in the subsequent consideration of lymphopoiesis in the non-infectious hyperplastic lymphatic states.

The normal physiologic stimulus for lymphopoiesis has not as yet been determined. Experimental procedures, such as light,^{17, 18} heat,¹⁹ roentgen-ray,^{20, 21} fat diets,²² extirpation of the spleen^{23, 24} and parenteral absorption of foreign proteins,²⁵ have all been shown to influence the peripheral level of lymphocytes, but none of these have been shown to be important in the physiologic or pathologic production of lymphocytic hyperplasias.

Equally obscure is the important selective mechanism by which certain lymphocytes are retained in the mother tissues and others are released to the lymph stream. It is clear that any intelligent attack upon the problem of the mechanism of production of the lymphatic dyscrasias is hampered by our lack of knowledge of these two fundamental physiologic processes.

THE PATHOLOGY OF LYMPHOPOIESIS IN NON-INFECTIOUS STATES

Although earlier investigators, particularly Haller,²⁶ had described whole blood which had the gross appearance of pus, it remained for Virchow²⁷ and

PLATE 1

Photomicrographs of paraffin sections of lymph nodes obtained by biopsy from cases of infectious mononucleosis and stained with hematoxylin and eosin.

FIG 1 *Case C W Z* Low power view of a section through the cortex of the node. The capsule is seen in the upper left hand corner. Note the pale staining germinal center tissue which has invaded the entire node and is in direct continuity with the ill-defined secondary (germinal center) nodule seen in the upper center of the photomicrograph. This tissue was removed *early* in the course of the disease.

FIG 2 *Case C W Z* Oil immersion view taken through the edge of the secondary nodule referred to in the description of figure 1. The invasion of the peripheral zone of small lymphocytes (center of photograph) by germinal center tissue (upper part of photograph) is clearly shown. Mature lymphoid elements are in the minority.

FIG 3 *Case H W* Low power view of a section through the cortex of the node. This tissue was removed *late* in the course of the disease. The germinal center tissue is less prominent and is evenly mixed with the more mature cells of the node. Mature units now greatly outnumber the primitive cells and secondary follicles can no longer be delimited.

FIG 4 *Case H W* Oil immersion view taken from the same section as figure 3. The view is representative of all portions of the section. Note the predominance of matured cells as compared with figure 2, above, and the corresponding decrease in primitive-cell units. Large lymphoblasts with heavily basophilic cytoplasm and large prominent nucleoli are now particularly abundant. A vessel runs through the center of the section.

PLATE 1

Bennet⁻⁸ first to interpret correctly this phenomenon as characteristic of leukemia. John Bennet in 1845 described a case with autopsy report in which death took place from "the presence of purulent matter in the blood." Bennet recognized the non-inflammatory character of the mechanism by which it was produced, but he believed that the white corpuscles arose in a "blastema formed of liquor sanguinis" and did not divorce his theory entirely from that of suppuration. Virchow, however, immediately recognized his discovery as a new disease, "White Blood," emphasized its unique nature and cautiously suggested as the possible mechanism a diseased spleen which transformed red blood cells into white ones. In a later communication,²⁹ Virchow classified the diseases characterized by lymphatic hypertrophy into four groups: 1, leukemic lymphoma (lymphatic leukemia), 2, simple hyperplastic lymphoma (probably a mixture of pseudoleukemia and leukosarcoma), 3, lymphosarcoma, soft form (lymphosarcoma), and 4, lymphosarcoma, hard form (Hodgkin's disease). Virchow therefore laid the foundations for a clinico-pathologic classification of the idiopathic lymphatic hyperplasias which, with minor changes and amplifications, has held to the present day. Cohnheim,³⁰ using the term pseudoleukemia, separated from Virchow's soft form of lymphosarcoma a lymphatic state in which the gross and microscopic tissue changes of lymphatic leukemia were present but without the blood changes. Kundrat³¹ further clarified this group by his observation of cases in which the disease, originating in an isolated single lymphatic node, became locally invasive and later metastasized by way of the regional lymphatics. Finally Steinberg³² in a monumental contribution, the importance and significance of which has not been generally recognized, differentiated a group of cases of lymphosarcoma which started locally as an invasive tumor mass but which eventually became leukemic in that the abnormal cells composing the growth gained entrance to the blood stream causing a leukemia of the large cell type. Virchow's fourth group (Hodgkin's disease) is now generally regarded as primarily an infectious granuloma.³³ The observations of Steinberg,³⁴ the recent studies by L'Esperance in Ewing's laboratory,³⁵ as well as observations and experiments from our own laboratory tend to implicate the tubercle bacillus rather than other bacteria³⁶ or viruses^{37, 38} as the initial causative agent.

This view of Hodgkin's disease is not, of course, necessarily in conflict with the fact that certain cases exhibit definite neoplastic characteristics. The phenomena of neoplasia arising in chronic lesions is not unusual in other tissues of the body. When neoplastic transformations occur in lymphoid tissues, however, the cell primarily involved is definitely not the lymphocyte, as suppression of lymphopoiesis with lymphopenia is an outstanding feature of the disease. Unpublished studies in our laboratory make it probable that either the reticulum cell, the monocyte or both are the elements in lymphatic tissue that undergo the characteristic pathologic changes. Hodgkin's disease, therefore, while a disease of lymphatic tissues, does not appear primarily to affect the lymphocyte itself and hence is not discussed further in this paper.

It is clear, therefore, that, with the exception of the separation of Hodgkin's disease from the group of primary lymphatic hyperplasias, little advance has been made toward an understanding of this group of diseases

CHART 3 This graph shows the result of the blood findings in case W S who had lymphatic leukemia. Serial 15 minute counts during the period indicated do not show parallel fluctuations in "young" cells (as classified by maturative criteria shown to be valid for normal lymphopoiesis) and total numbers. From Jan 14 to 22 there was a rise in these "young" types but not in proportion to the rise in the totals. It is believed that these facts suggest that increase in proliferation of lymphocytes in this disease is marked by the production of cells which do not exhibit the maturative characteristics seen in cells produced by physiologic lymphopoiesis. Tissue from this case shown on plate 2, figure 1.

since Steinberg's significant contribution in 1908. We have today then four clinico-pathologic states which are characterized by lawless proliferation of the lymphatic type of cell viz, lymphatic leukemia, lymphatic pseudo-leukemia, leukosarcoma, and lymphosarcoma. By a critical analysis of typical cases from each of these classes we shall trace certain facts which apparently help to explain the mechanism responsible for lymphatic leukemia and which, at the same time, suggest a relationship of each of these lymphatic dyscrasias to the others. Cases in addition to those cited have been studied with entirely similar findings and conclusions. To conserve space, only data relevant to this discussion will be given.

CHRONIC LYMPHATIC LEUKEMIA

Case IV S This patient, a white male, aged 52 years, first came under our observation on Dec 20, 1930. He gave a history of general glandular enlargement, increasing pallor, and dyspnea of three years' duration. No history of a primary local lymph node enlargement could be obtained. Physical examination showed, in addition to the generalized adenopathy, an enlarged spleen, the border of which reached the level of the umbilicus. The enlarged nodes were elastic to the touch, freely movable, discrete and not painful on pressure. The blood examination showed the presence of pathologic lymphocytes in increased numbers, as shown in chart 3. These lymphocytes were all of the small round type, uniform in size, and each possessed a very narrow rim of cytoplasm containing small spherical (not rod-like) mitochondria about a nucleus that exhibited a characteristically heavy chromatin cloud and occasionally a small nucleolus. Studies of the delivery of the young lymphocytes, classified according to standards of proved value in appraising normal lymphopoiesis, failed to show during the serial 15 minute interval studies of Dec 31 any correlation between germinal center activity and intensity of lymphopoiesis (chart 3), in sharp contrast to the findings in infectious mononucleosis (chart 2). It is also clear from chart 3 that although the lymphocytes ranged between 60,000 and 90,000 on Dec 31 (from 9 45 a m to 12 00 noon), at no time during this interval did "young" cells constitute more than 3 per cent of the total.

PLATE 2

Photomicrographs of paraffin sections of lymph nodes removed at biopsy and stained with hematoxylin-eosin, oil immersion views. Figure 1 (chronic lymphatic leukemia) is to be contrasted with figure 2 (pseudoleukemia). Figure 3 (leukosarcoma) is to be contrasted with figure 4 (lymphosarcoma). The cells of figures 1 and 2 are morphologically identical, similarly identical are those of figures 3 and 4. Note, however, the vast differences between the cells of figures 1 and 2 and those of figures 3 and 4.

FIG 1 *Case IV S Chronic lymphatic leukemia* Note the endless reduplication of one type of cell with heavily chromatic nucleus and small but prominent nucleolus. The cells tend to be uniform in size and shape. No mitotic figures were found in this section, and there was no tendency to invade the capsule.

FIG 2 *Case R D B Lymphatic pseudoleukemia* The morphologic characters of the cells in this section were identical with those of figure 1.

FIG 3 *Case E M Leukosarcoma* These cells vary greatly in size and shape, tend to be vesicular and do not have the characteristic chromatin structure of those shown in figures 1 and 2. Mitotic figures were plentiful in this section. This tissue showed definite invasive characteristics and invaded the surrounding structures by direct extension. (See figure 1.)

FIG 4 *Case F M Lymphosarcoma* These cells correspond in all particulars with those shown in figure 3. Mitotic figures were particularly rich in the section from this patient, and the tissue was locally invasive.

PLATE 2

The obvious conclusion is that the lymphopoiesis of chronic lymphatic leukemia is not of the normal germinal center type. This fact, in conjunction with the observations that the cytoplasm of the immature cells is often relatively deficient in basophilic substance, and that the cells tend to divide by amitosis (mitotic figures are a great rarity in the blood and in sections of tissue from chronic lymphatic leukemia), suggests that multiplication of cells in this disease is chiefly by amitotic division with *minimal maturation*. In Chart 1 this would be indicated by proliferation of cells in a horizontal direction with very little progressive development vertically, that is to say, very little multiplication *with* maturation. It is clear that this hypothesis would account for small cell (chronic) leukemias as well as for the more acute large cell types, the difference being dependent upon the cell level at which the abnormal proliferation took place. It will be recalled that, physiologically, lymphocytes multiply at the various levels with some maturation arrest, but normally the reserve of cells at each stage remains small at any one time, the majority maturing promptly. In chronic lymphatic leukemia it would seem that this normal physiologic equilibrium is reversed so that division *with* maturation is quite small and division without maturation is correspondingly large. The end result is an overproduction of immature cells of no functional value to the body. In this respect the mechanism is similar to that observed in the over-production of megaloblastic tissue in pernicious anemia. An alternative theory in explanation of the horizontal proliferation of lymphocytes at immature levels in lymphatic leukemia is one which would link the mechanism with a neoplastic alteration. This hypothesis will be considered in the discussion of leukosarcoma.

LYMPHATIC PSEUDOLEUKEMIA (COHNHEIM)

Case R D B This patient, a white male aged 64, first came under observation on Dec 13, 1933, complaining only of generalized lymph gland swelling. Physical examination added only the fact that the spleen was enlarged to the costal border. The lymph nodes varied in size from a pea to a walnut and had exactly the same characteristics as described for patient W S above. Biopsy was performed with removal of a left cervical node on Dec 20, 1933. Both supravital examination and the study of fixed paraffin sections revealed hyperplasia with metaplasia of the lymphatic elements, indistinguishable from the tissue changes seen in classical chronic lymphatic leukemia and identical with the tissue from patient W S. (Compare on plate 2 photomicrographs 1 from the tissue of W S and 2 from the tissues of R D B.) The hematologic examination showed *absolutely no abnormalities* either in the quantitative values or in the qualitative characteristics of any of the circulating cell types. All lymphocytes were of the normal types, although repeated studies with both the supravital and fixed technics were utilized in an effort to detect pathologic variations. Chart 4 is a graph of the cellular equilibrium prevailing in this patient and shows that for the 25 months he has been under our observation no leukemic tendency has been observed. Roentgen-ray therapy in suitable dosage has been applied to the superficial glandular swellings as indicated on the chart in order to control the local enlargements. Throughout, this patient has been in the best of health and has continued to fulfill his occupation as a railroad crossing watchman.

CHART 4 Results obtained by blood examination of patient R D B who had lymphatic pseudoleukemia. No abnormalities, either qualitative or quantitative, have been observed during the period of two years shown on this chart. Examination of a lymph node removed at biopsy on Dec 20, 1933 showed a histology indistinguishable from that of patient W S (chart 3) who had lymphatic leukemia with marked lymphemia. Local roentgen-ray treatments were given, as indicated on the chart, for the sole purpose of reducing the local swellings of the lymph nodes. Tissue shown on plate 2, figure 2.

From the facts as herein outlined the type of lymphatic hyperplasia is undoubtedly identical with that found in chronic lymphatic leukemia. In this patient, R D B, however, the barriers that allow only normally matured cells to gain entrance to the lymphatics and thence to the blood stream are effective in screening out the leukemic unmaturing types, thus confining them to the lymphatic tissues, whereas in the former case (W S) this mechanism has failed. The absence of leukemic cells in the peripheral blood in case R D B has resulted in an absence of infiltrative phenomena (large liver, anemia, etc.), as normal lymphocytes merely divide, mature and die and are not capable of endlessly dividing without maturing. Hence, unlike leukemic cells, normal lymphocytes do not crowd out, "infiltrate" and replace other tissue cells. It is clear that patient R D B is in good health and will continue so, as long as the leukemic cells do not gain entrance to the blood stream. That this screening mechanism may become ineffective at any time, thus converting the disease into a true leukemia has been observed by others^{39, 40}

LEUKOSARCOMA (STERNBERG)

Case E M This patient, a white child, aged 20 months, came under our observation Febr 11, 1935, eight weeks after the first evidence of the beginning of her illness. Pallor, dyspnea and generalized glandular enlargement with splenomegaly

developed rapidly. A careful history revealed that the first enlargement which appeared was a lump in the left submaxillary region. After a period of about four weeks there was an increase in the size of the spleen with a simultaneous enlargement of the lymphatic structures. A blood count six weeks before admission was said to have shown 35,000 white blood cells with the majority "mononuclear" leukocytes. Deep roentgen-ray therapy was applied over the mediastinum to relieve the dyspnea and reduce the number of cells. A careful hematologic examination made upon our first contact with the case revealed the classical findings of lymphatic leukemia with the one exception, that upon supravital examination it was possible to discriminate, after careful study, between two morphologically distinct types of lymphocytes existing side by side in the blood films. The one type was found not to depart from the normal in any recognized morphologic particular. The second type of lymphocyte

TABLE I

Important Supravital Criteria of Three Biologic Classes of Lymphocytes

CLASS	Characteristics of nucleus				
	Visible nucleoli	Chromatin distribution	Shape	Relative size of nucleus to cell	Nuclear membrane
Normal mature cell	Not prominent	Heavy cob web	Varies	Varies	Sharp
Leukemic cell	Prominent	Heavy splotches	Offer bizarre	Tends to be large	Sharp
Sarcoma cell	Large	Fine cob-web	Round	Large	Indistinct

CLASS	Characteristics of cytoplasm			
	Quality	Neutral red vacuoles	Refractive vacuoles	Mitochondria
Normal mature cell	Faint yellow	Rose-red if present	None	Large rods or spheres
Leukemic cell	Limpid clear	Largely absent	None	Small spheres
Sarcoma cell	Faintly grey	1-10 highly refractive vacuoles about periphery of nucleus Deep scarlet when stained		Dust-like

CLASS	Other characteristics of cell			
	Motility	Approximate size	Phagocytosis	Fragility
Normal mature cell	Present	95% less than 9 microns	Absent	Slight
Leukemic cell	Absent	Varies	Absent	Marked
Sarcoma cell	Absent	12-14 microns	Absent	Moderate

present was definitely abnormal but differed from the normal in details other than those previously described as characteristic of the cells in chronic lymphatic leukemia. These pathologic cells ranged in size from 8μ to 15μ the majority being similar in size to the normal intermediate lymphocyte. The cytoplasm consisted of a narrow rim about the nucleus with a moderate sprinkling of dust-like mitochondria and contained from one to a dozen vacuoles which either did not stain at all or else took the vital neutral red with a reaction strongly to the acid side of its indicator range. The nucleus of this atypical cell was vesicular and contained a fine web-like chromatin

FIG 1 *Case E M Leukosarcoma* Low power view through submaxillary salivary gland adjacent to submaxillary lymph node. A portion of the lymph node lies in the upper right hand corner. The capsule of the node has been destroyed, and the lymphocytic elements have invaded by direct extension the submaxillary gland in the center and lower part of the section.

with a rather large nucleolus. The nuclear membrane was indistinct so that not infrequently there was some difficulty in sharply delimiting the area occupied by the nucleus. This cell we have called the "sarcoma cell" to distinguish it from the other types of lymphocytes described. Morphologically, in supravital preparations it is similar to proved sarcoma cells found in round cell sarcomata of the connective tissues. Table 1 by description compares this with the other lymphocytes mentioned in this paper.

The lymph node, removed at biopsy from the submaxillary region, differed

markedly from those found in the usual case of lymphatic leukemia. The lymph node could not be removed with capsule intact, as it was bound to the surrounding tissue. Upon cut section, the contents of the node were gray in color, extremely soft in consistency and very cellular. Supravital examination of scraping of this material showed a mixture of normal lymphocytes and cells corresponding to those found in the peripheral blood and designated as "sarcoma cells." Mitotic figures among the latter were very frequent. Paraffin sections showed characteristic sarcoma tissue. Remnants of secondary nodules were invaded and destroyed by these abnormal cellular elements. The proliferative process had broken through the capsule and invaded, in typically neoplastic fashion by direct extension, the adjacent parenchyma of the submaxillary gland. Figure 1 shows the characteristic invasiveness of these cells.

Chart 5 depicts graphically the course of the hematologic events as they occurred in this patient. In this chart the sarcoma cells are shown by the circles connected with a solid line, and the normal lymphocytes are shown by the circles connected with a dotted line. Several points on this chart are of interest and of importance to the theory of the mechanism of production of leukemia and will be discussed to the exclusion of other interesting data shown but not vital to the tenets of this paper.

It is clear that the excess of white cells consists entirely of the "sarcoma cell type" of lymphocyte, the curve representing the total leukocytes paralleling that representing the sarcoma cells. The curve for the normal lymphocytes constitutes a virtual plateau fluctuating for the most part between 2,000 and 4,000 cells and deviating downward from this level only once, when the sarcoma cells were at a very high level (60,000). This fall in the number of normal lymphocytes was probably due to a suppression of multiplication in the tissues (infiltrative phenomena) and not to a roentgen-ray effect, as it will be observed that a considerable drop in the red blood cells occurred at the same time, and that larger doses of roentgen-ray were given both before and subsequent to this fall without disturbing the level of either normal lymphocytes or red cells. It is also clear from this chart that the two kinds of lymphocytes shown have a quite marked difference in susceptibility to the destructive effects of the roentgen-ray (note in particular the behavior of these two cells to the treatment given on March 6). This further substantiates the biologic difference between them suggested by their morphologic characteristics. It is also evident that the extraordinary radiosensitivity of these sarcoma cells, transcending considerably even that of the normal lymphocytes, tends to place these cells in the category of neoplastic cells of lymphoid origin.

From the foregoing it would appear probable that the leukemia observed in patient E. M. is a type of lymphatic leukemia which differs from those already mentioned in at least three important respects: 1, in the morphologic characteristics of the abnormal lymphatic elements, 2, in their relative radiosensitivity, and 3, in the histo-pathology of the affected lymphatic tissues. These points all indicate a mechanism responsible for the leukemia of leukosarcoma which is different from that of simple lymphatic leukemia. This mechanism, as clearly indicated by the facts recited, points strongly to a neoplastic alteration of lymphopoiesis. This malignant lymphocyte then invades the blood stream (causing "leukemia") and infiltrates the various tissues of the body, giving rise to a clinical and

0 2420 EJM Leucosarcoma

* Micrometabolism of blood cells performed on these dates

CHART 5 Blood findings in patient E J M who had leucosarcoma. Particular attention is directed to the charting of two types of lymphocytes, one labeled "sarcoma cells" and the other "lymphocytes." The charting is upon semi-logarithmic scale. The normal lymphocytes at no time greatly exceed the value regarded as normal for the average person in health. The "sarcoma cells," however, between the periods in which roentgen-ray therapy was applied rise to high values, independently of the normal lymphocytes. The effectiveness of small doses of roentgen-ray in reducing the number of sarcoma cells and the relatively ineffectual results of these doses upon the normal lymphocytes are clearly shown and bespeak further for a biologic difference between these two types of lymphocytic cells. Tissues shown as figure 1 and also on plate 2, figure 3.

pathological picture simulating ordinary lymphatic leukemia. This mechanism exemplifies the third type of lymphocytosis which is theoretically possible according to the chart presented in the discussion of physiologic lymphopoiesis.

LYMPHOSARCOMA (KUNDRA†)

Case F M This patient was a white male, aged 60, who was found to have "lumps" in his abdomen five months prior to the present observations. Physical examination on Febr 2, 1931 showed generalized swelling of the lymph nodes, including the mesenteric nodes. The nodes were discrete, rather hard, freely movable in some cases and fixed in others, but all were without tenderness to pressure. The spleen was enlarged to 5 cm below the costal border, and there was fluid in the abdomen. Gastrointestinal roentgen-ray series as well as other studies were negative. Repeated examinations of the blood showed no evidence of leukemic changes, either from a quantitative or qualitative standpoint (chart 6 shows two counts taken

P M N	4,864	2,604	3,132
Lym	1,292	966	1,392
Mono	1,368	588	1,160

CHART 6 Three blood counts taken on patient F M who had lymphosarcoma. These were typical of the many observations that were made. No evidence of leukemic change is noted. Tissue shown on plate 2 figure 4.

early in the course of his disease and one near the end, typical of many that were made). Biopsy examination was made on Febr 3, 1931, and a lymph node 1 by 1 by 1½ cm removed from the left cervical area. The contents were very cellular, and from the characteristics of the cells examined supravivally a diagnosis of lymphosarcoma was made. Examination of the paraffin sections showed a type of cell histologically indistinguishable from that of the preceding case, E M (see plate 2, compare figures 3 (Case E M) and 4 (F M)).

A review of the pertinent facts in this case, typical of many such that have been observed, shows a lymph gland tumor originating in one part of the body (in this instance in the mesenteric area), which first spread locally and eventually became generalized, probably by metastasis. Clinically and histologically this case was identical with the preceding case (E M) except that the malignant cells were not continuously delivered into the circulation, with the result that neither a leukemic blood picture nor the infiltrative phenomena of leukemia developed. That some cases, starting in this manner, at times become leukemic^{42, 43} cannot be doubted. In such instances at some time, often following roentgen-ray therapy, the pathological cells undoubtedly gain free access to the blood—that is to say, leukosarcoma develops from the localized neoplastic alteration of the lymphoid cells characteristic of lymphosarcoma.

ALEUKOCYTHEMIC (ALEUKEMIC) LYMPHATIC LEUKEMIA

From the previous discussion, it may be inferred that there are three forces which determine the number of cells in the peripheral blood. In physiologic lymphopoiesis the level is determined by the balance which

exists between the factors of production, delivery to the blood stream and peripheral loss or destruction. For example, in infectious mononucleosis cases with marked adenopathy but with low total blood counts apparently reflect the existence of a very effective barricade which prevents release of these elements to the lymph and blood streams. This is not the result of high peripheral loss because examination of the cells in the blood stream reveals large numbers of relatively old lymphocytes, a fact which suggests accumulation rather than accelerated peripheral loss.

Careful study of the material accumulated in this laboratory has indicated that, in the diseases characterized by pathologic lymphopoiesis, the factor of peripheral loss of cells is manifested chiefly by tissue infiltration with blood cells, a circumstance which rarely, if ever, occurs to an important degree in the infectious lymphadenopathies.

The withdrawal of enormous numbers of cells from the blood and their storage in the tissue spaces have been outstanding features in some cases in which the blood has shown an actual leukopenia. In fact, in our experience a falling peripheral level of cells in chronic lymphatic leukemia has often been associated with the appearance of signs of heavy tissue infiltration, as shown by roentgen-ray examination of lung fields, an enlarging liver, a developing anemia and thrombopenia, etc. The clinical course, the roentgen-ray studies and the laboratory data in case J B illustrate this phenomenon clearly.

Case J B This patient with a peripheral level of cells which averaged 24,000 lymphocytes per cu mm of blood for two months just prior to June 15, 1935 had shown no evidences of infiltration (figure 2). The patient then had a spontaneous exacerbation of his disease with total counts rising to an average of 48,000 lymphocytes, with no further changes in the chest roentgen-ray as compared with previous examination. One month after this increase in the cell count occurred roentgen-ray therapy was given until the peripheral count became stabilized at an average level of 21,000 lymphocytes. This level persisted for 12 days. During the nine days after the establishment of this plateau of 21,000 the count slowly fell spontaneously to an average level of 8,000 lymphocytes. Dyspnea and cyanosis slowly became more evident during the next 17 days, and one month after the spontaneous development of the aleukemic phase, respiratory distress was marked. A roentgen-ray at this time, with a lymphocyte count of 6,083 on Nov. 14, 1935, showed marked infiltration in the right lower lung field (Figure 3). This was treated with deep roentgen-ray locally with some clearing of the cellular infiltration, but without much clinical relief. A roentgen-ray taken 15 days later, Nov. 29, 1935, showed spread of the infiltrative process to the left lung (Figure 4). Throughout the aleukemic phase, which persisted 34 days until his death, the lymphocytes maintained an average level of 8,000 cells. There was no increase in size of the lymph nodes during this phase.

This discussion provides an explanation of the mechanism resulting in the so-called aleukemic types of lymphatic leukemia. In some cases with large lymph nodes but low peripheral cell count the "screening" mechanism in the lymph nodes is probably particularly efficient. These cases resemble the pseudoleukemic types exemplified by case R D B previously discussed, the difference being in the relative efficiency of this mechanism. Some

FIG. 2 *Case of J B A leukemic lymphatic leukemia* Chest plate taken on June 15, 1935 The tracheo-bronchial lymph nodes about the right and left hilus are enlarged, but the lung fields are clear

FIG 3 Case of J B Aleukemic lymphatic leukemia Chest plate taken on Nov 14 1935 Heavy infiltration of cells shown particularly in right lower lobe Beginning infiltration in left side

FIG 4 Case of J B. *Atypical lymphatic leukemia*. Chest plate taken on Nov 29, 1935. Deep roentgen-ray therapy given on Nov 16 resulted in some clearing of the involvement on the right side. However, the left side is now heavily infiltrated, particularly at the base.

cases, treated with roentgen-ray therapy with marked reduction in adenopathy, persist over long periods of time with low total counts and very little evidence of lymph node enlargement. Such cases are probably examples of aleukemic leukemia in which the proliferative forces have been reduced in activity. Other cases, with leukopenia developing after having shown previously high peripheral cell counts, may show marked evidences of infiltrative phenomena. These represent instances of aleukemic lymphatic leukemia in which loss of cells from the blood stream to the tissue spaces is particularly important. In this latter type it seems probable that the rate of production of the cells is not sufficiently high to balance the peripheral loss.

A consideration of these facts, therefore, suggests that, at times, in individual cases, any one of the three physiologic forces which are important in determining the peripheral level of cells may be the chief factor in the production of the so-called aleukemic state of lymphatic leukemia. The significance of analyzing each case from these standpoints for determining prognosis is obvious.

DISCUSSION

From the observations made in the above cases, each cited as type specific for its class, it would seem that there are at least three mechanisms by which lymphoid tissue becomes hyperplastic: first, by excessive multiplication and maturation occurring simultaneously (e.g., infectious mononucleosis), second, by excessive multiplication with little or no concurrent maturation (e.g., the common types of lymphatic leukemia and pseudo-leukemia), and third, by the metaplasia of cells with neoplastic alteration (e.g., lymphosarcoma). Each of these three basic pathologic states has been observed to occur in man. Cases of infectious mononucleosis with normal or nearly normal peripheral blood counts have been observed in our clinic (aleukocytic infectious mononucleosis), whereas the lymphemia in other cases has been so marked as to make the differential diagnosis between lymphatic leukemia and infectious mononucleosis a matter largely dependent upon a careful qualitative study of the individual lymphatic cells. In these latter cases the determination of a continuance of normal maturation and the absence of amitotic division in the cells (inactive nuclei) have been among the important differential criteria. Important to this discussion is the fact that the phenomenon of cellular infiltration (marked anemia, thrombopenia, large liver, etc.) has never been observed in this disease because 1, the cells are more mature and have correspondingly lowered potentialities for division, and 2, the cells continue to mature and hence tend to fulfill their life cycle, dying in large numbers. These factors discourage local growth tendencies in the tissue spaces where the cells may lodge, so that the phenomenon of infiltration (which largely represents in the last analysis local growth) is not seen in infectious states. In direct contrast with physiological lymphopoiesis as illustrated by infectious

mononucleosis, pathological lymphopoiesis is remarkable in that observed maturation of these cells is minimal in amount, whereas the evidence indicating profound propensities for division is an outstanding feature

The evidence introduced in the body of this paper would seem to make it necessary, in order adequately to explain the phenomena observed, to hypothecate two distinct types of mechanisms responsible for the pathological lymphatic hyperplasias. On the one hand, cytologic and histologic evidence indicates that in one type of lymphatic hyperplasia, the mechanism is neoplastic (lymphosarcoma and leukosarcoma). On the other hand the evidence secured by parallel methods of examination in the other group

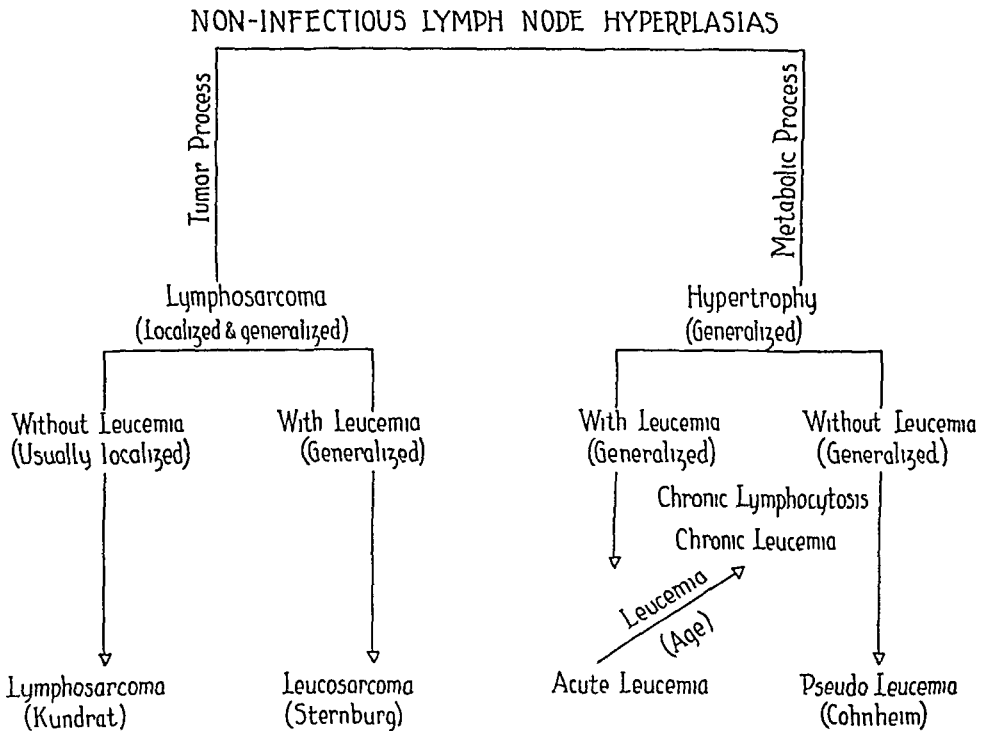

CHART 7 Graphic representation of the author's conception of the interrelationships existing between the primary non-infectious lymphocytic diseases. This scheme suggests that all of the lymphocytic hyperplasias of non-infectious origin consist essentially of two groups, that which is directly traceable to a neoplastic alteration in the reacting unit, the lymphocyte, and that group which is characterized by unlimited proliferation of lymphocytic elements resulting from an unknown but not a neoplastic mechanism. Either group may or may not exhibit leukemia.

(leukemia and pseudoleukemia) indicates that the mechanism is neither neoplastic in the same sense that lymphopoiesis is neoplastic in lymphosarcoma, nor essentially physiologic as in infectious states. In this latter (leukemic-pseudoleukemic) group the chief characteristic seems to be division without concomitant maturation, yet, withal, not neoplastic in character. The prototype of pernicious anemia immediately is recognized, and it is believed upon the basis of the evidence which we have secured that this type of lymphatic leukemia may be the result of a mechanism similar to

that which is responsible for the production of pernicious anemia. In order to account for the obviously neoplastic character of lymphosarcoma and leukosarcoma, it is necessary to postulate a second mechanism for the production of leukemia, that is, a neoplastic alteration in the lymphocytes which sometimes gain access to the blood stream (leukosarcoma). Lymphatic leukemia, according to this hypothesis which seems necessary to bring all the observed facts about this disease into accord, is the result of two vastly different etiologic agencies, the one neoplastic, the other possibly metabolic. The leukemias of the former type are usually more acute whereas those of the latter may be acute but usually are chronic. *The majority of the cases of chronic lymphatic leukemia are thus believed to be of metabolic origin.* Chart 7 illustrates the author's conceptions of the interrelationships of the various types of non-infectious lymphatic hyperplasias. Only those diseases which primarily affect the lymphocyte as such are shown.

It is emphasized that the conclusions as given above are not necessarily at variance with the well established data obtained from experimental leukemia in animals. The transmissibility of tumors in mice^{44,45} and chickens,⁴⁶ which in some instances show lymphatic leukemia and in others lymphosarcoma without leukemia, is simply a repetition of the same phenomena observed in man under the lymphosarcoma-leukosarcoma sequence described by Sternberg in 1908. In the case of chickens, many of the so-called leukemic states are undoubtedly the response to infectious agents⁴⁷ and are therefore not true leukemias but rather lymphocytoses. Similar states in man, difficult to differentiate from true leukemias, are regularly observed⁴⁸ (see also discussion concerning infectious mononucleosis). It is not believed, however, that any of the true leukemias of man are the result of infectious agents for the various reasons given in previous chapters concerning the mechanism of the production of the cells in leukemia and their physical characteristics.

CONCLUSIONS

1 All theoretically predictable variations in lymphopoiesis probably occur in man. Each type may give rise to nearly the same clinico-pathologic syndrome, but essential differences can be determined and established by a study of the physical characteristics of the cells involved.

2 A study of cases showing pathologic lymphopoiesis points to the concept that there are probably two etiologic forces responsible for lymphatic leukemia in man which operate through two different mechanisms, the one neoplastic, the other metabolic.

3 Analysis of the question of idiopathic lymphatic hyperplasias indicates that there are only two fundamental types: (a) neoplastic alterations of the lymphocyte without leukemia (lymphosarcoma) and with leukemia (leukosarcoma), and (b) "benign" hypertrophies without leukemia (lymphatic pseudoleukemia) and with leukemia (some of the acute cases and probably most of the chronic lymphatic leukemias).

4 Many acute leukemias are not true leukemic transformations of the underlying lymphatic tissues but are simply a vigorous cellular response to infectious agents conditioned by the host, the infectious agent, or both

5 Aleukocythemic (aleukemic) leukemia may be the result of either type of mechanism which can produce lymphatic leukemia, but in all cases a low peripheral level of the lymphatic elements in the blood, when the stimulus to lymphopoiesis is strong, is the result either of a partially effective mechanism which normally is completely effective in preventing pathologic and immature cell-forms from leaving the mother tissues and entering the blood stream, or rapid migration of the pathologic cells from the blood into the tissue spaces

METABOLISM STUDIES IN MYASTHENIA GRAVIS BEFORE AND DURING THE ADMINISTRATION OF GLYCINE¹

By MILDRED ADAMS, Ph D, MARSCHELLE H POWER, Ph D, and WALTER
M BOOTHBY, M D, F A C P, *Rochester, Minnesota*

SEVERAL attempts have been made to discover specific metabolic abnormalities in subjects with myasthenia gravis. The results in general have been contradictory and therefore inconclusive. The therapeutic value of glycine in this disease has caused a renewed interest in such studies, although the majority of the more recent investigations have dealt chiefly with the effect of glycine on the excretion of creatinine and creatine.

This investigation was undertaken, accordingly, to gain more complete information concerning the metabolism of patients with myasthenia gravis both before and during the administration of glycine. Complete studies in which the food, urine, and feces have been carefully collected and analyzed have been carried out on two subjects.

EXPERIMENTAL

Subject 1 was a woman, 40 years of age, who weighed 75.2 kg and whose height was 5 feet and 8 inches (173 cm). She had had myasthenia gravis for at least 10 years and for three years had been practically bedridden, until treatment with ephedrine was begun. Since that time she had been slowly improving, and at the time of this investigation she could get about fairly well with the aid of a wheel chair. She was still taking ephedrine—one 3/8 grain (0.025 gm) capsule of ephedrine sulphate twice daily—when she came to the clinic, and this medication was continued throughout the study. The patient was placed on a constant diet containing 12.2 gm nitrogen and about 1750 calories. The investigation consisted of a preliminary period of three days to allow the patient to come to equilibrium with the new diet, a control period of four days (I¹)† and a period of 11 days (II¹) on the diet plus 40 gm glycine (7.40 gm nitrogen) daily. At the end of this time the subject was unable to continue this regimen and the nitrogen of the diet was reduced to 10.7 gm and the glycine to 20 gm (3.70 gm nitrogen) daily. After an interval of two days, collections of urine and stool were again resumed for a third period of 10 days (III¹).

Subject 2 was a man 24 years of age, who weighed 66.9 kg, and whose height was 5 feet and 8½ inches (174 cm). Symptoms of myasthenia gravis first had been noted at the age of 15 years and had continued intermittently for about eight years. During the year before the patient's registration at the clinic, he had not been free of symptoms, and on admission he was extremely weak, had great difficulty in swallowing, and was confined to bed. For about one month he had been taking ephedrine sulphate, 3/8 to 3/4 grain (0.025 to 0.05 gm) thrice daily. This medication was reduced to 3/8 grain (0.025 gm) twice daily and was maintained at that level during our studies. This subject was placed on a constant diet containing 8.5 gm nitrogen and about 1900 calories. After a control period of four days (I²) there followed a period of 12 days (II²) on the diet, plus 30 gm glycine daily (5.56 gm nitrogen). At the end of this period it became necessary to institute tube feeding, and the metabolic studies were, therefore, discontinued.

* Submitted for publication December 9, 1936. From the Mayo Clinic, Rochester, Minn.

† The significance of these symbols is evident in the table.

The complete output of urine was collected for each 24 hours and the nitrogen and sulphur partition products were usually determined immediately, although in a few instances it was necessary to use aliquot portions of mixed, two-day specimens. Aliquot portions of four to six consecutive specimens were acidified and mixed for the determination of the inorganic constituents. An exact duplicate of the 24 hour diet was ground and thoroughly mixed, dried in a current of air at about 70° C, and again ground and mixed to obtain samples suitable for analysis. Two separate 24 hour samples of food were prepared in this way for each of the different diets used. All uneaten food was collected, dried in a manner similar to that described and analyzed so that accurate corrections of the intake were possible. The feces were collected for periods of from four to six days and an enema of warm, distilled water was used to close each period. Hydrochloric acid was added to prevent loss of nitrogen and the specimens were prepared for analysis by drying in a current of warm air at 70° C. The following methods of analysis were used: total nitrogen, macro-Kjeldahl, urea, manometric determination of carbon dioxide after treatment with urease (Van Slyke¹⁷), ammonia, aeration and titration (Van Slyke and Cullen¹⁸), preformed creatinine (Folin⁶), total creatinine, the method of boiling with picric acid (Folin⁶), uric acid (Folin^{8,9}), total amino acid (Van Slyke¹⁶ volumetric method, using an apparatus modified according to Koch¹¹). For the determination of total sulphur in urine 10 c.c. was completely ashed with fuming nitric acid in an apparatus similar to that of Rossenbeck¹³. The ashed solution was evaporated to dryness with the addition of water and hydrochloric acid to remove the excess nitric acid. The dry residue was then taken up in 5 or 10 c.c. of 87 per cent trichloroacetic acid and the sulphate present precipitated as the benzidine salt, essentially as described by Hubbard¹⁰. After centrifuging and washing, the benzidine sulphate was titrated with 0.01-normal sodium hydroxide. The inorganic fraction was similarly precipitated as benzidine sulphate from urine appropriately diluted with trichloroacetic acid. Hydrolysis of conjugated sulphates was accomplished by heating the trichloroacetic acid dilutions in calibrated tubes for 15 minutes in boiling water. The trichloroacetic acid lost by decomposition was replaced by the addition of a predetermined quantity of 40 per cent solution, the mixture made to a definite volume, and the sulphate present, inorganic plus conjugated, was precipitated and titrated as the benzidine salt. From these determinations the neutral sulphur and conjugated sulphate fractions were found by calculation. For the determination of total sulphur in food and feces suitable samples were burned in an oxygen bomb according to Berthelot as described by Sherman,¹⁴ after which the sulphate in the bomb washings was precipitated and weighed as barium sulphate.

The inorganic constituents of urine, food and feces were determined on hydrochloric acid extracts of samples which had been ashed in platinum in an electric muffle at 450° C. The colorimetric method of Fiske and Subbarow⁵ was used for the determination of phosphate. In the case of urine the inorganic phosphorus as determined in unashed samples agreed with the determinations on the ashed samples within 1 or 2 per cent. Calcium and potassium were determined according to Tisdall and Kramer¹⁵. Magnesium was precipitated as magnesium ammonium phosphate according to Tisdall and Kramer, after which the phosphate in the precipitate was determined by Fiske and Subbarow's method. Butler and Tutthill's⁴ adaptation of the zinc uranium acetate method of Barber and Kolthoff³ was used for the determination of sodium.

RESULTS

The results of the balance studies are summarized in table 1 in terms of the average daily balances for the control periods and the periods during which glycine was administered. In period I¹ for subject 1 the balances

TABLE I
Balance Studies in Myasthenia Gravis

Constituent	Subject 1 *				Subject 2 †

for nitrogen, sulphur, phosphorus, magnesium, and calcium were close to equilibrium. Likewise during period II,¹ when glycine was administered, there was remarkably little change in these balances. In a subsequent period, not shown in table 1, during which time the intake of food and glycine was reduced, the balances continued to be much like those observed for period II¹. Apparently there was a large retention of sodium in period I¹ but this may be ascribed to the fact that the supplementary sodium chloride of the diet was not sufficiently accurately weighed during this period. The retention of sodium in period II¹ was 0.49 gm per day, a value not abnormally high in view of the fact that no correction for loss of sodium through the skin could be made. The potassium balance in period I¹ appeared to be significantly negative. In period II¹ this balance became somewhat less negative.

In contrast to subject 1, subject 2 was, during the control period, in definite negative balance as regards nitrogen, sulphur, phosphorus, and calcium, but in approximate balance as regards potassium, magnesium, and possibly sodium. During the administration of glycine, period II,² the loss of nitrogen decreased but the balance was still highly negative. No marked changes occurred in the balances of the other constituents.

The data concerning the nitrogen partition products in the urine are summarized in table 2 in terms of the average daily values. For the purpose of showing in greater detail the changes in distribution during the periods of administration of glycine, the results of the daily determinations

Subject 1 Increased excretion of nitrogen = 101 per cent of increased intake of nitrogen

Sum of increase in urea, ammonia, creatine, uric acid, amino acid = 101 per cent of increased intake of nitrogen

Subject 2 Increased excretion of nitrogen = 81 per cent of increased intake of nitrogen

Sum of increase in urea, ammonia, creatine, uric acid, amino acid = 80 per cent of increased intake of nitrogen

have been grouped arbitrarily into three subperiods during each of which the daily values remained relatively constant

The nitrogen distribution during the control periods was apparently normal for each subject, except for the presence of some creatine, a condition occasionally encountered in myasthenia gravis¹ During the periods of administration of glycine there occurred in subject 1 a marked temporary retention of nitrogen for the first day or two This was later excreted, however, and the average increase in the urinary nitrogen for the entire period was equivalent to 101 per cent of the nitrogen ingested as glycine For subject 2, the increase in the nitrogen of the urine was equivalent to only 81 per cent of the glycine ingested

The increased urinary nitrogen was largely in the form of urea Changes in the other nitrogenous constituents were relatively small and accordingly the nitrogen partition products remained essentially normal For subject 1, the average change in urea accounted for 93 per cent of the increased nitrogen, and that of ammonia for 2.6 per cent In the urine specimens of subject 2 the urea appeared to be markedly unstable,* and the change in urea accounted for only 63 per cent of the increased nitrogen, while the ammonia was unusually high and accounted for an average of 30 per cent of the increased nitrogen Thus, for both subject 1 and subject 2, the changes in urea plus ammonia accounted for substantially the same fraction of the increased nitrogen in the period when glycine was being given

The excretion of creatinine during the periods of administration of glycine was unchanged as compared with the excretion during the control periods Creatine, however, was excreted in definitely increased quantities This response to glycine we have considered in detail in previous publications^{1,2} A slight increase in the excretion of uric acid by both subjects was observed This was characterized by an initial increase followed by a gradual return to approximately the levels of the control periods A marked increase occurred in the excretion of total amino acids by both subjects Analyses for amino acids by Folin's⁷ method indicated that the free amino acids accounted for only about 40 per cent of this increase It was found later, however, that the permutit sample used in these determinations absorbed both ammonia and amino acids, and subsequent analyses by the method of Van Slyke have shown that practically all of the increase in excretion of amino acid during the administration of glycine is in the free amino acid fraction Relative to the amounts of glycine involved, the increases were small, only about 3 per cent of that ingested

The increased excretion of urea, ammonia, creatine, uric acid and amino acids in the periods of administration of glycine accounted satisfactorily for all of the extra nitrogen appearing in the urine, 100 per cent and 99 per cent for subjects 1 and 2, respectively The average undetermined nitrogen fractions, therefore, were not appreciably altered by glycine, and

* We have encountered this same type of instability in the urine of several other subjects who were taking glycine

it appears that no very large amounts of unknown nitrogen-containing substances were formed, although the possibility of alterations in the character of the undetermined nitrogen fraction cannot be excluded

In table 3 the data for the sulphur partition products of the urine, and for the excretion of inorganic phosphate, are presented in a form similar to that employed in table 2. The excretion of total sulphur and inorganic sulphate by subject 1 during administration of glycine was roughly parallel to the excretion of nitrogen, while there was no change in the conjugated sulphate fraction. There was a small decrease in the excretion of total sulphur by subject 2, with a more marked decrease in the inorganic fraction. At the same time the conjugated sulphates increased considerably over the rather unusually low value of the control period. There were rather substantial increases in the excretion of neutral sulphur by both subjects. The excretion of phosphate by subject 1 was markedly increased on the first day of administration of glycine, but later returned to a level only slightly above that of the control period. On the other hand, the excretion of phosphate in the urine by subject 2 progressively decreased during the period of administration of glycine.

COMMENT

On the basis of these results it seems impossible to conclude that there is any particular metabolic abnormality in myasthenia gravis. The two subjects presented certain marked differences, particularly in respect to the balance studies. These may be ascribed to their widely different clinical conditions, and it may be suggested that the results of previous attempts to demonstrate metabolic abnormalities probably have been determined entirely by the condition of the patient when studied. The tendency toward a relative potassium balance observed in subject 1 may possibly have some significance, in view of the recent reports of Laurent and Waltham¹² that large doses of potassium salts afford temporary relief in this disease.

The response of the two subjects to administration of glycine, as shown by the nitrogen and sulphur partition products in the urine, was, on the whole, quite similar. Aside from the increased excretion of urea, ammonia, and amino acids there were small but definite changes in the excretion of creatine, uric acid, and neutral sulphur. This suggests that glycine exerts some influence on the so-called "endogenous" metabolism. On the other hand, the changes appeared at variable times after the beginning of administration of glycine, and did not run parallel courses throughout the experiments, so that it seems useless to attempt interpretations until many more data have been accumulated.

SUMMARY

In complete balance studies of two subjects who had myasthenia gravis, during which the nitrogen and sulphur partition products of the urine were also determined, it was not possible to demonstrate any metabolic abnormality which could be considered characteristic of the disease.

The type of balance obtained appeared to depend largely on the condition of the subject. One subject was in approximate equilibrium as regards the nitrogen, sulphur and inorganic constituents. The administration of glycine to this individual had remarkably little influence on the various balances. The second subject was in markedly negative nitrogen balance throughout the experiments although, during the administration of glycine, the large net loss of nitrogen was somewhat decreased. Glycine exerted little influence on the balance of the other constituents.

The extra nitrogen appearing in the urine during the administration of glycine was chiefly in the form of urea and ammonia. The urinary excretion of creatine, uric acid, amino acids, and neutral sulphur was also slightly but definitely increased.

THE TREATMENT OF ADDISON'S DISEASE WITH SODIUM COMPOUNDS, WITH THE REPORT OF ONE CASE AND THE SUMMARIES OF ELEVEN OTHER COLLECTED CASES THUS TREATED *

By EDWARD C REILNSTEIN, M D , F A C P , and EDWARD C RLIFENSTEIN, JR , M D , *Syracuse, N Y*

THE treatment of Addison's disease has undergone a marked change in the last five years. Ever since 1855, when Addison first described the insufficiency disease of the suprarenal cortex that now bears his name, investigators have been trying to devise an adequate treatment for this condition.

MUIRHEAD REGIME

Previous to 1930, physicians relied chiefly on the Muirhead regime,¹ which consisted of administering epinephrine by mouth, by rectum, and subcutaneously at frequent intervals and up to the patient's tolerance, together with "desiccated cortex" by mouth, 10 to 15 grains daily. Results from this regimen were observed in 10 to 20 per cent of the cases.

CORTICAL HORMONE THERAPY

In 1930 Swingle and Pfiffner² announced a potent extract of the adrenal cortex, and with Hartman³ and others developed the cortical hormone substitution therapy. This treatment has been of considerable value in meeting the critical episodes of the disease, and in restoring many invalids to a reasonable degree of health. Snell,⁴ however, in reporting 46 cases treated with the extract, pointed out that the patients have not been restored to full efficiency and their lives have not been indefinitely prolonged, consequently the therapy can not be considered entirely satisfactory. In addition, the cost of the cortical extract makes this form of treatment prohibitive at present.

SODIUM COMPOUND THERAPY

Recently sodium compounds have been found to have a definite place in the treatment of Addison's disease. G N Stewart⁵ in 1924 paved the way for this discovery by explaining the cause of previous discrepancies in the results of experimental adrenalectomy, as due to such factors as shock resulting from poor quality surgery, the nature and duration of the anesthesia, undue loss of heat, and lack of attention to the nutritive state of the animals before and after the operations. He found that the operations had

* Received for publication October 1, 1935.

From the Medical Service of the University Hospital, and the Department of Medicine of the Syracuse University College of Medicine.

not been performed in such a way as to insure complete removal of the glands, and in almost all instances the extirpation had not been controlled by adequate postmortem search for remaining adrenal tissue or accessory gland substance. Stewart pointed out that animals surviving only a few days after adrenalectomy cannot rightfully be assumed to be suffering from adrenal insufficiency.

Following such caustic criticism, investigators began to control their work more carefully, and results appeared which could be confirmed at other hands. Stewart himself, with Rogoff,⁶ was able to keep dogs alive for sufficient periods to rule out the question of shock, and among other observations noted that the use of Ringer's solution with dextrose intravenously, in seven out of 36 bilaterally adrenalectomized dogs, increased the span of life considerably and ameliorated the symptoms. In 1926 Banting and Cairns⁷ from their experience with 56 dogs found that saline increased the length of life. Lucas⁸ noted a fall in the chlorides of the blood in bilaterally supra-adrenalectomized dogs. In 1927 Corey⁹ reported that oral administration of large quantities of fluid to bilaterally adrenalectomized cats prolonged life, and that solutions of certain substances, notably glucose and sodium chloride, were more effective. Zwemer¹⁰ also found an amelioration of symptoms with administration of fluid following bilateral adrenalectomy. All of these investigators failed to realize the significance of the sodium ion.

The first significant step in the discovery of the value of sodium salts seems to have been taken by Baumann and Kurland¹¹ in 1927. Their adrenalectomized cats lived five to six days, consequently, they were able to compare the blood chemistry of such animals with a normal unoperated group. In the adrenalectomized animals the sodium of the blood plasma fell from a normal of 375 milli-equivalents per liter to 320, or a loss of 15 per cent, while the chlorides fell from 415 to 378, or a loss of 9 per cent. At the same time there was an increase of 42 per cent in the potassium of the plasma.

Marine and Baumann¹² studied the effect of various solutions on the length of life of bilaterally adrenalectomized cats. Their series included 167 cats, of which 101 were considered sufficiently free from possible complicating factors to be included in tables of analysis. They found that the animals would live five days without any medication, 10 days if cortical extracts were injected, and 15 days if a daily injection of 50 c.c. of normal saline was given intraperitoneally. Concentrated saline shortened the period of life, and hence it was assumed that water to bring the saline to a physiological solution was necessary. However, diuretic solutions, such as isotonic glucose, failed to prolong life materially, and therefore the value of the treatment could not be attributed to the fluid alone. Ringer's solution, physiological saline, sodium acetate, and sodium glycono-phosphate were found to have about the same effect, and consequently it appeared that the sodium and not the chloride is important. They felt their evidence indicated a specificity in the action of the sodium ion.

The next and most important step was taken by R F Loeb¹³ who made a complete analysis of the inorganic bases of the blood plasma of patients with severe Addison's disease. The normal level of sodium in the blood plasma he assumed to be about 138 milli-equivalents per liter (317.4 mg per cent), which corresponds well with the figure of 140 milli-equivalents given by Butler and Luthill¹⁴. Loeb found the chief abnormality in his patients to be in the sodium content, which in three cases was respectively 109, 131, and 108 milli-equivalents per liter (250, 301 and 248 mg per cent), a definite decrease in each instance. The potassium content was very high, in two cases being 8.7 and 7.1 milli-equivalents per liter (34 and 27.7 mg per cent), the normal being 4.8 (18.7 mg per cent), the chlorides being reduced to 70 and 73 (248 and 259 mg per cent), the normal being 103¹⁵ (365.6 mg per cent).

Working with Atchley, Benedict, and Leland, Loeb then made studies of the inorganic base balance in three dogs before and after adrenalectomy¹⁶. The removal of only one adrenal gland produced no change in any of the dogs, but the removal of the remaining gland caused a decrease in the sodium of the blood-serum from 147 to 126 milli-equivalents per liter, while the potassium level was slightly elevated. At the same time the sodium in the urine increased markedly, and the chlorides were increased also, but not to the same extent as the sodium.

These observations were confirmed by Harrop, Soffer, Ellsworth, and Trescher¹⁷. They produced bilateral adrenalectomy in dogs, and then maintained them in a state of normal health with cortical extract until the animals had fully recovered from the effects of the operation. Upon ceasing the extract, the dogs had a characteristic alteration in the blood and urinary findings: the plasma concentration increased, the sodium concentration in the plasma decreased, and with it the chlorides and part of the body water, while the potassium and magnesium were increased. At the same time within 48 to 72 hours the sodium, chloride, and water excretion in the urine was much increased. When the extract was resumed, there was retention of sodium, and with it chloride and water in the body in excess of the excretion. This continued until the animals returned to normal. In another series of dogs, the extract was continued, and the animals fed a salt-poor diet, following which insufficiency appeared. The dogs were returned to a normal state by injections of salt alone. These same animals were then placed on the identical salt-poor diet, with 1.5 grams of salt added, and no evidence of insufficiency appeared. From this, these investigators suggested that the dosage of the cortical extract may be reduced to a fraction of its original amount by using a high salt diet with it.

The proof of the connection between sodium and dysfunction of the adrenal cortex was finally established by Loeb,¹⁸ who gave a patient salt and found marked improvement. The patient, a woman, on admission had a classical picture: progressive weakness, loss of appetite and weight, increasing pigmentation of skin, nipples, and buccal membranes, mild sec-

ondary anemia and a blood pressure of 90 systolic and 60 diastolic. At that time the sodium concentration of her blood was 123 milli-equivalents per liter (284 mg per cent), normal being 138 (317.4 mg per cent). One week later the sodium had fallen to 107 (247.9 mg per cent), and the woman was in a much more severe condition, with profound exhaustion, slight dyspnea, increasing nausea, and recurrent vomiting. The chlorides had decreased proportionally, the potassium had risen and the blood pressure was 65 systolic and 48 diastolic. She was given 9.5 grams of sodium chloride daily by proctoclysis, and 5 grams a day by mouth in capsules. Within four days the clinical improvement was so striking that rectal administration was stopped, and the convalescence maintained with five to seven grams of salt a day in addition to a liberal amount in the diet. She continued to gain, and was discharged on a regular diet plus one and a half teaspoonfuls of salt daily.

She remained well for five months, gained seven pounds, and was able to do her housework. Her sodium level was then entirely normal. At this stage she developed some edema under the eyes, and was advised to take a low salt diet, containing about 2 grams of sodium chloride. Two days later she was so weak she had to go to bed, and for the next five days became progressively weaker and vomited at frequent intervals. She was readmitted to the hospital and was found to have a low serum sodium reading of 126 milli-equivalents (291.6 mg per cent), with a low chloride and a high potassium level. She was immediately given seven grams of sodium chloride by mouth, and a rectal drip of 200 c.c. of physiological saline every four hours. No other treatment was used. Within three days she had improved to such a remarkable extent that the rectal instillations were stopped, and she was discharged on the eighth day in excellent health, having gained four pounds. Her blood chemistry was again entirely normal. Subsequently Loeb¹⁰ reported that more than two years after the first admission the same patient continued to maintain her improvement, and complained only of usually feeling cold and of tiring rather easily. On her own initiative she had increased the sodium chloride to 15 grams daily. The blood sodium level and the blood pressure were still normal, with the pigmentation slightly decreased.

Loeb, Atchley, Gutman, and Jillson²⁰ have repeated this experiment on another patient. She was at first allowed to eat an ordinary diet with as much salt as she wanted. On this she was able to be up in the ward, although she complained of nausea, occasional abdominal pain, and slowly increasing weakness. She was then put on a low salt diet, and immediately became worse, with dizziness, nausea, and marked prostration, so that at the end of the first day she had to stay in bed. The sodium level in the serum, which had been falling gradually during the normal diet, took a decided drop after 48 hours on the low salt diet. The addition of excess salt to the diet led to rapid recovery, and the patient was able to get up in

two days, and leave the hospital in five, when the sodium had risen again to normal. She was instructed to continue oral salt in addition to a highly seasoned diet.

These observations have been confirmed by Hariop, Weinstein, Soffer, and Trescher²¹. They found that with a high salt diet they could diminish the potency of the cortical extract to such an extent that it would not have any effect in prolonging the lives of adrenalectomized dogs, and yet the patients remained symptomless, and continued to gain weight and strength on it for nine months. However, when the extract was replaced with a 'hypo' of sterile water in one patient, there was a relapse after six weeks. The patient improved again when put back on the low potency extract and the high salt diet. The authors then placed the patient on a low salt diet, while continuing the extract, and within two days the patient lost appetite and complained of great weakness. The sodium and the chloride levels in the blood serum were considerably lowered. When treated with intravenous saline the patient gradually improved, and 22 days after the start of the experiment, the blood findings were again essentially normal. The same workers had similar results in another case, with a definitely low sodium level, which was restored to normal after one week on a high salt diet and oral salt. The authors then removed the extract entirely from four patients, and placed them on a highly seasoned diet with additional salt. All continued to feel strong, were found to tire less easily, and were relieved of the persistent recurring nausea and vomiting that had been present before treatment. There was a definite gain in weight in one patient.

In January 1934, Sears²² in England studied a case of Addison's disease of seven years' duration. He found the blood sodium level to be very low on admission. After one week on a regular diet and sodium chloride by mouth daily, the sodium level had risen to well above normal, and there was marked subjective improvement. The patient was discharged on a maintenance dosage of salt. Shortly after, Snell²³ at the Mayo Clinic reported a case of Addison's disease of exceptionally long duration (17 years). The extended course of the disease seemed to be partially attributable to the fact that the patient of his own accord had been using salt excessively for the past few years. The patient had an acute episode in May 1934, and was treated with cortical extract and sodium chloride daily with marked clinical improvement but no change in the electrolytes of the blood. Howell²⁴ in England in May 1934 found the blood sodium level in a case of Addison's disease of six months' duration to be only slightly decreased on admission. He placed the patient on sodium chloride and reported a dramatic effect in 24 hours, with the patient changed from a listless, apathetic invalid to an alert individual sitting up in bed, reading. When the salt dosage was cut in half without the patient's knowledge, anorexia, weakness and vomiting occurred within one week. The patient was restored to normal by returning to the original dosage.

THE SALT-POOR DIET CONFIRMATORY TEST FOR ADDISON'S DISEASE

Harrop, Weinstein, Soffer, and Trescher²¹ suggested that the withdrawal of salt from the diet should be used to confirm the presence of Addison's disease. They recommended that this test should be used only if large amounts of potent cortical extract are available, as the condition of the patient may be very alarming after 24 to 48 hours on a low salt diet. If, however, the patient is no worse for the deprivation of salt, it must be considered extremely unlikely that he has Addison's disease.

Nettrour and Rynearson²⁵ at the Mayo Clinic made use of this test in the case of a 21 year old boy with a typical history of nausea, vomiting, and extreme weakness and fatigue, but without the characteristic pigmentation. On admission the blood pressure was 78 systolic and 52 diastolic while reclining, the sodium and chloride levels were considerably decreased, the basal metabolic rate was subnormal, and there was a mild secondary anemia. The patient was placed on a salt-poor diet for five days, with a marked increase in the severity of the nausea, vomiting and prostration, while the chloride fell to a very low level. Intravenous physiologic saline, cortical extract, and sodium chloride by mouth daily restored the patient to normal in four days, the blood electrolytes returning to approximately normal level. The therapeutic test of the salt-poor diet as an aid in the diagnosis of Addison's disease was therefore entirely successful.

Touw and Noordhoek Hegt²⁶ in Holland observed clinical manifestations and blood chemistry of two patients with Addison's disease during periods of normal, salt-poor, and excessive salt diets. There was a noteworthy parallelism between the clinical improvement of the patients and the rise of the sodium content of the blood after the oral administration of 20 to 35 grams of sodium chloride daily.

Loeb^{19b} recently reported a case clearly demonstrating the serious consequences that may follow the salt-poor diet test. His patient after four days of salt deprivation suddenly developed shock, although only a relatively small decrease of the sodium level was present, and then continued in an alarming state in spite of large amounts of cortin, fluid and salt. Hypoglycemia, ketosis, and dehydration were found to be complicating the picture, and were combated for a week with a continuous infusion of salt and dextrose before the patient was considered out of danger. Loeb says significantly, "It is unfortunate that a diagnostic procedure so highly specific as is salt withdrawal in Addison's disease should be attended by such grave consequences to the patient."

ANTERIOR LOBE PITUITARY EXTRACT THERAPY

Wilder²⁷ at the Mayo Clinic in November 1934 reported two cases of Addison's disease treated with cortical extract, sodium chloride by mouth, and anterior lobe pituitary extract. He pointed out that the majority of the patients with Addison's disease required a larger than normal supply

of sodium chloride even when receiving adequate amounts of cortical extract, and suggested a secondary deficiency in the hormone of the anterior lobe of the pituitary body because of changes in the basophile and chromophile cells of that gland found in cases of Addison's disease²⁸. He showed, as had previous workers, that the patients could be restored to approximately normal health with cortical extract and oral sodium salts, and that relapses occurred when either of these forms of medication was discontinued. He found, however, that when anterior lobe pituitary extract was given in addition to the cortical extract and the salt, the patients felt stronger and were considerably less sensitive to the deprivation of the sodium chloride. Wilder suggested that this sensitiveness may be due to secondary insufficiency of the anterior lobe of the pituitary associated with the adrenal insufficiency in Addison's disease.

THE SPECIFICITY OF THE SODIUM ION

It was pointed out by Loeb and his associates²⁹ that there is apparently a specific relation between the sodium ion and the adrenal glands. He suggested that these organs play an important rôle in the regulation of the sodium metabolism in the normal body, analogous to that of the parathyroid with calcium and phosphorus, and that the sodium depletion occurring in adrenal insufficiency is dependent therefore on a disturbance of this normal function. There is loss of sodium without a change in potassium excretion, whereas in other clinical states with base loss the sodium depletion is accompanied by a parallel loss of potassium, as in starvation,²⁹ diabetes,³⁰ ammonium chloride acidosis,³¹ and severe diabetic glycosuria.³⁰ Zwemer³² in 1934 reviewed the experimental data and similarly concluded that the adrenal cortex has a regulative effect on the salt and water metabolism of the cell.

The experimental evidence of the specificity of the sodium ion in adrenal cortex insufficiency can be found in the work of Marine and Baumann¹² already cited. They showed that the various isotonic fluids that were effective in prolonging the life of bilaterally adrenalectomized cats contained only the sodium ion in common, and that isotonic solutions such as glucose failed to prolong life materially.

Clinically this point was clearly demonstrated in the case reported in March 1935 by Blankenhorn and Hayman³³. They treated a case of Addison's disease of three months' duration with oral sodium chloride daily, and obtained subjective and clinical improvement. The blood sodium content and the blood pressure rose from low levels to approximately normal. The provocative salt-poor diet test readily confirmed the diagnosis. When the salt medication was discontinued the patient promptly had a relapse with weakness, anorexia, nausea and irrationality, and the blood chlorides again fell to a low level. The patient failed to respond to cortical extract intramuscularly and intravenously, and it was only by giving saline intra-

venously that he was saved from imminent disaster. The patient was then returned to oral salt daily, and remained in good health for several weeks. At that point it was decided to test the specificity of the sodium ion. Accordingly the sodium chloride was replaced by other chloride salts. In three days the patient developed abdominal pain, nausea, and vomiting. Intravenous saline and oral sodium chloride then restored the patient to normal, and after two weeks the patient was in excellent health. A mixture of sodium salts, the sulphate, the phosphate, and the bicarbonate, containing an amount of sodium equal to that previously given, was then substituted. This was given for 17 days without any discomfort, with the patient continuing apparently well. The specificity of the sodium ion was thus clearly demonstrated. The patient was put back again on sodium chloride medication, and after two weeks in spite of 16 grams daily, developed a severe crisis complicated by bronchopneumonia and expired.

We obtained similar results with the case herein reported. After demonstrating the improvement of the patient on sodium chloride and, after confirming the diagnosis with the salt-poor diet test, we restored the patient to normal by oral sodium chloride and then placed him on a mixture of sodium biphosphate and sodium bicarbonate. This sufficed to maintain excellent health according to all tests, for over two weeks, again demonstrating the specificity of the sodium ion.

THE PROLONGATION OF LIFE

The question of how much prolongation of life can be expected from these therapeutic advances naturally arises. Experimental adrenalectomized animals apparently can be kept alive almost indefinitely with injections of potent cortical extract. The effect of sodium salts alone on adrenalectomized animals has been studied by several investigators.

Rubin and Krick³⁴ found that untreated bilaterally operated rats could not be kept alive over 10 days, but if while exhibiting symptoms of severe insufficiency, they were given a special solution of calcium, magnesium, sodium and potassium chlorides, they could be restored to normal in four to five hours, and could be kept alive over four months. Gaunt, Tobin and Gaunt³⁵ in October 1934 studied another series of bilaterally adrenalectomized rats. Only four of the adult control series of 24 survived over 30 days. The experimental series of 23 rats was given a sodium chloride solution for 30 days following the operation. Five animals succumbed 14 to 25 days after operation with typical symptoms of adrenal insufficiency, six animals survived the treatment period and were in good health, but when returned to normal diet and distilled water, developed adrenal insufficiency and died in 10 to 15 days, 12 animals, approximately 50 per cent, survived in good health and remained well afterwards on normal diet and distilled water. When killed and autopsied eight or more weeks later, seven of these were found to have accessory glands.

Swingle, Piffner, Vais, and Parkins²⁶ fed sodium chloride to the point of tolerance to seven bilaterally adrenalectomized dogs while withholding cortical extract. Three animals remained free from symptoms for 14 days, one for 12 days, one 21 days, one 19 days, and one 50 days. Salt was withdrawn from the diet of the long surviving animal on the fiftieth day, and four days later the dog exhibited severe symptoms of insufficiency. They found that the interval between cessation of extract injections and development of adrenal insufficiency was somewhat prolonged by the feeding of sodium chloride, but concluded that the sodium chloride and water could not be regarded as an effective substitute for the cortical hormone in the bilaterally adrenalectomized dog since it was necessary to inject cortical extract to save the animals when they sooner or later developed severe symptoms.

Zwemer³² reported similar results on a series of completely adrenalectomized cats. The average length of life in the control group was 10 days, while the average survival period of the experimental animals, which were treated with a number of different sodium compounds, was 18.4 days.

It appears from this experimental work, therefore, that as far as animals are concerned, the administration of sodium compounds alone without cortical extract in adrenal insufficiency will increase the span of life to some degree but not indefinitely, and that sodium salts are therefore not substitutes for the cortical extract. In some animals, however, the presence of accessory adrenal glands (as in rats) makes the adrenal insufficiency only a relative matter, and in such cases the sodium compounds, by delaying the appearance of the symptoms, will allow time for this accessory gland substance to hypertrophy sufficiently to permit the animals to survive indefinitely.

Clinically, however, sodium medication alone seems to have been more successful. Loeb's¹⁹ original classic patient is still feeling well after two years on salt, and of the eight patients he has studied since 1932, six are still alive in fairly good health. Our patient has been in good health for over six months, and others have reported similar results. Harrop and associates³¹ kept four patients symptomless for nine months with sodium medication and a cortical extract that was too weak to prolong the lives of adrenalectomized dogs. The death of Blankenhorn and Hayman's³³ patient in spite of 16 grams of sodium chloride daily is less encouraging, although a bronchopneumonia complicated the picture. The fact that Snell's²³ patient had been consuming salt excessively for several years before receiving medical attention may partially explain the unusually long duration of that case. Whether sodium salts alone will suffice to keep patients alive indefinitely remains to be seen, and depends, perhaps, on the hypertrophy of the remaining undiseased portions of the adrenal glands in the individual case.

THE DOSAGE OF SODIUM CHLORIDE

In treating Addison's disease with sodium chloride it is recommended that the dosage of salt be large—10 to 15 grams a day.³⁷ Loeb²⁰ treated a

case with 20 grams daily, and the Holland investigators²⁶ have used as much as 35 grams daily. Divided doses seem to be most suitable, given either in milk, capsules, or tablets. We have had considerable success with plain uncoated one gram tablets. Enteric-coated tablets should be used with caution, as the coating may fail to dissolve.²⁵

In some patients it may not be possible to maintain health without the use of cortical extract, and others at first maintained satisfactorily on salt alone may later need the glandular preparation, but the dose of the extract in such cases is likely to be much smaller than if no additional salt were given. The extract of the anterior lobe of the pituitary should be tried in addition in refractory cases, as suggested by Wilder.²⁷

CASE REPORT

A G, aged 39, an Italian male, was admitted to the University Hospital, December 9, 1934, complaining of nausea, vomiting, chills, fever, and extreme weakness of 48 hours' duration.

His family history failed to reveal any hereditary tendencies. His past history showed pneumonia at 17 years of age, malaria at 24 years of age, and an appendectomy at 30 years of age. Otherwise he had been well until the present illness. He denied venereal disease. The patient has lived in the United States for 11 years, and has a wife and four children, living and well.

The patient stated that he had suffered from a similar attack in May 1932, which confined him to his bed for one month. Shortly after the onset of this original attack he noticed increasing prostration and darkening of his skin. Except for these two manifestations his condition remained unchanged until June 1934 when he was again confined to his bed with extreme weakness, and remained prostrated throughout the month of July. In August, notwithstanding the increasing fatigue, he worked as a laborer for the County Welfare Organization, but found the exertion required a great effort. Finally he became so weak that he could not continue. On December 8, 1934, the day before admission to the hospital, he suddenly developed an acute episode consisting of bowel movements every 20 minutes associated with frequent attacks of vomiting, severe chills, marked dyspnea, excessive perspiration, and generalized aches and pains.

The patient was admitted to the hospital by ambulance, acutely ill and in a state of collapse. The significant findings on physical examination were extreme prostration, emaciation and dehydration, marked pigmentation of the face, hands, axillae, elbows, knees, buccal membrane, and anal margin, feeble, distant heart sounds, blood pressure 58 systolic and 36 diastolic, flat abdomen, temperature elevated to 100 degrees, and radial pulse of 80 beats per minute. A diagnosis of Addison's disease was made, and a clysis of glucose and normal saline was given immediately. Laboratory studies on admission revealed hemoglobin 110, red cells 5,400,000, white cells 8,000, non-protein nitrogen 75 mg per cent, blood sugar 95 mg per cent, chlorides 335.1 mg per cent, serum protein 6.1, albumin 5, globulin 1. The urine contained acetone, diacetic acid, albumin, red cells, and granular and hyaline casts. Roentgen-ray evidence of an old tuberculous lesion affecting the upper right lung field was reported, but no calcified areas could be visualized in the kidney regions.

For the following six days he was given frequent clyses of glucose and normal saline, with slight improvement at first so that there was less nausea, vomiting, and restlessness. During this interval the blood pressure rose temporarily to 86 systolic and 58 diastolic, and then fell steadily to 73 systolic and 50 diastolic, the non-protein nitrogen remained elevated and the blood chlorides continued below normal. On

the night of December 17, eight days after admission, the patient became irrational, got out of bed, and attempted to get into bed with another patient. This episode occurred after a restriction of fluids. The following day two grams of sodium chloride were given every four hours with decided improvement, so that within 24 hours the patient was cooperative and cheerful. The non-protein nitrogen was then 46, and the blood pressure 89 systolic and 57 diastolic, with marked improvement in the condition of the patient, and at the end of 72 hours he was sitting up in bed reading. The sodium chloride was increased to 15 grams daily, whereupon the non-protein nitrogen became normal and the blood chlorides increased to 366.6 mg per cent.

One week later the patient was in excellent health, feeling better than he had for many months. At this point it was decided to confirm the diagnosis with a salt-poor diet. He was placed on this regime and all other medication was withheld. Within 12 hours he complained of increasing fatigue, which was followed by extreme restlessness and marked prostration. His sufferings excited the sympathy of a fellow ward patient who gave him a salt shaker when the attendants were not watching.

FIG 1 The typical low blood pressure and chloride levels and the elevated NPN in Addison's disease are relatively unaffected with fluids alone, but with sodium chloride are quickly restored to normal. The salt-poor diet confirms the diagnosis by reestablishing the original disease levels. Sodium medications other than the chloride prove equally efficacious in maintaining the values at normal levels. (The blood chloride and non-protein nitrogen levels were determined in every case after an overnight fast. The blood pressure values were calculated as an average of 9 to 12 readings over a period of 24 hours starting at 8 a.m. each day. All medications were given in 6 equal doses daily at 6, 9, 12, 3, 6, and 9 o'clock respectively. The sodium chloride was administered in 1 gram uncoated tablets, the sodium bicarbonate and sodium biphosphate were first given in tablet form, but the size of each dose made this unsatisfactory, later the bicarbonate was given as a powder followed by the biphosphate in solution with syrup of sarsaparilla, proving to be a convenient method of administration. The sodium sulphate was given in 2 gram capsules, but was discontinued because of the effect on the bowel. The subcutaneous and intravenous fluids consisted of physiological saline and 5 per cent glucose. The salt-poor diet consisted of the usual house diet with certain foods of high salt content exempted, served without a salt shaker. The chloride values are given as chloride in plasma.)

The following day further restriction of salt was attempted, and the patient soon exhibited marked dyspnea and restlessness, profound prostration, anorexia and vomiting. The blood pressure dropped to 65 systolic and 44 diastolic and the non-protein nitrogen returned to 66.

The effect of the salt-poor diet was thought sufficiently conclusive to terminate the test at this point. Four hundred c c of a 2 per cent sodium chloride solution were given intravenously with marked subjective improvement within several hours. The patient was then returned to 15 grams of sodium chloride daily by mouth, and in three days was again in good health.

It was decided to demonstrate the specificity of the sodium ion by substituting other sodium salts for the chloride. Sodium sulphate was used, but soon proved unsatisfactory because of the effect on the bowel. Sodium bicarbonate as a powder, and sodium biphosphate in solution with syrup of sarsaparilla were then given in quantity sufficient to supply sodium equal to that in 15 grams of sodium chloride. The patient continued to improve on this therapy for 18 days. The blood chemistry studies re-

vealed normal findings, and the blood pressure remained 85 systolic and 52 diastolic throughout the period. The serum protein, the albumin-globulin ratio, the carbon dioxide combining power of the blood, the glucose tolerance test, and the basal metabolic test were all within normal limits. The specificity of the sodium ion was apparent.

The patient was then returned to 15 grams of sodium chloride daily, and after another week of continued good health was discharged on a maintenance dosage of 12 grams a day. Because of the expense of supplying sodium chloride in tablet form, the municipal dispensary placed the patient on 12 grams by mouth in bulk. On this the patient soon developed oral and gastric distress, and lapsed into a state of restlessness and weakness. He was quickly restored to excellent health by substituting 1 gram tablets for the bulk salt. The patient has continued to take his medication daily and has remained well for nearly six months at this writing*. Figure 1 and table 1 show the effect of sodium medication on the blood chloride, blood non-protein nitrogen, and blood pressure levels in this case.

The 11 cases of Addison's disease treated with sodium compounds, which are summarized in the body of this article, represent the previously

* April 1936. Fourteen months after discharge our patient is in excellent health, with a blood pressure systolic 110, diastolic 74. He is faithfully taking 12 grams of sodium chloride each day.

published cases as determined by a search of the literature. The effect of sodium medication on the blood sodium level in nine of these is shown in figure 2 and in table 2.

FIG 2 The blood sodium levels in nine cases of Addison's disease collected from the literature were below normal before any treatment with sodium compounds was instituted. On an excess salt regime there was a rise in the level in every instance except in case 6, where the value was unchanged. There was a fall in the level in all cases on a salt-poor regime, and a rise toward normal in all when excess salt was again given. (The blood sodium levels of the various authors have been converted to milli-equivalents per liter in order that this comparison could be made. The milligram per cent values are given with the case summaries. The sodium is expressed as sodium in plasma, not whole blood. The normal value of 138 milli-equivalents per liter is that given by Loeb¹⁸.)

CONCLUSIONS ON THE RELATION OF SODIUM TO ADRENAL DYSFUNCTION

1 The sodium level in the blood serum is found to be considerably decreased in bilaterally adrenalectomized animals.

2 In patients suffering from Addison's disease a similar decrease in the sodium level of the blood serum is present.

3 Sodium solutions will prolong the life of adrenalectomized animals, and when used with cortical extract, the amount of cortical preparation re-

quired is much diminished. Sodium solutions alone will not prolong the life of adrenalectomized animals indefinitely, unless accessory glands are present and hypertrophy sufficiently to supply adequate cortical hormone. Sodium compounds therefore are not a substitute for cortical extract but an adjuvant.

4. Sodium administered to patients with Addison's disease will either render them symptomless, or else minimize the amount of cortical extract required to maintain them in relatively good health. In some cases sodium alone will bring about a complete remission of a severe relapse. Several patients treated with sodium salts alone still continue to remain well after more than a year, and the span of life of many other patients to date seems to have been indefinitely prolonged.

5. The loss of cortical hormone in Addison's disease apparently removes the normal regulatory mechanism of the blood sodium level, which consequently falls, initiating the train of symptoms known as adrenal insufficiency. An associated secondary deficiency in the hormone from the anterior lobe of the pituitary body has recently been suggested.

6. A confirmatory test for Addison's disease of considerable value is the salt-poor diet, which will provoke a typical crisis in a true case of adrenal insufficiency and thereby aid in establishing the diagnosis.

SUMMARY

1. The treatment of Addison's disease by the Munhead regime, and by cortical extract substitution therapy is briefly outlined.

2. The experimental and clinical evidence of the value of medication with sodium compounds in this disease is reviewed.

3. A case of Addison's disease which illustrates the beneficial thera-

		10 13 34 After 21 mo on NaCl	More than 2 years after first admission still relatively well	—	—	—	—	—	—	—	NaCl continued
2	Loeb et al. ²⁰	Before admission	Past history of tuberculous hip and pleurisy with effusion. Irregular abdominal pain and occasional vomiting for 2 years. Increasing brown pigmentation for 1 year. Weakness and dyspnea with slight cough for 6 months	112/80 to 76/50	—	—	—	—	—	—	None
		Admission, placed on normal diet	Up and about the ward for 18 days with nausea, occasional abdominal pain, slowly increasing weakness	—	135	310 5	—	—	—	—	Salt-poor diet
		After 2 days on salt-poor diet	Much worse with dizziness, nausea, increased prostration. Vomited 200 cc in 48 hours	—	124	285 2	—	—	—	—	20 grams NaCl orally daily
3	Harrop et al. ²¹	After 2 days on NaCl	Improved remarkably, out of bed	—	—	—	—	—	—	—	Oral salt continued
		After 5 days on NaCl, discharged	Much improved	—	138	317 4	—	—	—	—	Maintenance dosage 10 grams NaCl daily with highly salted diet
		Admission	Known case of Addison's disease with roentgen ray evidence of calcification	—	—	—	—	—	—	—	High salt diet and low potency cortical extract
		After 9 months on high salt diet and low potency extract	Patient symptomless, gaining weight and strength	—	—	—	—	—	—	—	High salt diet and sterile hypo instead of extract
		After 6 weeks on high salt diet and sterile hypo	Relapse	—	—	—	—	—	—	—	High salt diet and low potency cortical extract resumed
		After several days on high salt diet and low potency extract	Improved	—	134 8	300 0	106 8	379 1	—	—	Low salt diet and low potency cortical extract
		After 4 days on salt-poor diet and low potency extract	Marked weakness and anorexia, severe relapse	—	106 6	215 1	81 2	288 2	—	—	Low salt diet discontinued. Intravenous saline begun, cortical extract continued

Summaries of 12 Cases of Addison's Disease Treated with Sodium Compounds—Continued

Summaries of 12 Cases of Addison's Disease

6	Snell (Cont.)	1923 to 1929	Extreme weakness, increased pigmentation, palpable cervical glands, rales in both apices, roentgen ray of lungs positive on admission in 1923. Improved sufficiently on Muirhead regime to go home in 2 weeks where it was continued. 1924 tuberculous adenitis proved at biopsy. Radium treatment 1929 in good health. Muirhead treatment stopped.	110/80 100/75	—	—	—	—	—	—	Muirhead treatment epinephrine orally, rectally and subcutaneously at frequent intervals up to patient's tolerance daily with desiccated cortex orally 10 to 15 grams daily
		1929 to 1934	1932 failing strength, increasing fatigue marked craving for salty food. March 1934 losing weight.	—	—	—	—	—	—	—	None
		5 16 34 Admission	Marked weakness, confusion, loss of memory, severe constipation, pigmentation of exposed surfaces, oral mucosa and genitalia, weak, faint heart, both adrenals calcified on roentgen ray.	110/65	134 7	310 0	92 9	330 0	4 9	19 3	Intramuscular cortical extract (Kendall), sodium chloride 10 grams orally, and 1 liter physiologic saline daily
		After several days discharged	Much improved in 24 hours, followed by gain in weight, increased appetite and strength.	—	134 7	310 0	105 8	375 6	4 9	19 3	10 grams NaCl daily recommended on discharge
Wilder 7		July 1934 after 2 months on 10 grams NaCl daily	Well for 2 months. Admitted again in mild crisis improved with treatment, discharged.	—	—	—	—	—	—	—	6 c.c. cortin, 8 grams of salt pills and salt diet daily
		9 30 34 Admission after 2 months on 6 c.c. cortin and 8 grams NaCl daily plus salt diet	Severe crisis with abdominal pain, nausea, vomiting, restlessness, hic cough and extreme weakness.	—	—	—	—	—	—	—	Cortin and 0.9% NaCl by vein for 2 days, then 6 mg. cortin and 8 grams NaCl in pills plus 6 grams in diet daily
		10 4 34 After cortin and NaCl intravenously and orally	Out of bed but still weak and rest less.	—	—	—	—	—	—	—	0.3 c.c. anterior pituitary extract daily in addition
		10 9 34 After 5 days on cortin, NaCl and anterior pituitary	Marked improvement stronger than in many months.	—	—	—	—	—	—	—	Salt pills omitted, receiving only 6 grams NaCl in diet, cortin and anterior pituitary extract continued.
		10 11 34 After 4 days on cortin and anterior pituitary only	Weaker with nausea and hic cough.	—	—	—	—	—	—	—	NaCl by vein, daily salt pills resumed, cortin continued, anterior pituitary extract stopped.
		10 23 34 After 8 days on cortin and NaCl	Improved, some residual weakness.	—	—	—	—	—	—	—	—

THE LEUKOCYTE PICTURE IN HODGKIN'S DISEASE *

By GRACE M. ROTH, B S , and CHARLES H. WATKINS, M D , F A C P ,
Rochester, Minnesota

ALTHOUGH Hodgkin's ¹ disease was described by him as early as 1832, the blood picture in this disease was not seriously considered until 1910. At that time Fabian,² after a critical survey of the literature, reported that the blood picture was not sufficiently constant to be of any diagnostic value. He did state, however, that the most frequent hematologic finding in Hodgkin's disease was a moderate increase in the number of polymorphonuclear neutrophils and a relative decrease in the number of lymphocytes.

In 1911, following this survey, Bunting³ reported the analysis of a small series of blood counts in cases of Hodgkin's disease and described a specific blood picture for the diagnosis of the disease. He divided his cases into two distinct groups according to the differential count. In the first group, in which the disease had been present for less than a year, there was a normal or decreased percentage of polymorphonuclear neutrophils, in the second group, in which the disease had been present for more than a year, there was marked leukocytosis with an increase in the number of polymorphonuclear cells from 72 to 90 per cent. The transitional cells or monocytes were increased in both groups, the lymphocytes were sometimes increased in the early cases but showed a steady decrease as the disease progressed. Bunting also maintained that on examination of the blood smear a definite increase in the number of platelets was found.

In 1914 Bunting⁴ and Yates⁵ reported an additional group of cases of Hodgkin's disease with the same hematologic findings. In the period from 1915 to 1920 these findings of Bunting's were generally confirmed in isolated reports of cases. Also reported in this period were rare cases in which eosinophilia was present. The relationship between leukemia, sarcoma, and Hodgkin's disease received considerable attention at this time. Although the blood smear was used for differential diagnosis in some instances, the pathologic changes observed in excised lymph nodes were the criteria for differential diagnosis.

In 1920, however, Longcope and McAlpin⁶ in a comprehensive study of Hodgkin's disease stated that changes existed in the blood, which were so characteristic that they could be used to differentiate this disease from all other types of enlargement of lymph nodes. These constant changes consisted of a relative or absolute increase in the number of transitional cells (monocytes) and a total increase in the number of platelets throughout the

* Abstract of paper read before the Central Society for Clinical Research, Chicago, Illinois, November 1, 1935.

From the Mayo Foundation and the Division of Medicine, the Mayo Clinic, Rochester, Minn.

course of the disease. Relative or absolute eosinophilia seemed to be most marked when there was necrosis of the lymph nodes.

Following this survey with Longcope, in 1923 McAlpin⁷ studied 18 cases of Hodgkin's disease and arrived at conclusions somewhat contradictory to those of the earlier report. He stated that it would not be possible to diagnose Hodgkin's disease from examination of the blood smear. In this series of 18 cases the number of transitional cells was high in only eight cases and the platelets only in seven. When the cases were arranged in the order of their total leukocyte count there was no apparent relationship between this and the duration of the disease. The highest leukocyte count was 13,000 per cubic millimeter.

Weiss⁸ in 1924 reversed the original idea of an increase in polymorphonuclear neutrophils as being the most important finding and considered it to be instead the decrease in the number of lymphocytes. He stated that the neutrophils and eosinophils might be increased in number, and further suggested that a leukocytosis exceeding 20,000 cells per cubic millimeter warranted the suspicion that the diagnosis of Hodgkin's disease was incorrect.

The largest and most completely studied group of cases of Hodgkin's disease up to 1930 was reported by Falconer⁹. He had observed 40 cases, which he divided into two groups as Bunting had done. Falconer concluded that in the first group, in which the disease was of less than a year's duration, the total leukocyte and differential counts were within normal limits, whereas in the second group, in which the disease was of more than a year's duration, only a slight increase in the total leukocyte count occurred, with a slight increase in the percentage of polymorphonuclear cells at the expense of a decrease in the number of lymphocytes. Although Falconer had used Bunting's grouping of cases, his observations did not quite agree with the latter's. Falconer found, however, an average and fairly constant increase in the number of mononuclear cells. The eosinophile count averaged about normal or slightly below normal, although in one instance the percentage was very high. The platelet counts in Falconer's cases were not high.

Straube,¹⁰ in 1931, summarized his findings in 21 cases of Hodgkin's disease. He decided that no uniform or diagnostic hematologic picture for Hodgkin's disease existed, and that it was therefore not possible to establish the diagnosis on the basis of hematologic examination alone.

Thus the views regarding the diagnostic value of the blood picture in this disease differ greatly. Some workers consider the blood picture to be characteristic of the disease, whereas others are of the opinion that no characteristic blood picture exists. If there is a characteristic blood picture, it must have to do with the differential leukocyte count, as most investigators have found that in regard to the erythrocytes in general, a slight secondary anemia exists which is not in itself characteristic.

The present study was therefore undertaken to determine the diagnostic value of the blood picture in Hodgkin's disease. Owing to the fact that the method of determining blood platelets was changed during the course of this study, the platelets were not considered.

PLAN OF STUDY

The differential counts were made from blood smears in cases in which a diagnosis of Hodgkin's disease or lymphosarcoma was confirmed by pathologic study of an excised lymph node. The criteria for the diagnosis of lymphosarcoma were loss of normal architecture of the lymph node, absence of lymph follicles, and marked hyperplasia of the cellular elements, and for Hodgkin's disease fibrosis, with an increase of connective tissue throughout the node, presence of Dorothy Reed cells, and an increase in the number of eosinophiles in the node²¹. None of the patients had had any previous treatment. The duration of the disease was noted, and the cases were divided into four groups depending on the state of the disease when the patient was admitted to the clinic. Group I included those cases in which the disease was of six months' duration or less, group II included those cases in which the disease was of more than six but not more than 12 months' duration, group III included those cases in which the disease was of more than a year's but not more than two years' duration, and group IV included those cases in which the disease was of more than two years' duration. The longest duration was 13 years. The cases were also divided into four groups according to the situation and extent of the disease. Group A in which a single cervical, supraclavicular, or axillary lymph node was involved, group B in which a single inguinal lymph node was involved, group C in which two cervical, axillary, or supraclavicular lymph nodes were involved or in which a single lymph node in two of these situations was involved, and group D in which there was general adenopathy.

DATA

Sixty-five differential counts were made from blood smears in 40 cases of Hodgkin's disease and 18 differential counts were made from blood smears in nine cases of lymphosarcoma.

Group I In 12 of 25 differential counts, or 48 per cent, the percentage of neutrophils was greater than 68, the highest being 85. The shift to the left was not marked, the nonfilament count of the polymorphonuclear neutrophils being only 81 cells in 200. The average percentage of lymphocytes was well within the normal limits of 25 to 30. In 15 of 25 counts, or 60 per cent, the percentage of lymphocytes was less than 25, in 20 per cent of the counts it was greater than 30. The average percentage of monocytes was within normal limits, in five counts, or 20 per cent, it was greater than eight. The average percentages of eosinophils and basophils were within normal limits, in one instance being 8.5.

Group II In this group, in which the disease had existed from six months to one year, four of the 11 patients, or 36 per cent, had leukocyte counts higher than 8000, whereas two had counts lower than 5000 per cubic millimeter. The average percentage of polymorphonuclear neutrophils was slightly higher than in group I but was at the upper limit of normal, in nine of 17 counts the percentage was greater than 70, whereas in two it was less than 60. The nonfilament count showed only a very slight increase over that in group I. The average percentage of lymphocytes was definitely decreased below normal, in 14 of 17 counts being less than 25. The average percentage of monocytes was slightly increased, in seven of 17 counts, or 41 per cent, being more than eight. The percentages of eosinophiles were all within normal limits.

Group III Seven of the nine patients in this group, or 77.8 per cent, had leukocyte counts greater than 8000 per cubic millimeter. The greatest increase in the percentage of polymorphonuclear neutrophils took place in this group. In 12 of 16 counts, or 75 per cent, this percentage was increased above 68. The shift to the left was almost doubled in this as compared to groups I, II, and IV. The average percentage of lymphocytes, on the other hand, was the lowest of any of these groups, of 16 counts on the nine patients in the group, 15, or 94 per cent, were below 25. In 16 counts of monocytes, or 25 per cent, the percentages were more than eight. The percentage of eosinophiles was 1.8, in all but two instances being within normal limits. The basophiles likewise were within normal limits.

Group IV The leukocyte count in this group was the lowest of any of these groups. The average percentage of polymorphonuclear neutrophils in this group could hardly be called abnormal, in four of the eight counts the percentage was above 68. The shift to the left or nonfilament count was slightly increased over the previous groups. The average percentage of monocytes was seven, with only two counts being above the normal eight. The average eosinophile count was the highest of any of the groups, although only two counts were above the normal of four.

The summary of groups I to IV, inclusive, is given in table 1.

Group A In 20 of 28 counts, or 71 per cent, the percentage of polymorphonuclear neutrophils was increased above the normal 68. The nonfilament count was the least in group A. In 23 of 28 counts, or 82 per cent, the percentage of lymphocytes was less than the normal of 25. The percentages of eosinophiles and basophiles were all within normal range.

Group B The findings for this group were practically the same as for groups A, C, and D.

Group C The average leukocyte count was the lowest of those in groups A to D, inclusive, in only one case being increased to more than 10,000 cells per cubic millimeter of blood. In only 33 per cent of the counts was the average percentage of polymorphonuclear neutrophils above normal. The shift to the left or nonfilament count was slightly increased to 12 cells in 200. In two counts the percentage of lymphocytes was increased above

TABLE I

Summary of Average Leukocyte Counts in Groups I to IV, Inclusive

Group	Cases	Duration, years *	Leukocytes, per cubic millimeter	Nonflament count, per cent	Differential count, per cent				
					Polymorphonuclear neutrophiles	Lymphocytes	Monocytes	Eosinophiles	Basophiles
I	15	1/2 or less	7,693	8.1	63.8	27.2	5.9	1.9	0.7
II	11	1/2 to 1	7,307	9.2	71.0	18.7	8.4	1.6	0.3
III	9	1 to 2	11,055	16.0	75.3	14.8	7.2	1.8	0.6
IV	5	2 to 13	6,940	12.3	69.8	18.8	7.0	3.8	1.0

* Exact limits of the groups are given in the text

30, whereas in the others, with the exception of one case, it was practically within normal limits. The percentage of monocytes was increased in four counts whereas the average percentage was normal. The percentages of eosinophiles and basophiles were both within normal limits.

Group D The average percentage of polymorphonuclear neutrophiles was normal, however, in 13 of 21 counts, or 61 per cent, the percentage of polymorphonuclear neutrophiles was slightly increased. The shift to the left was not marked. The average percentage of lymphocytes was slightly below normal, with 66 per cent of the counts being below 25. While the average monocyte count was normal, the percentage was increased above normal in 29 per cent of the counts. In two instances the percentage of eosinophiles was increased above the normal limits while the percentage of basophiles was normal.

The summary of groups A to D, inclusive, is given in table 2.

Cases of Lymphosarcoma The findings in cases of lymphosarcoma differed only slightly from those in cases of Hodgkin's disease. In two cases in this group the leukocyte count was above 8000 per cubic millimeter. In 23.5 per cent of the counts the percentage of polymorphonuclear neutrophiles was increased above normal. Of the lymphocyte counts, 41 per cent were below normal, 29 per cent above normal. There was also an increase above normal in 18 per cent of the monocyte counts. In two counts, or 11 per cent, the percentage of eosinophiles was increased above normal. The basophile counts were increased in two instances.

COMMENT

From this study it appears that there is no specific morphologic blood picture diagnostic of Hodgkin's disease. Estimations of the number of

TABLE II
Summary of Average Leukocyte Counts in Groups A to D, Inclusive

Group	Extent of involvement	Cases	Leukocytes, per cubic millimeter	Nonfilament count, per cent	Differential count, per cent				
					Polymorphonuclear neutrophils	Lymphocytes	Monocytes	Eosinophiles	Basophiles
A	Cervical, supraclavicular, or axillary (1 node) *	17	8,218	6.3	71.6	18.1	7.5	2.2	0.6
B	Inguinal (1 node)	5	10,480	17.0	74.6	17.6	5.9	1.4	0.4
C	Cervical, supraclavicular, or axillary (2 nodes) †	6	5,950	12.0	61.8	28.1	6.7	1.8	0.6
D	General adenopathy	12	8,517	9.3	67.5	22.6	6.8	2.4	0.7

* Only one node affected in any of these three situations

† Two nodes affected in one of these situations or one node in each of two of these situations, namely, two cervical nodes, or one cervical and one axillary node, and so forth

leukocytes per cubic millimeter of blood showed them to be within normal limits, as were also the various percentages in the differential counts (group I, table 1). It is true that in an occasional case there was a deviation from the normal of slight degree, but this in itself is without significance as the averages of the group were well within those recognized as normal. In group II, however, in which Hodgkin's disease was of slightly longer duration, there was definite polymorphonuclear leukocytosis with a decrease in the number of lymphocytes, as has been observed by other investigators. In these groups I and II there was no tendency toward a shift to the left of the neutrophils, the values being well within normal limits, that is, 8.1 and 9.2 nonfilamented cells, respectively, per 100 neutrophils.

In group III, in which the duration of the disease was longer, the most definite changes occurred. There was a definite but slight increase in the number of polymorphonuclear neutrophils, a relative decrease in the number of lymphocytes, and an increase in the number of nonfilamented neutrophils. This is probably due to the more widespread involvement of the body by the process, with incursions of sufficient degree to produce toxic changes. Yet in group IV, in which the disease was of longer duration, such results are not found. This in itself seems at first sight to contradict the conclusions for group III, but in an individual who has had the disease for more than two years there is probably a good deal of natural resistance to the process, it may be growing slowly and therefore not produce much general effect on the peripheral blood. On the other hand, the process may

be in a terminal stage and by reason of this prevent a normal reaction of the hematopoietic elements in the peripheral blood

It is of interest that in this series of cases the most marked changes in the blood were seen in cases of inguinal adenopathy (group B). It is probable that in such cases there was associated involvement of the abdominal and pelvic retroperitoneal nodes, resulting in more widespread involvement than would be expected, consequently, more change in the cellular elements of the peripheral blood might have occurred. It is difficult to understand why individuals with generalized adenopathy (group D) should not present more changes in the cells of the blood, for as shown in table 2 this group has, on the average, leukocytes and individual cells in normal numbers. Apparently the extent of involvement of the process has but little effect on the changes in the blood.

Monocytosis did not occur in any of the groups, which is in accord with the conclusions of recent investigators in this subject. The individual cells have a greater tendency to be indented (shift to the right) than normal, but as this may occur in many other conditions it is without diagnostic significance.

Polymorphonuclear leukocytosis is not a constant finding but was present in this series in cases in which the disease had been present for more than one year and less than two years. The absence of polymorphonuclear leukocytosis in earlier cases would be contradictory evidence for the thesis that Hodgkin's disease has its origin in an infectious process.

SUMMARY AND CONCLUSIONS

The analysis of the findings in 40 cases of Hodgkin's disease revealed that leukocytosis of slight degree was present in cases in which the disease was of between one and two years' duration. Polymorphonuclear neutrophils were slightly increased in the differential count in cases in which the disease was of six months' duration or longer. A slight relative decrease in the number of lymphocytes occurred in the same cases. The monocytes showed a greater tendency toward a shift to the right than occurs in normal individuals. Extensiveness of the disease apparently does not produce more marked changes in the blood. There is no specific change in the leukocyte picture which is diagnostic of Hodgkin's disease.

In the nine cases of lymphosarcoma, the average percentage of polymorphonuclear neutrophils was slightly decreased and the average percentage of lymphocytes slightly increased as compared with the results in cases of Hodgkin's disease. The percentages of other leukocytes and the total leukocyte count were nearly the same as they were in cases of Hodgkin's disease.

THE INTERRELATIONSHIP OF GASTROINTESTINAL AND RENAL DISEASE *

By HARRY GAUSS, F A C P , *Denver, Colorado*

CLINICALLY disease of the kidney and disease of the gastrointestinal tract are clearly differentiated in a majority of the cases. Frequently, however, the various types of renal disease give rise to symptoms referred mainly or even exclusively to the gastrointestinal tract. In a majority of these cases a careful examination will reveal the source of the disturbance. In some instances, however, severe gastrointestinal distress alone may result from pathological changes in the urinary tract which are not detected in a routine examination. It is with this group of cases that this paper is concerned. The digestive disturbances are purely functional and clear up entirely when the underlying renal abnormality is corrected.

An explanation of the reference of symptoms between these two systems may be sought in their anatomic, neurologic, and metabolic relationships. The anatomic relationship may be summarized by pointing out that the anterior surface of each kidney is in close apposition to important structures forming part of the gastrointestinal system. On the right the kidney is in close vicinity to the liver, the duodenum, and the hepatic flexure of the colon, while on the left the kidney is in contact with the stomach, spleen, pancreas and descending colon. The innervations of both the digestive and urinary tracts are similar in that they contain autonomic fibers of both vagal and sympathetic type which have passed for the most part through the celiac plexus. From a metabolic point of view both the digestive tract and the kidney possess excretory functions. A definite balance exists as to the proportion of certain substances which will be excreted in the stools or in the urine. In case of renal failure an added excretory function may be laid upon the digestive glands.

In all these interrelationships must lie the secret of the functional disturbances so frequently set up in one system as a result of a disease process localized in the other. Of the exact mechanisms involved we are still quite ignorant. From the clinician's point of view, however, the following notes upon the incidence of such referred symptoms may be of practical value.

Anatomically almost the entire anterior surface of both kidneys is in close relationship with various parts of the digestive apparatus. They are separated from it by a layer of fatty areolar tissue, and by the peritoneum which in places forms folds or ligaments which extend to neighboring organs. Traction on the duodenorenal and nephrocolic ligaments is believed to be an important factor in the production of gastric symptoms (Hinman, Longyear).

Both the kidneys and ureters and the gastrointestinal tract, including

* Read before the Eighteenth Annual Clinical Session of the American College of Physicians, Chicago, Illinois, April 20, 1934

the liver, gall-bladder and pancreas, derive their nerve supply from almost the same sources the vagus and the sympathetic fibers from the celiac plexus

To a lesser extent pathological conditions in either system may affect the other through alterations in the chemical composition of the blood and body fluids which they may bring about This is seen most strikingly in the digestive disturbances so common in uremia

Hydronephrosis Hydronephrosis from various causes is frequently associated with gastrointestinal symptoms Renal symptoms may be slight or absent, and there may be no abnormality in the urine when tested

The difficulty in differentiating renal and gall stone colic is well recognized Forman calls attention to the following signs and symptoms which suggest a renal origin there is reflex rigidity of the lumbar muscles, the pain is radiated caudad, bile does not appear in the urine, blood or pus may be present in the urine, although between attacks the urine may be normal, bimanual examination may elicit tenderness in the kidney area, and roentgen-ray may show evidence of renal disease, such as stone, stricture, hydronephrosis, etc

Movable Kidney Morrissey regards the production of gastrointestinal symptoms in movable kidney as the result of direct traction on the gastrointestinal tract Traction, he believes, is exerted on the second portion of the duodenum through its areolar tissue connection with the right kidney The lack of mesentery prevents it from moving forward, so that it is stretched and its lumen becomes diminished Interference with the digestive current and secondary dilatation of the stomach follow, while at the same time, the bile ducts are elongated and narrowed, and the passage of bile through them is interfered with On the left side similar disturbance of digestion may follow the pull of the kidney on the stomach and colon

Nephrocoloptosis Longyear believes that the kidney alone cannot exert sufficient traction on the gastrointestinal tract to produce symptoms, but that the combined ptosis of kidney and colon can initiate gastrointestinal symptoms In the production of these symptoms the nephrocolic ligament plays an important part Four factors, he states, are necessary for the occurrence of nephrocoloptosis, namely (1) a weak or absent hepatocolic ligament, (2) a loose kidney attachment at its hilum and to Gerota's capsule, (3) a strong and short nephrocolic ligament, and (4) a prolapse of the cecum and ascending colon Nephrocoloptosis occurs commonly on the right side but rarely on the left side, the reason being that on the right side the hepatocolic ligament, which helps to support the ascending colon, may be weak or absent, while on the left side the phrenocolic ligament, which supports the descending colon at the splenic flexure, is always present Further, it is uniformly strong and dependable, and so prevents the downward displacement of the gut at this point Fowler believes that ptosis of the adrenal gland is also a factor in producing this syndrome

In nephrocoloptosis there is traction on the duodenum, causing angulation of the bowel and interference with the function of the biliary and pan-

creatic ducts The symptoms are commonly gastrointestinal in character rather than renal The patients complain of indigestion, distress after eating, gas eructations, nausea, constipation, flatulence, pain in both hypochondria which is either dull or colicky, and pain in the right lower quadrant For treatment Longyear recommends an abdominal support, and also the surgical operation of nephrocolopexy which fixes both the kidney and colon

Not all writers agree that ptosis of the kidney is always secondary to ptosis of the colon According to Hinman, most authorities believe that the majority of surgical nephroptoses are not accompanied by enteroptosis, and that not all cases of visceroptosis are accompanied by nephroptosis

Ureteral Stricture Ureteral stricture is one of the diseases of the urinary tract which are most frequently associated with gastrointestinal disturbances We owe to Hunner credit for demonstrating the relatively frequent occurrence of this condition

Ureteral stricture may be of congenital or acquired origin The acquired form which predominates is attributed to focal infection, infectious disease, or traumatism

The symptomatology is variable In one group of cases attention is directed at once to the urinary tract by attacks of ureteral colic These are attributed by Watkins and Cumming to sudden occlusion of the ureter by edema of the strictured area

In a much larger group the symptoms are so diverse and so predominantly gastrointestinal in character that without painstaking study the stricture may be overlooked Thus in a series of 50 cases reported by Dabney severe digestive disturbances occurred in over 75 per cent, and pain referred to the right lower quadrant occurred in 34 per cent

Pain is the most frequent symptom of ureteral obstruction It varies in character from a constant dull nagging ache to a sharp violent paroxysmal pain This may be present in the right lower quadrant, or it may be diffuse over the entire abdomen, and not referred to the urinary tract Other symptoms frequently met with include indigestion, anorexia, nausea, vomiting, headache, flatulence, diarrhea, and rectal pain Hunner emphasizes that careful inquiry will often elicit a history of occasional slight irritability of the bladder, or frequent micturition, particularly when nervous or excited, or at the menstrual period, or in association with a cold Painful coitus may be complained of

Urine analysis is not always helpful Hunner found in 20 per cent of his cases a chronic pyelitis with characteristic abnormalities in the urine In 50 per cent minor abnormalities were found a few erythrocytes, a few leukocytes, albumin in varying amounts, or casts, or a combination of these elements In 30 per cent the urine was normal

Physical examination may reveal tenderness on bimanual palpation over the kidney region, or on pressure over the point where the ureter crosses the pelvic brim, approximately one and a half inches lateral to and below the umbilicus This may elicit pain which radiates to the bladder On vaginal

examination pressure over the ureters in the broad ligament above the bladder may cause tenderness or pain which may be recognized by the patients as identical with that with which they are familiar

Difficulties often arise in the differentiation of chronic appendicitis from ureteral stricture. As Dabney has emphasized, both conditions are characterized by a chronic course, by a tendency to digestive disturbances and constipation, by pain in the right lower quadrant of the abdomen, and by the fact that exercise is not well borne. In both there is often tenderness in the right lower quadrant, and occasionally a slight elevation of the temperature and leukocyte count, while the urine may show no abnormality. Whenever there is a reasonable possibility of ureteral stricture a urologic examination should be carried out, including ureteral catheterization and a urogram.

CASE REPORTS

The following case reports illustrate some instances of renal disease that presented essentially gastrointestinal symptoms.

Case 1 Renal Tuberculosis with Stricture of the Right Ureter Miss M. M., aged 26, complained of loss of appetite, gas pains, excessive flatulence, bilious spells, dizziness, loss of strength, and inability to gain weight, all of which were several years in duration.

Physical examination showed an asthenic young white woman, 102 pounds in weight, 5 feet 5 inches in height, pulse 90, temperature 98, respiration 14, blood pressure systolic 105, diastolic 65, who was not acutely ill. The eyes reacted to light and to accommodation. The heart was not enlarged and the sounds were clear. The lungs were normal. The liver and spleen were not palpable. The descending colon was spastic, palpable and tender. There was vague abdominal distress in the entire lower abdomen which was not clearly localized. A pelvic examination was not made.

The blood count showed a moderate secondary anemia. The urine was quite normal, there was only an occasional leukocyte and an occasional epithelial cell present. The basal metabolic rate, Ewald test meal and stool examinations all were normal.

Roentgen-ray showed normal lung fields, dropped type heart, ptosis and spasticity of the colon.

The diagnosis at this time was Undernutrition of 31 pounds, secondary anemia, visceroptosis, spastic colon. There was no evidence of tuberculosis and little reason to suspect it.

On a full diet she gained 12 pounds during the next two months, and the digestive symptoms subsided.

However in the third month she complained of polyuria and dysuria. The urine at this time contained large numbers of leukocytes and acid-fast bacilli which, on guinea pig inoculation, proved to be tubercle bacilli. The lungs again showed no evidence of tuberculosis on physical and roentgenoscopic examination. Cystoscopic examination by Drs. T. L. Howard, J. M. Lipscomb and J. E. Hartley revealed that the left kidney was normal and that the leukocytes and acid-fast bacilli came from the right kidney. A catheter encountered a stricture a short way up the right ureter. The kidney was subsequently removed by Drs. Howard, Lipscomb and Hartley and the patient made an uneventful recovery.

Comment This patient probably had a renal tuberculosis at the time she presented herself for examination. However there were no external

manifestations of the disease. The symptoms she presented were essentially gastrointestinal, and the urine was entirely normal. When the focus of tuberculosis in the kidney broke through into the urine, the diagnosis became apparent.

Case 2 Stone in Left Ureter. Mr. M. D., aged 22 years, complained of attacks of indigestion which came on at irregular intervals over a period of several months. During these attacks he had severe pain in the left lower quadrant of the abdomen, he was nauseated, had a distaste for food, usually had a diarrhea. The attacks were completely relieved by bromides. Between attacks he felt well, but was very nervous and high strung. He had been examined in a large clinic, and prostatic massage had been advised.

Physical examination showed a well nourished young man, weighing 138 pounds, 5 feet 8 inches in height, pulse 78, respiration 14, temperature 98, blood pressure 115 systolic and 80 diastolic. The eyes reacted to light and to accommodation. The throat and mouth were normal. The heart and lungs were approximately normal. The liver and spleen were not palpable. The descending colon was spastic, palpable and tender. There was tenderness on the left side of the abdomen which seemed to correspond more or less with the descending colon. The reflexes were present, equal and exaggerated. The blood count, Ewald test meal and urine were normal. The urine contained no blood, no albumin, only an occasional leukocyte.

Roentgen-ray of the gastrointestinal tract showed a spasticity of the descending colon, otherwise it was normal.

At this time, a diagnosis of spastic colon was made. There are no symptoms referable to the urinary tract, no polyuria, no dysuria, no pain in lumbar region or the genitals.

Several months later the patient had a sharp attack of pain, more severe than any of the preceding attacks. The attack was located in the lumbar muscles as well as in the abdomen, and it radiated down the leg. The urine at this time contained large numbers of erythrocytes, and the roentgen-ray showed a small stone in the left ureter which had not been discovered in any of the previous examinations. The stone was removed by transureteral manipulation. The patient has been free from symptoms for two years.

* The small ureteral stone was undoubtedly present at the time the patient presented himself for examination, though it did not at first elicit the characteristic symptoms commonly associated with that type of lesion. In this case, only the appearance of the ureteral colic led to a correct diagnosis.

Case 3 Chronic Pyelitis with Stricture of Left Ureter. Mr. H. C. complained of attacks of severe pain coming on after eating. The pains were located in the right upper quadrant of the abdomen in the region of the liver. The pain was sharp, paroxysmal, colicky, it spread to the entire abdomen, and was so severe that it required sedative medication for relief. These attacks had been coming on about once a week for two months. The attacks commonly came on about one half hour after eating. Between attacks he was free of pain, but felt tired and languid, he had no strength and had lost some weight. He was troubled with excessive gas, belching and flatulence.

Physical examination showed a white male of 140 pounds, 5 feet 6 inches in height. His pulse was 72, the temperature 97, the respiration 15, the systolic blood pressure 130, and the diastolic 67. He was not acutely ill at the time he was seen. The eyes reacted to light and to accommodation. The tonsils were enlarged but not infected. The heart and lungs were approximately normal. The abdomen did not relax well. There was marked tenderness in the right upper quadrant, particularly along the costal margin. The entire right side of the abdomen was spastic. There

was some tenderness over the cecum. The reflexes were present, equal and exaggerated.

Roentgen-ray of the stomach, intestines and gall-bladder showed all of them to be normal.

The blood count gave a leukocyte count of 18,400. The Ewald test meal was normal, and the urine was loaded with pus cells and colon bacilli, but was free from bile. The stool contained the normal bile pigments. Cystoscopic examination showed the left kidney and ureter to be normal, the pus came from the right kidney, and a stricture was encountered in the ureter.

Diagnosis. Pyelitis, right side, with stricture of ureter.

This patient was seen through the courtesy of Dr. Maurice Levy of Denver.

The diagnosis in this patient presented little difficulty because examination of the urine indicated at once an involvement of the renal system. The case is of interest because all the symptoms were gastrointestinal in character and suggested a gall stone colic. The patient never mentioned a single symptom referable to the urinary system, and it was only on subsequent interrogation that the patient recalled that years previously he had had trouble with his kidneys.

SUMMARY

1 While renal disease and disease of the gastrointestinal tract can usually be differentiated clearly, in a small group of cases the symptoms are confusing and may lead to errors in diagnosis.

2 The renal and gastrointestinal systems are related anatomically through their juxtaposition and their ligamentous attachments, and neurologically through their common innervation.

3 The following renal disorders have been reported as being common sources of gastrointestinal symptoms: stricture of the ureter, hydronephrosis, movable kidney, pyelitis, stone.

4 In these conditions examination of the urine may reveal no definite abnormality and therefore be of no aid in diagnosis.

5 Physical examination may be helpful in eliciting characteristic pain or tenderness on palpation of the kidneys or the ureters where they cross the pelvic brim, or at their lower ends within the broad ligaments.

6 A definite diagnosis can usually be established by means of ureteral catheterization and urograms.

FURTHER OBSERVATIONS ON THE CAROTID SINUS REFLEX

By LOUIS H SIGLER, M D , *Brooklyn, N Y*

IN previous communications^{1, 2, 3} I reported the incidence and the degree of cardiac slowing induced by the carotid sinus reflex in a series of 345 cases. The cases were divided into five groups as follows: Group I, coronary artery disease with definite myocardial damage, Group II, hypertension and hypertensive heart disease, Group III, rheumatic heart disease, Group IV, individuals with cardiac symptoms but no demonstrable cardiac disease, Group V, general constitutional disease (non-cardiac).

It was shown that the order of frequency and degree of response were Groups I, II, III, V and IV—the first showing the highest frequency and degree of response and the last the lowest. Males showed a higher frequency and degree of response than females, and there was an increase in frequency of response with advancing age.

The present communication deals with an analysis of 426 additional cases, consisting of 243 males and 183 females. These were all ambulatory cases, most of whom had cardiovascular disease.

The grouping of this series was as follows: Group I, arteriosclerotic heart disease, Group II, hypertension and hypertensive heart disease, Group III, arteriosclerotic and hypertensive heart disease, Group IV, rheumatic heart disease, Group V, psychoneurotic heart disturbances, Group VI, heart disturbances or disease of various other causes, and, Group VII, cases without cardiovascular disease. This finer subdivision was adopted in order to see how the carotid sinus reflex exhibits itself in more precise types of disease.

As in the previous paper only the cardio-inhibitory part of the carotid sinus reflex is reported. The vasomotor depressor effect of the reflex, exhibited by fall in blood pressure, and the other reflex effects induced by the carotid sinus pressure were not studied.

DETAILED ANALYSIS OF CASES IN THIS SERIES

Group I consists of 113 cases, 96 males and 17 females. All showed clinical evidence of general arteriosclerosis and coronary sclerosis of various degrees. In the majority of cases the electrocardiogram corroborated the presence of myocardial involvement. Many cases also had aortic sclerosis. Besides coronary disease, three cases had chronic bronchitis and emphysema, one Menier's syndrome, one congenital patent ductus arteriosus, three neurocirculatory asthenia, two diabetes mellitus, six obesity, one pulmonary tuberculosis, and three chronic cholecystitis and cholelithiasis.

* Received for publication December 14, 1935

In 10 cases there was a history of recent or past coronary occlusion, which in one instance was followed by pulmonary embolism

Group II consists of 45 cases, 14 males and 31 females. Although all showed more or less cardiac hypertrophy secondary to hypertension, none had gross evidence of insufficiency of the coronary circulation. In three cases the hypertension was of nephritic origin. In the rest it was of the so-called essential type. Fourteen cases showed marked obesity, six cases had definite psychoneuroses, two had chronic arthritis, one psoriasis, three cholecystitis and cholelithiasis, and one early multiple sclerosis.

Group III consists of 89 cases, 50 males and 39 females. All gave a history of hypertension and showed more or less hypertension at the time of the examination. All showed evidence of more or less general arteriosclerosis and coronary sclerosis. In addition, two had evidence of nephrosclerosis with early renal insufficiency. All had evidence of aortic sclerosis with more or less marked dilatation. Twelve cases showed considerable obesity, six gave a history of past coronary occlusion, four cases were diabetic, three showed psychoneurotic symptoms and three showed symptoms attributable to the menopause.

Group IV consists of 43 cases, 19 males and 24 females with chronic rheumatic heart disease. Fifteen showed mitral stenosis, one with auricular fibrillation, 16 had mitral insufficiency and mitral stenosis, four of whom had auricular fibrillation, two had mitral stenosis, mitral insufficiency and aortic insufficiency, three aortic insufficiency and stenosis, one aortic stenosis and mitral stenosis, three aortic insufficiency, three had mitral insufficiency. In addition two had hypertension, one chronic bronchitis, and one showed evidence of hyperthyroidism.

Group V consists of 23 cases, 10 males and 13 females with various cardiac manifestations of psychoneurotic origin. Care was taken to exclude from this group definite organic cardiac disease. All symptoms referable to the heart were entirely subjective. If objective findings were present, such as murmurs, various tachycardias and arrhythmias, they could invariably be considered to be functional in type.

Group VI consists of 52 cases, 26 males and 26 females. Some presented abnormal cardiac signs and symptoms of such character that the diagnosis of heart disease could not be made with certainty. Others had distinct heart disease of unknown etiology. Still others had cardiovascular disease of known etiology, but because they were relatively few in number no separate groups were made of them. Thus there were six cases of syphilitic aortic disease with reactive cardiac changes, six with thyrotoxic heart disease, two with congenital heart disease, one of chronic myelogenous leukemia with suspicious cardiac involvement, one secondary to marked chronic pulmonary lesions. Some cases might have been classed as neurocirculatory asthenia, but there was evidence suggesting early cardiovascular disease of arteriosclerotic origin.

Group VII consists of 61 cases, 28 males and 33 females. It includes cases of obesity, neurasthenia, menopause, gastric and duodenal ulcers,

anemias, diabetes, Hodgkin's disease, and so on. None showed clinical evidence of cardiovascular disease, although in a few, premature contractions or other cardiac abnormalities were observed, which could be attributed to reflex disturbances.

CARDIAC RESPONSE TO THE CAROTID SINUS REFLEX

In a previous report¹ a separate analysis was made of the reflex cardiac response to right and left carotid sinus pressure, and to combined right and left pressure. Some individuals exhibited only a right pressure response, others a left, but most showed a bilateral response. The degree of response varied for the two sides in many individuals.

In this series, in order to simplify the results, only the maximum response was used to classify each case. This, as before, was obtained on right or left carotid sinus pressure or equally on both sides.

TABLE I
Response to Carotid Sinus Pressure among Males and Females

Groups	Total No. Cases		Total Not Responding		Total Responding and Percentage Response			
	Males	Females	Males	Females	Males		Females	
					No	%	No	%
I	96	17	18	4	78	81.2	13	76.5
II	14	31	2	7	12	85.7	24	77.4
III	50	39	8	13	42	84	26	66.6

VII	28	33	6	12	22	78.5	21	66.6
Total	243	183	50	67	193	79.4	116	63.3

Group I—Arteriosclerotic heart disease

Group II—Hypertensive heart disease

Group III—Arteriosclerotic and hypertensive heart disease

Group VII—General constitutional disease (non-cardiac)

Group IV—Rheumatic heart disease

Group V—Psychoneurotic heart disease

Group VI—Other forms of heart disturbances and disease

Table 1 and figure 1 represent the response of this series of 426 cases. An analysis of the figures shows that the greatest frequency of response is in the hypertensive and in the arteriosclerotic and hypertensive groups. Rheumatic heart disease occurs next in frequency as does the non-cardiac group. The least response is seen in psychoneurotic heart disturbances and in the miscellaneous group of heart abnormalities. The latter shows a somewhat higher frequency of response than the psychoneurotic group. In all groups, females showed a definitely lower frequency of response than males.

Group IV—Rheumatic heart disease

Group V—Psychoneurotic heart disease

Group VI—Other forms of heart disturbances and disease

Degree of Slowing In the previous report, slowing of the heart under the carotid sinus reflex was divided into three degrees—those showing less than 25 per cent slowing as compared to original heart rate, those more than 25 per cent, and those where the heart stopped for at least two seconds. In

FIG 2 Degree of slowing among males. + Slowing less than 25 per cent of the original rate, ++ Twenty-five to 50 per cent, +++ Fifty per cent to short stoppage of heart, ++++ Where the heart stopped for more than two seconds. Disease groups are represented by Roman numbers. Ordinates represent percentage response in the various groups, abscissae represent the degree of response.

this series the degree of slowing was divided into four groups. Those showing less than 25 per cent slowing were designated as one plus, those showing 25 per cent to 50 per cent slowing as two plus, those showing 50 per cent slowing to temporary stoppage of the heart as three plus, and those where the heart stopped for more than two seconds as four plus. Table 2

and figures 2 and 3 show the degree of response of the various groups among males and females respectively

It will be seen that, with few exceptions, the tendency is for a greater percentage of cases to show the highest degree of slowing in the arterio-sclerotic group. In the hypertensive group this tendency appears to be in the opposite direction. It is also interesting to note that adding hypertension

FIG 3 Degree of slowing among females. + Slowing less than 25 per cent of the original rate, ++ Twenty-five to 50 per cent, +++ Fifty per cent to short stoppage of heart, ++++ Where the heart stopped for more than two minutes. Disease groups are represented by Roman numbers. Ordinates represent percentage response in the various groups, abscissae represent the degree of response

to arteriosclerosis has a tendency to lessen the degree of slowing. All other groups likewise show a tendency toward a lesser degree of slowing except in the psychoneurotic group. In this group, however, no conclusions may be drawn because of too small a number of cases.

There is a definite tendency for females to show a lesser degree of slowing. In cases with 4 plus response, females invariably showed a shorter

stoppage of the heart than males. In most of the females the stoppage was for no more than two seconds and the average was about 2.5 seconds. Most of the males, on the other hand, showed a stoppage of more than three seconds and the average was about four seconds. The longest stoppage occurred in severe forms of arteriosclerotic heart disease where in a few

FIG 4 Percentage response of the cardio-inhibitory carotid sinus reflex at given ages for both sexes. Ordinates represent percentage response, abscissae represent age groups. Disease groups are represented by Roman numbers.

cases the heart stopped for 5 to 14 seconds. In the non-cardiac group, if the heart stopped it was never for more than two seconds, and that was produced only by strong pressure.

Response at Various Ages. Table 3 and figure 4 are an analysis of the response at various age groups in this series. Although the first age group is marked 5 to 20 years of age, there were only two cases less than 10 years

FIG 5 Percentage response of the cardio-inhibitory carotid sinus reflex at given ages for males Ordinate represent percentage response, abscissae represent age groups Disease groups are represented by Roman numbers

It will be seen that males have a tendency to show a greater incidence of response earlier in life than do females Females show a more regularly progressive increase in response with advancing age In males, on the other hand, the type of disease seems to be more important as a determining factor than the age The greatest *degree* of response occurred in later life, in each sex

DISCUSSION

It was well established by many investigators that stimulation of the carotid sinus induces two major independent reflexes—slowing of the heart and fall in blood pressure. Heymans⁵ found three other reflexes—a direct cerebral vascular reflex, changes in adrenalin secretion, and changes in respiration. That each one of these reflexes is independent of the others has likewise been well established. Thus Hering⁶ found that vagotomy and atropinization abolished the cardio-inhibitory reflex, while the fall in blood pressure could still be induced by carotid sinus pressure. Koch,⁷ Heymans,⁵ and various other observers have likewise demonstrated this point repeatedly.

The investigation reported in this paper as well as in the previous ones deals only with the cardio-inhibitory part of the carotid sinus reflex. Although slowing of the heart thus induced reflexly may to some extent be due to inhibition of the cardio-accelerator nerves as shown by Raginiers,⁸ and Bronk, Ferguson and Solandt,⁹ it is dependent predominantly upon reflex vagal stimulation, as evidenced by the effects of vagotomy and atropinization mentioned before.⁶ The cardio-inhibitory carotid sinus reflex response may then be considered to be an index of sensitivity of the vagus to reflex stimulation. This sensitivity varies in frequency and in degree. In normal individuals Sander¹⁰ found a fairly high incidence of response. The degree of response, in normal persons, however, is comparatively low.

Various forms of local and constitutional disease increase the incidence and degree of the vagal response. Hering,⁶ Koch,⁷ and Heymans⁵ attributed an increased response in some individuals to sclerosis of the carotid artery in the region of the sinus. This seems to have been disproved by Keele¹¹ who found no relationship between fall in blood pressure induced by carotid sinus pressure and localized sclerosis, in a series of 55 autopsy cases. Braun and Samet¹² found marked response associated with coronary disease. Danielopolu and Missirlin¹³ found an exaggerated reaction in chronic myocardial disease. Wenckebach¹⁴ likewise found it in association with cardiac disease. Various authors such as Koch, Hering, Heymans and others found that drugs, as digitalis, morphine, calcium chloride and chloroform, increased the carotid sinus reflex response.

The results reported in this paper and in the previous ones substantiate the fact that the incidence and degree of response are greatly enhanced by arteriosclerotic heart disease, where the greatest degree of response is obtained. Other disease states, however, are associated with the reflex in greater or less incidence. Sex and age play a rôle in determining the response, being greater among males and in advancing age. Various types of disease likewise appear to have some influence. Patients with neuro-circulatory disturbances and no real organic disease appear to present the least incidence and degree of response. Hypertension, although increasing the incidence, decreases the degree of response. One interesting observa-

tion in this paper is that besides the greater male incidence of increase in the carotid sinus reflex, the reflex seems to occur in greater number and degree earlier in life among males than among females

All these factors point to a constitutional vagotonic tendency which is influenced by various factors. Disturbances in internal secretions undoubtedly play a part in influencing the reflex, as evidenced by the variations in the sex incidences of response, in the same disease states. The nervous state of the individual is another factor as evidenced by the diminished response in neurocirculatory asthenia. The gradual increase in response with advancing age may be due to a gradual and progressive sensitization of the vagal center by toxic states. The increase in the *incidence* of response in hypertension may be explainable on the basis of sensitization of the receptor nerve endings in the carotid sinus by increased intra-carotid pressure. This also partly explains the diminished response in neurocirculatory asthenia where the blood pressure is usually low. The persistent stimulation in hypertension appears to induce a moderate fatigue of the receptors, diminishing the *degree* of response.

SUMMARY

In previous reports an analysis was made of the slowing of the heart induced by the carotid sinus reflex, in a series of 345 cases. This paper deals with a similar analysis of 426 additional cases. This series was divided into seven groups: (1) arteriosclerotic heart disease, (2) hypertension and hypertensive heart disease, (3) arteriosclerotic and hypertensive heart disease, (4) rheumatic heart disease, (5) psychoneurotic heart disease, (6) other forms of heart disease or disturbances, and (7) general constitutional disturbances (non-cardiac).

It was found that the greatest frequency and degree of slowing occur in arteriosclerotic and hypertensive heart disease. Rheumatic heart disease comes next and general constitutional disease follows. The psychoneurotic and the miscellaneous groups of heart disease showed the least response. Hypertension seems to increase the frequency but to diminish the degree of the carotid sinus reflex response. The incidence and degree of response are greater among males than females and increase with advancing age. Males show the response in greater degree and incidence earlier in life than females.

The cardio-inhibitory reflex appears to depend on a constitutional vagotonic tendency which is more marked among males and develops with advancing age. General toxic or irritative states, endocrine factors, intra-carotid blood pressure, and local disease or disturbances in the heart itself, seem to play a part in sensitizing the reflex.

PHOSPHATASE CONTENT OF HUMAN SERUM IN PULMONARY TUBERCULOSIS FOLLOWING THE ADMINISTRATION OF VITAMIN D²

By PAUL D. CRIMM, A. B., M. D., F. A. C. S., and J. W. STRAYER, A. B., M. D.,
Evansville, Indiana

PHOSPHATASE is an organic catalyst capable of either synthesizing or hydrolyzing any mono-ester of phosphoric acid. It was first discovered in rice and wheat bran by Suzuki, Yoshimura and Takaishi¹ in 1907. (For a full review of the literature see Kay².) It is present in large quantities in the intestinal mucosa, kidney and bone. Smaller quantities are found in practically all other organs and secretions. Fetal bone and the bone of young animals are richest in the enzyme, but the content diminishes as maturity is reached. The optimum pH in vitro is around 9—it is activated by Mg (Erdtman³) and inhibited by pepsin, iso-leucine and glycine (Bakwin and O. Bodansky⁴). Robison and Soames⁵ have shown its importance as a local factor in bone formation and have demonstrated the precipitation of calcium phosphate in bone slices, from a rachitic animal, immersed in calcium glycerophosphate. We have recently shown,⁶ supporting the work of other investigators,^{7, 8} that in the rat the phosphatase content of serum and kidney is reduced following massive doses of viosterol and that it is greatly increased in the small intestine. Changes in the bone were found to be variable.

METHOD

Determinations of serum phosphatase were made upon normal human beings and upon tuberculous individuals before and after the administration of viosterol, according to the method of Bodansky^{9, 10}. Blood samples were obtained in each case within an hour after the noon meal. The blood was centrifuged and all determinations were made immediately. The unit of phosphatase is equivalent to 1 mg. of phosphorus liberated from a glycerophosphate substrate in one hour at pH 8.6 and at 37° C. The calcium determinations were made simultaneously from the same specimen of serum.

EXPERIMENTAL

Blood Serum Phosphatase in Normal Humans Serum phosphatase determinations were made on 19 normal human beings (table 1). The lowest figure was 1.68 units and the highest 4.96 units per 100 c.c., the average being 3.31 units. In one case, not recorded in the table, the serum phosphorus and substrate phosphorus were respectively 4.49 and 14.14,

* Received for publication November 13, 1935.
From the Research Laboratory, Boehne Tuberculosis Hospital.

yielding 9.65 units of phosphatase. There was no apparent reason for this. Bakwin and Bodansky¹ give the normal range as being between 1.5 and 4.5 units per 100 c.c.

Average	3.43	6.74	3.31

Blood Serum Phosphatase in Pulmonary Tuberculosis The phosphatase of the serum of 32 cases of pulmonary tuberculosis ranged from 1.36 to 4.45 units, with exception of one case which was 6.38 units (table 2). In three additional cases, all of which were moribund, the phosphatase content averaged 12.06 units per 100 c.c. (table 3).

In any stage of pulmonary tuberculosis the phosphatase activity is not greatly disturbed, and the values fall within normal limits. The reason for the elevation in the moribund cases is not known. The three cases mentioned above were in an extreme state of emaciation and cachexia. It is not to be inferred, however, that an elevated phosphatase content is a sign of impending death, since other patients in this series have since died, and bloods obtained post mortem on still others were quite normal for phosphatase.

Blood Serum Phosphatase in Tuberculous Patients Following Administration of Vitamin D Twenty-four tuberculous patients were given viosterol, 10,000 X,* 1 c.c. daily for 10 days. The calcium, phosphorus and phosphatase content of the sera was determined before and after administration. No attempt was made to secure a great elevation of serum calcium. If the patients became toxic before taking the full dosage of 10 c.c. the drug was discontinued. The average serum calcium before the administration

22	12.6	16.3	3.53	1.64
23	12.7	13.5	4.61	3.45
24	12.4	14.2	3.33	3.43
Average	11.8	14.2	3.29	3.06

the phosphatase content. A detailed analysis shows that a decrease of phosphatase occurred in 14 cases, whereas in 10 there was an increase of phosphatase in the blood serum. However, in 11 patients who had an elevation of the serum calcium over 14.0 mg per 100 c c, seven showed a decrease in the phosphatase content, while four showed an increase.

SUMMARY

1 The phosphatase content of a normal human serum was found to average 3.31 units in a series of 19 cases.

2 In 32 cases of pulmonary tuberculosis, all stages, the phosphatase content averaged 2.95 units.

3 Administration of viosterol, 10,000 X, in dosage resulting in hypercalcemia, caused a slight reduction of serum phosphatase in blood serum. Fourteen cases of pulmonary tuberculosis showed a decrease while ten showed an increase. Seven of the 11 whose serum calcium was 14.0 mg or over showed a decrease in serum phosphatase content.

DIAGNOSIS OF DISSECTING ANEURYSM OF THE AORTA¹

By EDWIN E. OSGOOD, M D, M F GOURLEY, M D, and RUSSEL L BAKER, M D, *Portland, Oregon*

ALTHOUGH more than 400 cases of dissecting aneurysm have been reported, only 11 have been correctly diagnosed during life. Shennan,¹ in an extensive review of the literature up to 1933, accepts six cases. He does not accept the cases of Finny (1885), Prescott (1897), Mager (1908), and Heller (1904). Since Shennan's review, five more cases² have been diagnosed during life. Hamman⁴ and Gatewood⁵ have each diagnosed a case after death but before the necropsy findings were known.

The purpose of this paper is to report two additional cases diagnosed during life and to outline briefly the clinical and pathologic features of this condition. It is hoped that our summary of the salient characteristics of dissecting aortic aneurysm will result in its more frequent recognition during life.

CASE REPORTS

Case 1 J N S, a white male, aged 50, entered Multnomah County Hospital on Oct 18, 1934, complaining of pain in the abdomen and chest, with vomiting. The patient was well until 2 30 p m, of the day of entrance when, following a heavy meal, he was suddenly seized with a steady, sharp pain in the epigastrium and lower chest, radiating to the right and left sides of the abdomen, to the back of the chest and into the left flank. The pain was diffuse and poorly localized. Lying flat on the floor was the only position which afforded relief. There was no vomiting at this time but definite nausea. After a short time the pain gradually subsided but soon recurred with greater intensity and remained steady with no cramp-like exacerbations. There was some shortness of breath associated with the pain, and the patient felt as though his heart was "about to jump out of his body." There was also some dizziness and spots before the eyes. Vomiting first occurred at 7 00 p m and was repeated six times in the next four hours.

From the past history it was learned that the patient contracted syphilis about 1917 but was treated for only a short time. In August 1932, he entered Multnomah County Hospital where a diagnosis of syphilitic meningitis and hypertensive cardiovascular renal disease was made. The Kolmer and Kahn were 4 plus. Following his discharge he was treated in the Outpatient Syphilis Clinic. In September 1933, he reentered the hospital with a diagnosis of basilar subarachnoid hemorrhage on the basis of hypertensive disease or syphilitic vascular changes. The blood pressure at this time was 190 systolic and 118 diastolic. He was discharged Dec 10, 1933 and was in fairly good health until the onset of the present illness.

Physical examination on Oct 19, 1934 revealed a well developed, well nourished, middle-aged male, obviously in pain, preferring to lie on his right side but occasionally turning from side to side and very apprehensive. His face was flushed but not cyanotic. There was no dyspnea. The blood pressure was 182 systolic and 88 diastolic and equal in both arms. The pulse was 98 and regular, the temperature,

100° F (37.8° C) Vigorous systolic pulsation was visible in the carotid vessels and palpable in the suprasternal notch and over the left subclavian artery. The peripheral vessels were tortuous and thickened with some sclerotic beading. The heart was enlarged, particularly to the left, and the pulsations were strong. The impact of the aortic valve closure was palpable. Percussion showed upper sternal dullness of considerable degree. The heart was aortic in configuration with widening of the base. The heart tones were clear and sharp, and there was a long blowing systolic murmur over the mitral area. The aortic second sound was markedly accentuated but not metallic in character. There was no murmur over the aorta posteriorly. The lungs showed no evidence of congestion. There was moderate resistance over the upper abdomen particularly on the left side, but no definite area of localized tenderness. Excursion of the costal margin with deep inspiration was normal. There were no changes in the extremities, the peripheral vessels showed equal normal pulsation.

The diagnosis on admission was coronary thrombosis or some form of acute abdominal disease. Because of the presence of long standing hypertension on the basis of hypertensive cardiovascular renal disease, the diffuse nature of the pain, radiating to the back, the maintenance of good heart tones and high systolic blood pressure, the absence of evidence of congestive failure and of clear cut evidence of intra-abdominal pathology, a diagnosis of dissecting aneurysm of the aorta was made by the staff physician (M F G).

Laboratory examination showed 2 plus albumin and 4 plus acetone and diacetic acid in the urine. The blood examination revealed 14.3 gm (103.3 per cent) of hemoglobin (Osgood-Haskins), 4.09 million red cells, 9,900 white cells, with a normal differential count. The sedimentation rate by the modified Westergren method⁶ was 12 mm in 15 minutes and 20 mm in 45 minutes, increasing to 45 mm in 15 minutes and 97 mm in 45 minutes by the fifth day. The blood urea nitrogen was 14.50 mg per 100 cc of blood. The icterus index was 7. The Kolmer and Kahn were negative at this time.

A roentgenogram (figure 1) of the chest showed deviation of the upper mediastinum to the right and an enlarged heart of aortic configuration with evidence of an aneurysm of the descending limb of the aorta.

The electrocardiogram (figure 2) showed left axis deviation, regular sinus rhythm, an inverted T-wave in Leads I and II, and a depressed S-T interval in Lead I.

For the first few days the patient had a slight fever. The pain remained about the same in character but was relieved by morphine sulphate, 10 mg every four hours, a little later paraldehyde, 8 cc, once or twice in 24 hours, controlled the pain. The pain and temperature gradually decreased and the patient was discharged Dec 16, 1934, 59 days after entrance.

He reentered the hospital Feb 16, 1935, complaining of shortness of breath, swelling of the ankles, chest pain, headache, dizziness, spots before the eyes, palpitation of the heart, and weakness. Since his discharge the previous December, the pain, though much diminished, had persisted, and there was some shortness of breath and swelling of the ankles associated with nocturia of three to four times. This condition persisted until Feb 16, 1935 when he was again incapacitated by the increase in lower chest pain and shortness of breath. The dyspnea was so severe that he was forced to sit up in bed. The pain at times radiated through to the back and down the inside of the right arm.

Physical examination showed extreme orthopnea, flushed face, nervousness, and marked pulsation of the carotid vessels. The blood pressure was 135 systolic and 110 diastolic, the respirations were 30, the pulse, 100 and regular, the temperature, 99° F (37.3° C). The chest showed bilateral basal moisture. The cardiac findings were the same as at the previous examination. The trachea was slightly deviated to the

right There was some engorgement of the systemic veins The liver was tender but not enlarged There was no edema of the ankles

The laboratory examination was essentially the same as on the previous entrance

An electrocardiogram (figure 3), Feb 18, 1935, showed a regular sinus rhythm, a left axis deviation, a depression of the S-T interval in Leads I and II and a high

FIG 1 Roentgenogram of the heart in Case 1, taken Oct 18, 1934 Note the aneurysmal dilatation of the descending aortic arch, the aortic configuration of the heart and the deviation of the trachea to the right

take-off in Lead III, and a diphasic T-wave in Lead I These findings were strongly suggestive of a recent coronary thrombosis and differed decidedly from the previous tracing

The patient expired suddenly five days after admission

Necropsy revealed pericardial tamponade due to hemorrhage from intapericardial perforation of a recent dissecting aneurysm confined to the ascending aorta. In addition, an old dissecting aneurysm extending from the arch of the aorta into the common iliac arteries was found. The walls of this aneurysm were completely re-endothelialized. The heart weighed 650 gm. Serial sections of the coronary arteries

FIG 2 Electrocardiogram in Case 1, taken Oct 26, 1934. Note the negative T-waves in Leads I and II and the evidence of left axis deviation.

showed numerous atherosclerotic plaques but the lumens were widely patent. The myocardium showed no fibrosis. The final anatomic diagnosis was perforation of dissecting aortic aneurysm with hemorrhage into the pericardial sac, dissecting aneurysm of the aorta and common iliac arteries, and syphilitic aortitis.

Case 2 R A Y, a huge white man, aged 43, entered Multnomah County Hospital at 3 30 p m, Jan 28, 1935, complaining of severe tearing pain in the chest, ab-

domen, and back. He had felt well until Dec 25, 1934, when, following a heavy Christmas dinner, he called a physician for an attack of "indigestion." The physician told him he had high blood pressure and that he had had a heart attack. A second similar attack occurred Jan 5, 1935, following which he returned to his work as a boiler fireman. He was awakened at 11 00 p m Jan 27, 1935 by a mild pain in the chest which at 1 00 a m became suddenly very severe and tearing in character as if

FIG 3 Electrocardiogram of Case 1, taken Feb 18, 1935. Note the marked change from the previous electrocardiogram and the evidences of coronary occlusion, although none was found at necropsy.

"something had broken" in his chest. The site of maximum intensity of the pain changed from the front of the chest to the left shoulder and then to the abdomen and the lumbar region. The pain became excruciating and he vomited once at 4 00 a m. The pain had continued unabated, notwithstanding two hypodermic injections, presumably of morphine.

Physical examination revealed a powerfully built man weighing 297 pounds, obviously in severe pain. The temperature was 99.2° F (37.3° C), the pulse, 93, and respirations, 20 per minute. The blood pressure was 260 systolic and 145 diastolic. The fundi showed notching of the veins and narrowing of the arteries. A vigorous carotid pulsation was noted on the right side of the neck. The heart was markedly enlarged, of aortic configuration with a forceful apex beat, regular rhythm,

FIG 4 Electrocardiogram of Case 2, taken Feb 4, 1935. Note the diphasic T-waves in Leads I and II, the depressed S-T interval in Lead I and the elevated S-T interval in Lead III as well as the left axis deviation.

a loud booming aortic second sound, but no murmurs. The peripheral vessels showed 2 plus thickening of the "rubber tube" type characteristic of hypertensive cardiovascular renal disease.

Laboratory studies revealed a 2 plus albuminuria with hyaline casts, normal red cell count and hemoglobin, an icterus index of 18, a white cell count of 10,000 with 67

per cent segmented neutrophils and 3 per cent staff cells. The sedimentation rate⁶ was 55 mm in 15 minutes and 85 mm in 45 minutes. The blood urea nitrogen was 17 mg per 100 cc of blood. The Kolmer and Kahn tests were negative.

The electrocardiogram (figure 4) showed a regular sinus rhythm with a rate of 88, a P-R interval of 0.18 second, a diphasic T₁, a depressed S-T interval in Lead I, a high S-T interval in Lead III, and left axis deviation.

FIG 5 Roentgenogram of Case 2, taken Feb 11, 1935. Note the aneurysmal dilatation of the aorta and the deviation of the trachea to the right.

A six foot roentgenogram (figure 5) of the chest revealed passive congestion at the bases of both lungs, a greatly enlarged heart of aortic configuration with a widened, distorted aorta shadow of increased density displacing the trachea to the right but showing no saccular dilatation.

The pain in the chest and back persisted until his death, February 17. It was not affected by a test dose of nitroglycerine and was only partially relieved by 15 to 30 mg of morphine sulphate administered every three to four hours until death. February 12, a systolic murmur was noted over the dorsal and lumbar spines with

the point of maximum intensity at the level of the tenth dorsal spine. The blood pressure maintained a level of about 240 systolic and 140 diastolic. The pulse rate varied between 80 and 100 and the temperature between 97.0° F (36.1° C) and 100.0° F (37.8° C). At 2:30 a.m., February 17, the patient was sleeping when seen by the nurse. At 3:30 a.m., he was found dead in bed.

A clinical diagnosis of hypertensive cardiovascular renal disease with acute coronary thrombosis was made on admission by the intern (R. L. B.). The tearing quality of the pain and its radiation to the back with no signs of congestive failure and no fall in blood pressure suggested the diagnosis of dissecting aneurysm of the aorta to the staff physician (E. E. O.). This diagnosis was confirmed by discovery of the murmur radiating down the spine, by the findings in the roentgenogram, and by the icterus index. The final clinical diagnosis was dissecting aneurysm of the thoracic and abdominal aorta with terminal rupture, hypertensive cardiovascular renal disease with left ventricular hypertrophy, regular sinus rhythm, and familial obesity.

Necropsy revealed hypertrophy and dilatation of the left ventricle and a dissecting aneurysm extending from the level of the attachment of the ductus arteriosus to the bifurcation of the aorta, with a perforation just beyond the arch into the left pleural cavity into which a massive hemorrhage had occurred. Microscopically, sections of the aorta revealed many small scars in the media with lymphocytic infiltration about the vasa vasorum. An organized blood clot was attached to one side of the split media. The intima was thickened and diffusely infiltrated with lymphocytes and plasma cells.

DISCUSSION

Dissecting aneurysm, or aneurysm dissecans, of the aorta is characterized, clinically, by the sudden onset in a patient with hypertension, of severe, tearing pain in the chest, usually radiating to the back, followed, after a variable interval, by sudden death, and is characterized, pathologically, by a primary rupture of the intima with a splitting of the media, and a secondary rupture externally or, less commonly, back into the lumen.

Etiology. The exciting cause in nearly all cases is hypertension. The cause of the hypertension is usually hypertensive cardiovascular renal disease, less commonly nephritis. Thirteen cases have been reported in patients with coarctation of the aorta and one⁷ in a patient with basophilic adenoma of the pituitary. The usual predisposing cause is a sudden rise in blood pressure due to excitement, exertion, trauma, distention of the stomach, or vomiting. A history of static strain as in wrestling, lifting, or straining at stool is especially common. The age distribution is that of the diseases causing the hypertension. The youngest cases are those with coarctation of the aorta or nephritis. The majority occur between the ages of 40 and 70 when hypertensive cardiovascular renal disease has its greatest incidence. The condition is more common in males (65 per cent) than in females probably because of the greater exposure to unusual strain.

The rôle of syphilitic aortitis is controversial. Loeschke,⁸ 1928, believed that syphilis had a tendency to bind the aortic wall, thus preventing wide dissections. Kellogg and Heald,^{3b} 1933, stated "It seems probable that the lesions of syphilis in the aorta, being more focal in their intensity, lead to a localized rather than a generalized weakening of the wall."

Samson,¹⁰ 1931, said "It seems probable that a lumatic meso-aortitis, through an interference with the blood supply leads to a degeneration of the medial fibers, and a somewhat displaced arrangement, saccular aneurysm being the sequel instead of the dissecting type." Shennan,¹ 1934, feels that syphilis may play a dual rôle in the production of dissecting aneurysm. In some cases it seems that the process is not sufficiently established to resist the splitting of the laminae, and in others, a toxic necrosis of the muscularis, in the absence of infiltration and adventitial changes, so weakens the aortic wall as to allow wide dissection. The association of the two conditions seems to us to be merely a coincidence. We do not believe syphilitic aortitis either predisposes to, or prevents, dissecting aneurysm. The incidence of syphilis (10 per cent) in patients with dissecting aneurysm is not materially greater than the incidence of syphilis in the general population of this age and sex group. The site of rupture is usually in an area of medial degeneration of the type occurring in hypertensive cardiovascular renal disease rather than at the site of a syphilitic lesion. Syphilis is certainly not an important predisposing factor because the great majority of the patients had no clinical or pathologic evidence of this disease, and in the cases which were associated with syphilitic aortitis there was usually coexistent hypertension or otherwise unexplained left ventricular hypertrophy.

Pathology The pathology has recently been thoroughly discussed by Shennan¹ and most of the statements that follow are summarized from his data. Dissecting aneurysm is noted once in every 300 to 500 necropsies.^{3c} The essential pathology is a rupture of the intima with a splitting of the media. In most instances there is a secondary rupture externally and, in a few cases, secondary rupture back into the lumen of the aorta.

In about 70 per cent of the cases the initial rupture is in the ascending aorta, in about 20 per cent in the transverse arch, and in about 10 per cent in the descending thoracic or abdominal aorta. The length of the dissection varies from a few centimeters to the entire length of the aorta and occasionally extends as far down as the popliteal arteries. In about 30 per cent of the cases the dissection is confined to the ascending or transverse arch, and in about 35 per cent the abdominal aorta is involved. Usually the major dissection is in a distal direction, but in about 10 per cent of cases it is in a proximal direction.

In about 95 per cent of cases, death is due to secondary rupture of the aorta. Seventy per cent of cases rupture into the pericardial sac, 20 per cent into the left pleural cavity, 5 per cent into the mediastinum, and a few cases into the right pleural cavity, the abdominal cavity or the retroperitoneal tissues. One reported case ruptured into the pulmonary artery.

The most constant associated pathology is left ventricular hypertrophy, present in about 85 per cent of the cases reported. Some degree of medial degeneration is usually demonstrable. Syphilitic aortitis is associated in about 10 per cent of all cases. Atheromatous changes are present in about

50 per cent of the cases, as might be expected from the age distribution, but the atheromatous lesions show little relation to the dissection

Shennan² discusses the various theories of pathogenesis and concludes that medial degeneration is the most important factor. From the analysis of his data and the other reported cases, it seems to the authors that hypertension is by far the most important factor in the pathogenesis.

Clinical Characteristics The patient is usually first seen just after the sudden onset of severe pain in the chest and back. Questioning may elicit a familial history of a "stroke" or high blood pressure, and a past history of high blood pressure, nocturnal polyuria, or occipital headaches suggestive of hypertensive cardiovascular renal disease. In younger patients there may be a history characteristic of preexisting nephritis or coarctation of the aorta. The pain usually begins following excitement, exertion, or injury. It is described as sharp, tearing, or as if something had broken in the chest. Its point of maximum intensity is usually over the middle or upper sternum and its most common radiation is into the region of the mid-dorsal spine. It may radiate to the abdomen, lumbar region, shoulder blades, neck, or down the arm. Its segmental distribution is likely to be higher than that of coronary artery disease.¹⁰ It is often diffuse, localized with difficulty, and is usually very severe, requiring large doses of morphine to control it. It is associated with extreme restlessness and persists unabated for many days. There is a tendency to sudden exacerbations in intensity with migration of the points of reference, indicating the development of further dissections. Dysphagia is sometimes present.

Physical examination reveals an apprehensive individual, obviously in severe pain. Cyanosis and dyspnea are often present. Fever of slight degree is common. The increased rate of pulse and respiration is probably secondary to the severe pain. The blood vessels show the "rubber tube" type of thickening, characteristic of hypertensive cardiovascular renal disease. Unless in shock, the blood pressure is high. It may be lower in the left arm or in the lower extremities than in the right arm. Absence of the pulse in the left arm, carotids, or inferior extremities has been recorded. The trachea may be deviated to the right. Percussion of the heart reveals an aortic configuration with dullness under the upper sternum. Signs of congestive failure are usually absent. The aortic second sound is typically accentuated but murmurs over the heart are not characteristic. Auscultation over the dorsal and lumbar spines, the abdominal aorta, or the femoral arteries may reveal a systolic murmur transmitted downward. This may develop late in the course of the disease, so should be looked for daily. Coarctation of the aorta may produce a similar murmur but may be recognized by finding its characteristic collateral circulation. Signs of obstruction of any branch of the aorta may be present. Among these signs are coma, hemiplegia, anuria, gangrene of the extremities, paralytic ileus, or localized swellings over the chest, neck, or abdomen.

Sudden death supervenes within a few minutes in 65 per cent of the cases, a few days in 10 per cent of the cases, and after an interval of weeks to months in the majority of the remainder, although a few cases have been known to live for years. Death is due to rupture of the aorta, usually into the pericardium, less commonly into the pleural cavity, mediastinum, or abdomen. While only of academic interest, the site of rupture may be determinable after death by percussion of the absolute cardiac dullness, the lung fields, and the abdomen.

The most valuable laboratory change, when present, is an increase in the icterus index due to bilirubin formation from hemoglobin destruction in the clotted blood. Urobilinogen may be increased in the urine but bile pigment does not appear. Clinical jaundice is usually absent but occasionally slow hemorrhage may occur into the mediastinum or retroperitoneal tissues of sufficient extent to produce it as well as an anemia. A moderate neutrophilic leukocytosis is often present. Serologic tests for syphilis are usually negative but a positive test does not exclude this diagnosis. Renal function may be decreased or normal as in any patient with hypertension and should be determined.

Roentgenographic features have been well summarized by Wood, Pendergrass and Ostrum.⁹ These features consist of a diffuse widening along the shadow of the aortic arch with diminished pulsation, an enlarged heart of aortic configuration, displacement of the esophagus and trachea to the right, shadows of dissections along the branches of the aorta and evidences of fluid in the left pleural cavity.

The electrocardiogram shows nothing characteristic of this condition but frequently shows left axis deviation and evidences of myocardial damage from coronary disease as is common in any case of severe hypertension. If clear cut evidence of recent coronary thrombosis is absent the electrocardiogram is helpful, but evidence of coronary occlusion does not exclude dissecting aneurysm. The changes usually ascribed to coronary occlusion may occur in dissecting aneurysm when necropsy fails to reveal evidence of infarction as was true in our two cases.

Diagnosis. The diagnosis of dissecting aneurysm should not be difficult if this possibility is given adequate consideration. This diagnosis should be considered in any patient who develops sudden pain in the chest or who dies suddenly. Evidences of co-existing hypertensive disease, radiation of the pain to the back, migration of the pain, and the increase in the icterus index are the most helpful features. Evidences of congestive failure are usually absent. If, in addition, a systolic murmur over the dorsal and lumbar spines develops and coarctation of the aorta is excluded, the diagnosis becomes almost certain. The sequence of sudden chest pain followed by sudden death is in itself strongly suggestive of this condition.

Dissecting aneurysm must be differentiated from coronary occlusion, from syphilitic aneurysm, from pulmonary embolism, and from the other

causes of sudden death. The great majority of the reported cases of recent years were erroneously diagnosed as cases of coronary occlusion.

The differential diagnosis of coronary occlusion is not complete without a consideration of dissecting aneurysm. The chief points of differentiation are the radiation of pain to the back, the migration of pain, and the elevation of the icterus index in dissecting aneurysm, and in coronary occlusion the occurrence of pericarditis, and signs of myocardial degeneration such as a fall in blood pressure, congestive failure and typical electrocardiographic changes. Radiation of pain to the back is extremely rare in coronary occlusion and radiation to the lumbar or sacral regions is almost unknown. Pain in coronary occlusion is usually described as constricting or vise-like, that of dissecting aneurysm as tearing or as if something had broken. The elevation of the icterus index has not heretofore been described, but it is logical to expect that it would be present in most cases of dissecting aneurysm if studied between 12 hours and two weeks after the time of onset. The two conditions not infrequently coexist so that, contrary to some authors,³⁰ electrocardiographic evidence of coronary occlusion does not exclude dissecting aneurysm. Sudden death from rupture of the heart may follow a coronary occlusion.¹¹ These cases may be especially difficult to distinguish from cases of dissecting aneurysm with rupture into the pericardial sac.

Syphilitic aneurysm of the aorta is not necessarily associated with hypertension and rarely causes pain for the first time with the dramatic suddenness characteristic of dissecting aneurysm. It is usually preceded by a history of substernal oppression and syphilis, and is often associated with aortic regurgitation, or a ringing aortic second sound, or with laboratory or clinical evidence of syphilis. The greatest difficulty in differentiating syphilitic aneurysm from dissecting aneurysm will be encountered in those cases first seen after sudden death from rupture as both types of aneurysm may rupture into the same locations.

Pulmonary embolism may produce death with equally dramatic suddenness but occurs usually in patients who have been in bed for some length of time or who have chronic right sided cardiac dilatation.

Cases of traumatic dissecting aneurysm seen in shock might be confused with internal hemorrhage from a ruptured viscus but the arterial and cardiac evidences of preceding hypertension should be of help and the subsequent course decisive. All aneurysms secondary to trauma are of the dissecting type.

Coarctation of the aorta must be excluded in cases with a systolic murmur transmitted down the spine because it is the only condition other than dissecting aneurysm giving rise to this type of murmur. The collateral circulation in the back and roentgen evidence of erosions of the lower margins of the ribs characteristic of coarctation should be most helpful because both conditions may result in a lower blood pressure in the inferior extremities.

than in the upper. Coarctation of the aorta and dissecting aneurysm may coexist.

Prognosis The prognosis is very grave. Sixty-five per cent of the cases so far reported have died from perforation within a few minutes and 10 to 15 per cent more have died within a few days of the onset. Most of the remainder died within a few weeks or months but cases have been reported that have lived for many years. Most of these proved to be cases that have perforated into the lumen of the aorta.

Treatment The most important point in the treatment is absolute rest with avoidance of all types of strain which tend to raise the blood pressure. Education in methods of avoiding such strains in persons with an extremely high diastolic pressure may prevent the development of this condition. As soon as the condition is recognized, large doses of morphine should be given to allay the extreme pain and anxiety and should be repeated as necessary until the pain can be controlled by other medication, usually a matter of weeks. Special nursing care to relieve the patient of the necessity of making any exertion on his own behalf is desirable during the first week. Mineral oil and mild laxatives should be given to secure a soft enough bowel movement so that there is no necessity for straining. Bleeding and administration of nitrites would seem logical procedures if the blood pressure is markedly elevated. Just how long the period of rest should be continued is difficult to say but it certainly should be a matter of months after all pain has ceased, and the return to physical activity should be very gradual. The diet should be soft and adapted to the needs of the patient as regards calories and quality, taking into consideration the body weight and build, and the renal function. Symptomatic therapy should be given as indications arise.

SUMMARY AND CONCLUSIONS

Dissecting aneurysm should be diagnosed during life but only a few cases have been clinically recognized. Two cases diagnosed during life are reported. The essential features of the condition are summarized and the criteria which may aid in the recognition of this condition are given. If dissecting aneurysm of the aorta is considered whenever severe pain radiating to the back develops suddenly in a patient with hypertension and the case is analyzed by the methods here outlined, a correct diagnosis should usually be made. Careful analysis of the history is the most important single feature.

DIET OF THE BLUFF DWELLERS OF THE OZARK MOUNTAINS AND ITS SKELETAL EFFECTS ⁴

By E G WAKEFIELD, M D, *Rochester, Minnesota*, and SAMUEL C DELLINGER, *Fayetteville, Arkansas*

IN another study we presented data on the diseases of bone which were prevalent among an ancient primitive race of people who inhabited the shelters of the bluffs in the Ozark Mountains of Arkansas and Missouri. The period of their occupation, from whence they came, or where they went are questions which cannot be answered. The absence of smooth stone or iron gadgets among their burial effects is mute evidence that they lived in ancient times and that they were very primitive people. Whether they lived twenty, thirty, or more centuries ago is irrelevant in this study.

In making a study of the osseous remains, the age of the bones is not as important as is the state of preservation. In the museum of the University of Arkansas there are four or five skeletons of children which are in a good state of preservation, and the isolated parts of many more. We believed that this number of bones of children of an extinct race, combined with a study of a great number of adult bones, would serve to indicate whether there was, at least, a tendency toward the development of deficiency diseases. In this material there also were several parts of bodies which were mummified. We were particularly interested in these mummified parts, in the hope that we could find some feces which we could examine for the presence of ova or parasites.

For burial, the bodies were usually flexed and placed in crude feather-down bags or under pieces of baskets. In or near the body were deposited various objects which were mute evidence of the meagerness of the food and clothes which these people possessed. They apparently cultivated corn, sunflowers, gourds, pumpkins, squash, pigweed, lambs-quarters, and beans, presumably for food, as many of these seeds were found in the caches. They had means of procuring fish, mammals and birds, as many bones of these animals were found in the caches and in the bluffs which these people inhabited. Thus, the data obtained from the caches indicate that these people lived on a mixed diet, if they ate what we assume they did. In the case of one of these people, we do not have to assume what was eaten during the last days of life. In an exceptionally dry shelter, where characteristic caches were found, there was a part of a dried body. The tissues of the lower part of the abdomen, pelvis, left leg to the middle third of the thigh, and the right leg and foot were dried and shrunken but well enough preserved so that the distal third of the large blood vessels of the abdomen, the sigmoid flexure of the colon, and the rectum could be definitely identified.

* Research Series No 411 Received for publication Jan 6, 1936

From the Division of Medicine, The Mayo Clinic, and the Department of Zoology, University of Arkansas

In the rectosigmoid or rectum were dried pellets of feces (figure 1), which were removed by means of long tissue forceps. The situation of this material obviates any question as to its true nature. The only questionable feature is whether this person might not have been buried more recently than has been assumed.

The present natives of this district do not bury their dead in these shelters. The American Indian in this part of the country did not utilize these shelters for any known purposes. There were no "top layer cultures" in any shelters of this immediate district. A fugitive from justice might be considered as a possibility. This possibility is ruled out because the remains from which the feces were obtained were those of an elderly woman.

FIG. 1 Pellets of feces obtained from mummified body

The identification of the remnants of food particles in the feces was most interesting. This work was done at the Bureau of Biological Survey, United States Department of Agriculture, by Clarence Cottam and his staff, who are in charge of Food Habits and Wild Life Research. They were aided by various members of other divisions and bureaus. The report was as follows: "Our office has examined the material and we find that the principal food item consisted of the fruit of the sumac (*Rhus*? *Capallina*). The other common food item consisted of ground acorns (*Quercus*), apparently black oak (*Quercus velutina*). Incidentally this is a common species of oak occurring in Arkansas. In addition to these two items, there seems to be a little unidentifiable vegetable material, perhaps from some fruit substance. There was also a fair amount of charcoal which may have been eaten deliberately or mixed with the food. At any rate it was well mixed with the material submitted.

"Within the intestinal material were two small early stage coleopterous larvae of the family Nitidulidae. Dr. A. G. Boying of the Bureau of Entomology and Plant Quarantine believes that these probably belong to the genus *Steliodite*. Most species of this family of small beetles feed on the juices of fruits, fermenting sap, dried or stored fruits, and a few feed on flowers, fungi and carrion.

"The photograph (figure 2) accompanying your letter is stated by Dr. H. W. Ewing of the Bureau of Entomology and Plant Quarantine to represent some species of mite of the family Tyroglyphidae. Members of this family feed largely on stored food products and decaying materials.

FIG. 2. Photomicrograph of insect contained in the feces.

"In addition to these, a fragment of an ant (*Formicidae*) and a number of lice and mites have been transmitted to specialists for further study. I will communicate with you further as soon as we obtain more specific identification of the minute items held out.

"A fungus growth was found on some of the material which undoubtedly developed after the individual was buried. It seems entirely possible that the insect material may have been taken accidentally or incidentally with the food and probably as a result of not being unduly selective in the choice, nor insisting on a high degree of sanitation. It seems probable that this represents a winter food."

The report on the foregoing material was as follows "Coleopterous larva belonging either to the family Nitidulidae or one of the small families relating to the Nitidulidae, possibly the Monotomidae. Definite determination cannot be given from the two fragments. Det. A. G. Boving.

"A few specimens of a species of *Cheyletus*, a predacious mite that feeds largely on other mites.

"Fragments of a species of the family Tyroglyphidae. Det. H. E. Ewing."

We were very anxious to find intestinal ova or parasites, if any were present. Many searches of the material have been made by Dr. T. B. Magath, but all these failed to reveal ova or parasites. A pellet of the feces was cracked and cultures were made from the center, but neither spore-forming nor non-spore-forming microorganisms grew. Tests for bile were negative. Quantitative chemical analyses of the feces were done by Dr. Mildred Adams, the results of these analyses are shown in table 1.

CHEMICAL ANALYSES OF FECES OF AN OZARK BLUFF DWELLER AND FECES OF A NORMAL PERSON

	Normal Feces Percentage of Dried Weight	Feces of an Ozark Dweller Percentage of Dried Weight
Nitrogen	5.10	4.77
Calcium	3.10	4.37
Magnesium	0.67	0.50
Sodium	1.00	0.67
Potassium	2.00	3.92
Phosphorus	1.70	1.63

Several of the crude cradles obtained from these shelters during the excavations were smeared with material which probably was feces. In this material there was an occasional insect, but nothing which resembled food material, intestinal ova, or parasites.

We have objective data which indicate that these people ate the fruit of the sumac, and acorns. We have circumstantial evidence that they ate corn, pumpkins, squash, sunflowers, lambs-quarters and beans, and the flesh of mammals, fish and birds. One can imagine that the food supply of these people was uncertain. However, they stored many of the natural foods which were gathered from the forests, such as hickory nuts, chinapins and acorns, and then cultivated crops of corn, sunflowers and other seeds for winter consumption and spring planting. These crops must at times have been limited and uncertain. These people did not possess sufficient implements to carry on more than a limited amount of agriculture, nor did they possess sufficient weapons to obtain a very great amount of meat by hunting. Their hunting equipment consisted of spears, darts, crude axes, and, of course, sticks and stones. It is of sufficient importance here to mention the fact that almost invariably they split the bones of the animals utilized for meat, in order to obtain the marrow for food. This splitting of the bones was probably done on account of the scarcity of meat.

The teeth of both the children and the adults were generally very good (figure 3). There was no evidence of either congenital or acquired diseases.

At the present time, it is recognized that ossification occurs earlier among females than it does among males. In the newly born this difference of ossification may be one of days, while later in life the time at which fusion of the epiphysis occurs may differ by years in the two sexes. There is some evidence to suggest that ossification occurs earlier among children who are well cared for than it does among children who are neglected and underfed.

Many factors appear to influence ossification, which is the determining influence on normal shape and size of the adult bone. Some of these factors are fresh air, food, sunlight (or ultraviolet light) and exercise. Ossification is advanced in certain conditions, such as *pubertas praecox*, and

FIG 3 Teeth of an adult of this race

is retarded in disorders of certain endocrine glands, such as dysfunction of the thyroid gland or pituitary body.

It is evident that the bluff dwellers possessed all the necessary requisites for the production of normal skeletal systems. Food may have been abundant enough at times, but the supply was uncertain. The food supply of the growing children after the period of nursing undoubtedly was uncertain, and according to present standards, it was meager; however, normal skeletons did develop. The possible influences of dysfunction of the thyroid gland or pituitary body have been carefully considered. There were no examples of disturbances in growth and development which would suggest dysfunction of these glands.

The femurs and tibias of a child were put aside for study on account of their lightness of weight and increased transverse diameters at the distal ends. So light and fragile were these bones that great care had to be ex-

excised in handling them, and in spite of this care the lower end of the right femur was broken. Satisfactory roentgenograms were difficult to obtain on account of the thinness of these bones. At the distal ends of these femurs and at both ends of the tibias there were dense transverse lines in the roentgenograms, otherwise the roentgenologic appearance of these bones was normal. These lines serve to indicate periods of growth. In the absence of any more marked deformities than were present in the lower ends of

FIG 4 Maximal amount of anterior bowing of tibias of this race

these femurs or in their condyles, and because of the minimal degree of anterior bowing of the tibias, a definite diagnosis could not be made. However, these bones were not normal, and without doubt this child had suffered a prolonged illness with secondary dietary deficiencies.

There were two adult tibias which showed anterior bowing and which were suggestive of rickets (figure 4).

The infant and adult skeletal remains of this primitive race of Americans impressed one by the absence of good evidence of rickets, scurvy and endocrine diseases or evidence of secondary deficiency diseases, which are common among present races. This absence of evidence of deficiency diseases is still more striking when one considers the possible effects of uncertain food supplies during that all important period of growth and development from five to ten years of age. The conclusion to be drawn is that this race possessed indomitable qualities in their germ plasm for the development of normal skeletons under adverse conditions and that this race also possessed a remarkable flexibility of digestive apparatus, which permitted them to eat large quantities of inferior, and perhaps unclean food and to utilize from it the so-called essentials of a normal diet. In other words, perhaps what is ingested in the way of food is not so important as how it is utilized in the process of alimentation and absorption.

The absence of findings indicating the presence of deficiency diseases in the Ozark bluff dweller is in keeping with studies made on other primitive races.¹

SUMMARY

The undigested food residue contained in the feces of an Ozark bluff dweller consisted of the fruit of the sumac, acorns, and insects. Their remains indicate that they had existed on a mixed diet of vegetable materials, meat and fish. No good evidence of primary dietary or endocrine deficiency diseases was found. This race must have possessed an indomitable germ plasm to be able to produce and maintain normal skeletal parts without evidence of deficiency diseases under most adverse dietary and sanitary conditions.

CASE REPORTS

TERMINAL HEMORRHAGIC NEPHRITIS A CASE EXEMPLIFYING THE PROTEAN CHARACTER OF ITS SIGNS AND SYMPTOMS *

By IRVINE H PAGE, *New York, N Y*

CHRONIC hemorrhagic nephritis is a disease exhibiting signs and symptoms of protean character. So elusive are many of these that prognosis and effects of various treatments are often seriously misjudged. It is for this reason that the record of this patient, illustrating many of these pitfalls, is presented.

The Patient This patient, a 49 year old woman, complained of swelling of the ankles beginning three years ago. The past history was irrelevant. Edema of the ankles began insidiously and was not associated with an obvious infection. Arterial pressure was found to be 200/120 mm of Hg. Dr Francis O'Connor, of Kingston, New York, who kindly referred her to us, has written that she complained at that time of severe headaches, spots before the eyes, and scanty urine. Red cells, casts, and protein were found in the urine. She was able to continue her work, but nine months later she seemed to be entering the terminal stage of nephritis. The blood pressure was 220/130 mm, non-protein nitrogen 44 mg per cent, and creatinine 2.9 mg per cent. Two months later she was admitted to this hospital.

She was a small woman appearing chronically ill and markedly anemic. Except for a slight amount of perivascularitis near the discs, the fundi were normal. All teeth had been removed. The heart was not overactive, nor was it enlarged. A₂ was accentuated and there was a soft systolic murmur heard over the apex. Arterial blood pressure was 196/110 mm of Hg. Slight edema of the sacrum, ankles and legs (grade 2) was present.

The electrocardiogram showed the T-waves diphasic in Lead I, and negative in Leads II and III. R₂ was split and R₃ was both split and of low voltage. Atrio-ventricular conduction time was 0.22 second.

Renal efficiency, as measured by the urea clearance test of Moller, McIntosh and Van Slyke,¹ as recently described by Van Slyke, Page, Hiller, and Kirk,² was reduced to 13 per cent of normal. The maximum ability to concentrate glomerular filtrate as measured by the specific gravity of the urine was 1.009. Correction was made for the protein present in the urine, that is 0.003 subtracted from the total specific gravity for each 1 per cent of protein. The number of formed elements in the urine was estimated by the technic of Addis.³ On admission, 3,200,000 red blood cells were found in a 12-hour specimen of urine passed during the latter half of a 24 hour period, during which the patient received no fluids, 500,000 red blood cells are considered the upper limit of normal. Casts numbered 684,000, of which 80 per cent were granular and 20 per cent hyaline. Protein in the urine was estimated by the method of Shevky and Stafford.⁴ The excretion amounted to 6 grams in 24 hours. Hemoglobin as recorded in terms of volumes per cent of oxygen capacity was reduced to

* Received for publication October 2, 1935.

From the Hospital of the Rockefeller Institute for Medical Research, New York, N Y.

14.8, while 19.0 is the normal value for a woman of her age (see Peters and Van Slyke⁵). Gastric analysis showed free hydrochloric acid was not present even after histamine. Total acid was low, averaging only 7.0

Gastric Analysis	Volume cc	Free HCl	Total Acid
Fasting	12	0	5.8
20 minutes after alcohol	17	0	7.4
40 minutes after alcohol	18	0	9.6
20 minutes after histamine	13	0	9.3

THE COURSE

1 Edema, Plasma Proteins, Urinary Proteins and Diet A diet of 2200 calories containing 80 grams of protein and 1.0 gram of salt was prescribed. Usually about one-half of the protein consisted of casein. Although the total plasma proteins were reduced to the level at which edema may appear, the albumin fraction was above the edema level. Fifteen days after admission the edema almost disappeared without a significant rise in either total plasma proteins or plasma albumin. This result was probably due to withdrawal of salt from the diet. Protein in the diet was raised to 100 grams. Urinary excretion of protein varied from 5 to 7 grams in 24 hours. After approximately one month, the dietary protein was reduced to 20 grams making up the deficiency of calories with carbohydrate. After 45 days of this regime no significant change in plasma proteins occurred, but urinary excretion fell slightly to 3 to 4 grams in 24 hours. Again the protein in the diet was raised to 100 grams and maintained at this level for five months. A slight rise occurred in the total plasma proteins, but no significant change was observed in the albumin fraction. Urinary protein excretion rose 5 to 6 grams, but fell toward the end of the period to an average of 2 to 3 grams. The protein in the diet was again reduced, this time to 30 grams, and maintained at this level for 4½ months, but no significant reduction of plasma or urinary proteins occurred. Two months after this period had started the patient had a severe hemorrhage from the descending colon which caused temporary slight depression of plasma protein. The following 11 months no restriction was put on her diet except that it contained the usual amounts of meat, and free salt was avoided.

This patient illustrates the fact that in patients who are well nourished and not losing large amounts of protein in the urine, protein in the diet may be varied within wide ranges without significantly affecting the plasma protein level or its excretion in the urine. But she remained free of edema only so long as salt was allowed in small amounts. It is of interest that although for 13 months the patient received not more than 1.5 gram of salt in her diet and excreted little more than a gram in 24 hours in the urine, she showed no signs of chloride deprivation. Examination of the serum after nine months on this low chloride intake showed that the chlorides were not significantly reduced, that is, 99.7 milli-equivalents per liter at pH 7.31.

2 Renal Efficiency The urea clearance remained well below the level of 20 per cent of normal, which is the level set by Van Slyke and his associates⁶ as that below which uremia may be expected to supervene. Except for insignificant variations, an average level of 10 per cent of normal was maintained for at least 19 months. Ability to concentrate urine was also reduced to a minimum.

3 Hemoglobin and Hematuria Throughout the course in the hospital the hemoglobin fell slowly from 14.5 volumes per cent O₂ capacity to 11.2 shortly before death. A hemorrhage from the lower colon caused considerable loss at one time, but within two months it had regenerated to its original level. Reduced iron (3 grams a day) was fed during this period and may have aided in regeneration. Iron fed over a two-month period prior to this (the seventh and eighth months in the chart) had no significant influence on the level of hemoglobin. Hematuria was not pronounced until two months prior to death. Usually, however, the number of red cells excreted was

FIG 1 Course of the patient as observed in the hospital. Blood pressure measurements were taken daily with patient in bed. They were averaged for convenience in charting. Fundus changes are represented as (a) arteriolar constriction, (b) sclerosis, (c) exudate, (d) hemorrhage, (e) papilledema. The first figure following the word "months" on the bottom line of the chart represents the probable date of onset.

slightly above normal. The loss of hemoglobin in the urine, at least as measured by the number of red blood cells, could not have contributed materially to the anemia.

4 Blood Pressure, Eyeground and Electrocardiographic Changes Fluctuations in arterial blood pressure were great. For periods of weeks it was normal, only to rise again to an abnormal height. During the terminal six months it rose markedly and maintained the high level until just before death. Slight constriction of the retinal arterioles was usually observed. Sclerotic changes in them were also present, but of very moderate degree. It is of especial interest that not until a few days before death were hemorrhage, exudate, and papilledema noted.

The electrocardiograph changes were as follows:

On admission, T_1 diphasic, T_2 negative, T_3 negative, R_2 split, R_3 split and low voltage, conduction time 0.22 second.

Eighteen months later, T_1 negative, T_2 positive, T_3 positive, R_3 split and low voltage, conduction time 0.16 second.

Twenty-four months later, T_1 positive, I_2 diphasic, I_3 negative, R and S_{1-3} low voltage, conduction time 0.18 second.

Although it was suggested on the basis of the prolonged conduction time that bundle branch block might develop, this did not occur. The size of the heart increased but moderately. Twenty days before death the measurements from a roentgen-ray plate were, maximum left 9.7 cm, maximum right 6.5 cm, and internal chest diameter 26.0 cm.

Terminal Stage The terminal stage was of more than usual interest because of the long period of almost complete anuria during which she had but few symptoms. Four months prior to death she withstood an attack of bronchopneumonia in the North Country Community Hospital. Two months later vomiting began. It varied in intensity, but in general became progressively worse. Eighteen days before death the output of urine began to diminish and three days later had fallen to a low level (figure 2). As fluid intake was not reduced, her weight increased only to fall sharply five days before death.

FIG 2 Blood pressure, weight and fluid intake and output during terminal period in which almost complete anuria occurred

Ten days before death urea clearance was 12 per cent of normal, and blood urea nitrogen 155.6 mg per cent. Little change was noted in ability to concentrate urine, but marked hematuria had appeared. Hemoglobin was somewhat more reduced and plasma proteins a little increased. Blood pressure had risen from an average level of 156/98 to 242/140 mm of Hg. Constriction of the arterioles of the fundi was more marked. About one month before death the eyegrounds were normal except

FIG 3 Section of kidney showing marked thickening of the blood vessels, atrophied and dilated tubules, loss of glomeruli, hyaline scars, and interstitial sclerosis

for slight arteriolosclerosis and faint hyperemia of the nerve heads. Examination made the day before death showed that a few small fresh hemorrhages and early patches of exudate were present. There was no papilledema. Constriction of the arterioles was less marked than that observed in the previous examination.

She complained from time to time of pain in the stomach and moderate rectal bleeding. She was moderately clear mentally up to death. A few days before it she exhibited periods of Cheyne-Stokes respiration and a little dyspnea. An attempt was made to promote urine excretion by means of glucose given intravenously (500 cc) with 10 per cent of 95 per cent alcohol added. No diuresis resulted, but the patient had a long restful sleep. One day before death the content of CO₂ in the serum was 13.47 millimols per liter at pH 7.13. The serum chloride was 90.5 milli-equivalents.

During the morning of the day of her death slight fibrillary twitching was observed, but except for nausea she had no complaints.

Autopsy (Dr. C. P. Rhoads), 4-1/2 Hours Postmortem. The findings of especial interest during the gross examination of the body were, absence of pericardial effusion, marked left ventricular hypertrophy (weight 480 grams) and diffuse atherosclerosis of the coronary vessels. In many places the intima of these vessels had become thin and brittle. Throughout the aorta, confluent atherosclerotic patches were present. There was marked emphysema of the lungs. The vessels of the spleen were markedly thickened. The mucous membrane of the stomach and intestine was edematous and deeply injected. Extending from the duodenum to the end of the large intestine there were many areas which were deeply injected, in the center of which were shallow ulcerations (10 to 30 cm. in diameter) extending through the mucosa and covered with yellow exudate. The sternal bone marrow was pale brick red in color and fairly cellular. No gross abnormality was observed in the brain or pituitary gland.

The left kidney weighed 32 grams and the right 38 grams. Both were markedly reduced in size. The capsules stripped with difficulty leaving an irregular contracted surface. The cortex was 10 to 30 mm. in width. Branches of the renal artery showed markedly thickened walls.

Microscopic examination showed that marked intimal sclerosis with necrosis and formation of cellular, sclerotic scars was present in the coronary vessels. Most of the vessels in the spleen and liver showed sclerosis. Very striking increase in the number of basophilic cells in the anterior lobe of the pituitary gland was present. Chromophobe cells were few in number, while acidophile cells were numerous.

Sections of the kidney (figure 3) showed extremely advanced sclerosis and infiltration of interstitial tissue with lymphocytes. Many glomeruli had disappeared and others were converted into hyaline scar tissue. Others exhibited hyaline thickening of the capillary wall with proliferation of epithelial and endothelial cells, and decrease of intravascular red blood cells. The tubules were atrophied and dilated, many containing a basophilic exudate. The arteries and arterioles presented most marked morbid change. Very marked fibrous intimal thickening was present along with hyaline change of the nuclei, with almost complete occlusion in many instances.

DISCUSSION

Onset of the disease was insidious in character. Gross hematuria, headache, fever and evidence of infection—so characteristic of the acute onset—were lacking. She was not aware that she was ill until swelling of the ankles occurred. By that time the blood pressure was elevated to 200/120 mm. of Hg, indicating, probably, that the morbid process was already of months' or years' standing. It has been the experience in this clinic that those patients in whom the onset is insidious are likely to die usually within a few years, contrasting with those in whom the onset is stormy, many of whom recover completely.

When she was first seen in this clinic she had entered the terminal stage Van Slyke and his associates⁶ define this as the stage during which urea clearance is below 20 per cent of normal and uremia may supervene at any time. Usually it lasts less than a year, but, as this patient illustrates, may continue for 20 months or more.

Physical examination showed that she was in a poor state of nutrition. A diet, liberal both as to calories and protein content, rapidly brought improvement. She was able to maintain good nutrition until within a few weeks of death. Coincident with improvement of nutrition was a feeling of well being. It is our belief that if patients with nephritis are properly nourished they may enjoy life to within weeks or months of death.

Since edema was almost the only symptom of which she complained, it was desirable to rid her of it. Excretion of protein in the urine was not great, but nevertheless she was unable to keep the plasma protein at a normal level, probably due to inability to synthesize them. Edema in this case appeared to be largely due to salt, for if it were withdrawn the edema disappeared and reappeared on resuming it. A diet containing 100 grams of protein for one month did not cause the plasma proteins to rise, nor did an isocaloric one containing 20 grams fed for 45 days cause them to fall. Again the high protein diet was resumed, this time for five months, without significantly affecting them. Reduction of protein to 30 grams for a period of 4½ months followed, again without effect. Nor was any close relationship found between the level of protein in the diet and excretion of protein in the urine. It appears that in this patient, who was well nourished, protein intake of from 20 to 30 grams covered the amount lost in the urine and the requirements of the tissues, but that even 80 to 100 grams were unable to raise the level of the plasma proteins. It is for this reason that it was our belief that ability to synthesize them was impaired.

Since it was necessary to interdict salt in the diet, an excellent opportunity was afforded to observe the effects of its deprivation. For 19 months she received little more than a gram of it a day. This was controlled by estimation of the salt content of the urine two days of each week. At no time were symptoms referable to its withdrawal evident, nor did the chloride in the serum fall below the lower limits of normal. Since polyuria was not present it appears that she did not wash out sufficient tissue chlorides to cause symptoms of hypochloremia.

Anemia was not marked until shortly before death. It appears to be of significance that the hemoglobin fell slowly. It is often observed that rapid diminution of hemoglobin may be associated with early termination of the patient's life. Large doses of reduced iron did not increase hemoglobin, but following a hemorrhage it appeared to aid in its recovery to the level maintained before the hemorrhage. Hematuria was never sufficient to contribute to the anemia.

The periods of marked hypertension alternating with those during which arterial pressure was nearly normal are of interest. One might well have been deluded into thinking that therapeutic success had been achieved were treatment to have been instituted at a time coincidental with the naturally occurring pressure reduction. Such more or less rhythmic changes recurring within a cycle of weeks or months are not rarely observed in this clinic. Changes in arterial pressure were unaccompanied by changes in renal efficiency as measured by urea clearance.

Morbid changes in the eyegrounds were limited to arteriolar constriction until weeks or days before death, when both exudate and hemorrhages appeared. We believe this to be an especially good prognostic sign. Lack of fundus changes often aids in differentiating the terminal stage of malignant hypertension from that of hemorrhagic nephritis. In the former profound changes may be the presenting symptom from onset of the disease, and always are observed in the terminal stage. Exudation, destruction of vessels, old and new hemorrhages and papilledema characterize these changes. Although similar changes may be observed in the fundi of a nephritic patient, they often follow the course illustrated by this patient. It is then that fundus examination is of differential diagnostic value.

The vascular system of this patient, including the heart, withstood the hypertension well. Although the arterial pressure was often higher than may be observed in cases of malignant hypertension, the heart enlarged slowly and caused but a minimal number of symptoms. The electrocardiograph showed, however, that damage was occurring. Autopsy confirmed the belief that the morbid changes in the blood vessels were extensive. They consisted of sclerosis and deposition of lipids without the hemorrhages into the vessel wall which are so often observed in malignant hypertension.

She suffered from oliguria approaching anuria for 18 days before death. In spite of this and a marked rise in retention products in the blood, there were few classical symptoms of uremia except vomiting. Only on the last few days were occasional fibrillary twitching of the muscles and a little drowsiness observed. It is a matter of surprise that a patient who for 19 months or more had suffered from severely restricted renal efficiency was able to withstand 15 days of almost complete anuria without exhibiting many symptoms or signs. Anuria resulting from a surgical procedure or that occurring during the acute stage of nephritis may end fatally in shorter periods.

Autopsy revealed two facts of interest which are not usual in such cases, and for which we have no explanation. The first was the presence in the anterior lobe of the pituitary gland of an increased number of basophile cells. The second was the absence of pericarditis, either old or fresh.

SUMMARY

A case of terminal hemorrhagic nephritis has been presented to illustrate the elusive nature of the signs and symptoms and their relationship to diagnosis and prognosis. The following points were especially well exemplified.

1. An insidious onset usually means a fatal termination of the disease.
2. The terminal stage (urea clearance less than 20 per cent of normal) may last for many months and at times more than a year.
3. Poor nutrition contributes to the discomfort and ill health of the patient. Good nutrition may spell the difference between well being and invalidism. Protein should be sufficient to cover the needs of the tissues and to replace that lost in the urine. High protein feedings need not restore the plasma protein level to normal, nor low protein diets reduce it. It is assumed that the ability of some patients to synthesize plasma proteins is impaired.
4. Interdiction of salt may abolish edema even though plasma proteins do not rise above the level at which edema may occur. If polyuria does not occur with

washing out of large quantities of tissue chlorides, chloride restriction may be as extreme as little over one gram without producing symptoms of hypochloremia or significantly reducing the chloride in serum

5 Even when hemoglobin is not markedly reduced and further reduction is slow, death may occur in uremia. Administration of iron will not affect its level except under certain special circumstances such as hemorrhage when it appears to aid in regeneration of the lost hemoglobin

6 Arterial blood pressure may alternate between being markedly elevated for periods of weeks or months and being almost normal. This is peculiarly deceptive when treatment designed to lower blood pressure is being investigated. Associated changes in renal efficiency as measured by urea clearance do not occur

7 Morbid changes in the eyegrounds other than arteriolar constriction may not be present until weeks or days before death, aiding thus in the differential diagnosis from malignant hypertension in which fundus changes are always advanced in the terminal stage and usually during its onset

8 Oliguria approaching anuria may last for relatively long periods (18 days) in spite of a preliminary period of severe renal inefficiency without producing marked signs or symptoms

9 An increased number of basophile cells may be found in the pituitary gland

TONSILLITIS ASSOCIATED WITH ACUTE ASEPTIC MENINGITIS *

By DAVID RIESMAN, M D, Sc D, F A C P, *Philadelphia, Pennsylvania*

CASE REPORTS

Case 1 Mr I B, a married man of 45 years, a native of New York City, had always enjoyed good health. On Tuesday, April 4, 1933, he awoke with a severe headache and a sore throat. The headache was obstinate, not yielding to codeine

* Read before the Section on Medicine of the College of Physicians of Philadelphia, February 25 1935 with additions

or other anodynes Sinus roentgen-ray and blood Wassermann test were negative The blood count was entirely normal, the fasting sugar 120 mg per 100 c.c. of blood The tendon reflexes were exaggerated on the right side and the Babinski reflex was present on that side Eye ground examination showed dilated vessels but no papilledema Lumbar puncture revealed the following Pressure 22 mm of mercury, globulin increased, sugar 55.4 mg, Wassermann and colloidal gold tests negative The cell count was surprising—there were 1125 cells to the cubic mm The fluid was sterile on culture

I had the opportunity of seeing Mr. B. with his physicians Drs. Goodheart and Ginsburg, on April 9 The notes of the result of my examination are as follows

The patient looks ill and is exceedingly apprehensive, perhaps because of the persistent headache, perhaps because of the many examinations and tests which the obscurity of his illness has rendered necessary The headache is apparently very severe and he is inclined to dig his head into the pillow The pupils are slightly unequal, markedly contracted but react to light, all ocular movements are normal The tongue is covered with a thick white coating Over the right tonsil a whitish exudate is visible like that of follicular tonsillitis, the left tonsil cannot be seen satisfactorily The heart and lungs are normal The liver is a little enlarged, the abdomen slightly distended, the suprapubic region dull on percussion, the spleen is not palpable The knee jerk is normal, the Babinski reflex is absent, but there is a suggestion of an ankle clonus on both sides While there is no real ataxia of the arms, the tips of the fingers are not easily brought together The knee-heel test is normal There is no rigidity of the neck, no Kernig sign The eye grounds are normal The temperature is 102 to 104°, blood pressure 122 systolic 70 diastolic, the pulse ranges from 70 to 90, respiration 20 The leukocytes in the blood are 16000 per cubic mm

On questioning the patient I obtained information about an incident that may have had considerable bearing upon his case On April 1, three days before the onset of the illness, he had been unexpectedly called to the home of an aged uncle When he arrived he found his relative lying dead on the floor It was the first death he had ever seen and the shock was, as he expressed it, terrible It would not seem to be an unwarranted assumption that this psychic trauma had something to do with the localization of the poison in the cerebral meninges

I was of the opinion that the tonsillitis was the primary element in Mr. B.'s case and that with its subsidence the meningitic symptoms would also disappear As a therapeutic measure I advised the application of leeches to the mastoid processes Recovery was rapid, the patient leaving the hospital on April 14 On April 27 he came to see me in my office in Philadelphia He felt fairly well but still had some ringing in the ears, a feeling of a "kink" in the back of the neck and occasionally weak spells, relieved by lying down He was nervous, irritable and easily upset Physical examination revealed nothing of significance except a momentary ankle clonus on both sides but no Babinski reflex I have heard of the patient since then He is entirely well

Case 2 The second case occurred at the Children's Hospital in the service of Dr. Joseph Stokes, through whose courtesy I am privileged to include it in this report The patient was a boy of four years, of Italian parentage, who apparently as the result of some birth injury had had convulsions up to the age of three years They then ceased and the child was subjectively normal until one day in May 1933, when he suddenly became feverish and had a convulsion His breathing was of the Biot type, temperature 102 The limbs were alternately rigid and relaxed, the Babinski reflex was present on both sides, no Kernig sign, some rigidity of the neck Examination of the throat showed a slight degree of tonsillitis Spinal puncture yielded a somewhat opalescent fluid, pressure 18 mm of mercury, globulin increased, sugar present, 500 cells to the cubic mm, nearly all were lymphocytes After the spinal puncture the child had no further convulsions A second puncture showed 1000 cells,

chiefly lymphocytes. There was no pellicle, and no organisms were found. Blood culture showed *Streptococcus viridans*, the Wassermann test was negative. The child's temperature became normal and the cell count in the spinal fluid was reduced to 10. A second blood culture again showed a profuse growth of *Streptococcus viridans*, but a third taken five days later was negative.

The diagnosis in this little boy was obscure but Dr. Stokes and his colleagues concluded that he had had a sterile meningitis, streptococcus tonsillitis and *Streptococcus viridans* septicemia without endocarditis. The child made a satisfactory recovery.

I am prompted to report these two cases because they illustrate certain unusual complications of acute tonsillitis. Although I did not see the first patient in the beginning nor the second one at any time, I believe the conclusion is justified that the tonsillitis was the primary disease.

The promptness of the recovery of both patients is unusual and puts this type of meningitis in a class by itself.

The literature is very meager on the subject of tonsillitis and meningitis. Kioll¹ is the only author among the many I have consulted who speaks of tonsillitis (angina) as a possible cause of acute serous meningitis. Cases of septic meningitis following tonsillitis, usually of the quinsy type are recorded. There are also references in the literature to encephalitis complicating tonsillitis. Fanny Halpern reported six cases, all in the female sex, of pontine-cerebellar encephalitis in persons ranging from 11 to 60 years. Halpern was unable to determine whether the inflammation of the brain was due to organisms or toxins of the tonsillitis or to a lessening of resistance to the encephalitis virus produced by the tonsillar infection. It must be remembered that the differential diagnosis of meningitis and encephalitis is sometimes difficult.

That there was a definite meningeal involvement in both the cases here reported cannot be doubted in view of a spinal fluid cell count of 1000 in one and 1100 in the other. As the fluid was sterile, I was inclined to the opinion that a virus might have been responsible, although the action of a bacterial toxin could not be ruled out. The fact that the cases were "aseptic" brings them in line with a number of similar ones recorded within the last few years—those of Wallgren,² under the title of "Meningitis 'Aseptica' Acuta," of Viets and Watts,³ as "Aseptic (Lymphocytic) Meningitis" and of Dickens,⁴ under the same title. Dickens in his article asks the question whether he was dealing with "a new disease entity due to a filterable or nonfilterable virus." In 1934 Armstrong and Lillie⁵ called attention to a virus they had encountered in monkeys which had shown definite signs and symptoms of meningitis, mice and guinea-pigs proved also to be susceptible to the virus. In May of this year Rivers and Scott⁶ reported the isolation of a virus from two human cases of meningitis, and stated that the serum from these cases protected animals from the virus. Crossed serological tests indicate the identity of the two viruses, that of Armstrong and that of Rivers and Scott.*

Armstrong and Dickens†† in four human cases of "aseptic" meningitis found that the blood serum obtained in one case three years and eleven months,

* The Armstrong-Rivers and Scott virus appears by serologic tests to be identical with a third virus, that of Traub, found in white mice.

† I want to express my thanks to Lieutenant Commander Dickens and to Dr. Charles Armstrong of the Public Health Service for letting me have a manuscript copy of their forthcoming article.

in one a year, in one three and a half years after the attack protected mice against the Armstrong virus. In the fourth case protective bodies were absent at the beginning of the illness, but appeared two months after the onset of the meningitis.

The clinical picture in these cases was similar to that of I B except that in the cases recorded by Dickens and Armstrong infections of the upper respiratory tract and not a well-defined tonsillitis preceded the onset of meningeal symptoms. The disease lasted from ten days to two weeks and left no residual features of any kind. In all these cases the cellular response of the spinal fluid was almost entirely lymphocytic. It is easy to see how such a cytologic finding might suggest the diagnosis of tuberculous meningitis. There is however, no pellicle and animal inoculation is negative. The sugar, chloride and urea content of the fluid is within normal range.

As far as our present knowledge goes the disease is self-limited and requires little treatment except lumbar puncture which is the best means of controlling the most distressing symptom the headache. As an adjunct to or substitute for lumbar puncture, leeching from the mastoid process may be tried.

It is desirable that those who hereafter see cases of aseptic meningitis * have laboratory tests made with the spinal fluid for the discovery of a possible virus and with the blood serum which in the virus cases ought to protect mice against the virus.

Meningeal symptoms are not rare in the acute infections of childhood and also in pneumonia. These symptoms are often attributed to meningism, whatever that may mean. If lumbar puncture is done in such cases, it may reveal a pleocytosis suggestive of acute lymphocytic meningitis †.

In conclusion I should like to say that as far as tonsillitis is concerned experience has long ago convinced me that it is a potentially serious disease and should be treated with more respect than is customary.

INTERMITTENT HYDRARTHROSIS ASSOCIATED WITH UNDULANT FEVER

By JOHN C SHARPE, M D , *Omaha, Nebraska*

ARTHRALGIA has long been recognized as part of the symptom-complex of undulant fever. However, true arthritic changes associated with the disease have not been emphasized as a predominant feature. We have had the opportunity in the past few years to see several such cases, which form the basis of another paper¹ dealing with these rheumatic manifestations.

The following case is of sufficient rarity and interest to warrant its individual consideration.

CASE REPORT

History J. F. 25, white, male, grocery clerk, entered the University Hospital on December 12, 1934, complaining chiefly of pain and swelling of the knees. The family and past history were non-contributory. He had always enjoyed excellent health until the onset of the present illness five years before admission. At that time he had first noted pain and swelling of both knees, the right ankle and the right wrist joint which persisted for six weeks. During the following year, the pain and swelling of the knees came and went at irregular intervals. On two occasions aspiration of fluid from these joints was required for the relief of pain. He was not aware of any associated fever at that time. One year before entrance to the hospital, the pain and swelling of the knees returned and again required several aspirations of the joints for the relief of pain. From that time to the present, he had noted a definite intermittent character of the swelling. He had been aware of an evening rise of temperature, at times reaching 102°. He had had little or no appetite and had lost 20 pounds in weight. As the result of his difficulty in walking, he had been unable to work. Additional history revealed the facts that at the time of the onset of the first arthritic symptoms, he had lived on a farm in Nebraska where he had drunk raw cow's milk, and that there had been several instances of abortion in cattle on nearby farms.

Physical Examination Examination revealed a well developed but poorly nourished young man with a moderate pallor of the face and mucous membranes. The temperature was 100.4°, the pulse 90, the respirations 20, and the weight 117 pounds. The blood pressure was 120 systolic, and 70 diastolic. There was a suggestive bilateral exophthalmos. The tonsils were small and adherent. There was a moderate generalized lymphadenopathy present, especially of the axillary nodes. The thyroid was not enlarged. The lungs were clear to percussion and auscultation. The heart was not enlarged. The first sound at the apex was accentuated, followed by a short systolic murmur. The splenic tip was palpable 2 cm. below the left costal margin. The liver was not enlarged. Examination of the joints showed some stiffness of the left elbow and some swelling of the right ankle. There was bilateral swelling of the knees (figure 1), the right measuring 37.5 cm., the left 35.5 cm. in circumference. There was a definite patellar ballottment, a moderate limitation of motion and no local hyperemia of the overlying skin. The patient complained of pain in the knees only at the time the swelling reached its highest level. The remarkable feature of the case was the periodicity of the swelling which occurred at the same time in both knees, in seven to ten day cycles. The measurements of their circumferences varied from 0.5 cm. to 6.0 cm. During the period of recession, the swelling never entirely

* Received for publication July 19, 1935.

From the Department of Medicine, University of Nebraska, College of Medicine, Omaha, Nebr.

FIG 1

disappeared from the right knee but occasionally did so on the left side. During the diagnostic study and progress of the case, daily noon-day measurements were recorded (figure 2).

Laboratory Examinations The blood showed a hemoglobin of 52 per cent, erythrocytes 3,440,000, leukocytes 5,000. The differential cell count was normal. The smear showed moderate anisocytosis and poikilocytosis. The bleeding and coagulation time were normal. The urine was normal, Wassermann reaction negative. The blood chemistry was normal. The basal metabolic rate was ± 18 . Roentgenograms of the knees (figure 3) were interpreted as showing rheumatoid arthritis of moderate degree. Agglutination with the Brucella group, by the Huddleston technic, was found to be positive in a dilution of 1-400. Repeated cultures of the blood, urine and synovial fluid for *Brucella abortus* and *melitensis* were negative after three weeks. The cultures were made on blood plates, brain broth, liver infusion. Duplicate cultures on the latter medium were incubated in an atmosphere containing CO_2 . A direct smear of the synovial fluid sediment showed many segmented neutrophils, but no bacteria could be observed.

Course The temperature was usually normal in the morning but would rise as high as 101° to 103° during the evening, usually accompanied by profuse sweating, occasionally chills. The increasing doses of undulant fever vaccine (Lederle), administered subcutaneously, caused little or no appreciable effect on either the dramatic intermittent swelling of the knees or the nocturnal rise of temperature. He was discharged from the hospital January 28, 1935, and then followed in the out-patient department where vaccine therapy was continued at bi-weekly intervals until a total

FIG 2 Intermittent Hydrarthrosis

(Continued on next page)

FIG 2 Intermittent Hydrarthrosis

FIG 3

of 10 c.c. had been given. At the end of this time, there appeared to be slight but definite decrease in the fluctuations of the swelling of the knees, a moderate decrease in the evening temperature and an improvement in his general strength.

Further Course At the suggestion and under the direction of Dr. A. E. Bennett, Lutheran Hospital, Omaha, the patient was given a course of fever therapy by means of a Kettering hot air cabinet. Each weekly treatment consisted of raising the patient's temperature to 105° to 106° and maintaining it for four hours. During the first four weeks, the size of the knees varied widely, but after the fourth treatment the right knee remained approximately uniform in size, moderately swollen. The left knee continued the periodic swelling every six to eight days. The patient ceased to complain of pain in the knees, and there was less limitation of motion. There had also been a gain of eight pounds in weight. However, the evening rise of temperature continued, there was no improvement in the anemia, and the enlargement of the lymph nodes persisted as well as the splenomegaly. The agglutination reaction remained positive in dilutions of 1-500. Continued attempts to cultivate organisms from the synovial fluid were unsuccessful.

COMMENT

Because of our patient's loss of weight, the perspiration, the tachycardia, the moderate bilateral exophthalmos and the moderately increased basal metabolic rate, an associated hyperthyroidism was at first considered. Curtis² reports a patient with undulant fever complicating toxic goiter who improved greatly following operation. He emphasized the similarity of the symptoms of the two diseases. We have also seen such a case that improved following operation.

Up to the present time, there has been only one previous report of intermittent hydrarthrosis of the knees definitely proved to be due to *Brucella*. This case was reported by Baker³ in 1929 at the Johns Hopkins Hospital. His patient was a 47 year old Virginia man who, while slaughtering hogs, after an exposure to cold developed periodic swellings of both knees that continued for several months. The swellings were found to alternate precisely in seven day cycles. Although the agglutination reaction of the blood was at first negative, *Brucella abortus* was cultivated from the synovial fluid of both knees, the blood and the urine. Vaccine therapy was effective in reducing both the nocturnal temperature and the swelling of the knees, but only while the patient remained in the hospital. The hydrarthrosis reappeared when he returned to work which necessitated standing. Our case showed only moderate improvement following vaccine therapy and further slight improvement after seven fever treatments.

Baker suggested that infection by a member of the *Brucella* group of organisms might prove to be the cause of the interesting and rare clinical syndrome, intermittent hydrarthrosis. With this in mind we studied our patient, and while we were not able to prove definitely that the hydrarthrosis was due to *Brucella abortus* or *melitensis*, there was little doubt that our patient presented an active and persistent case of undulant fever. We are in accord with Baker in stating that because of the lack of uniformity of opinion regarding the etiology of intermittent hydrarthrosis and since many of the recorded cases give a history of "fever" simulating malaria and finally because two cases of undulant fever have now been reported associated with intermittent hydrarthrosis, further attempts to determine the relationship of the two conditions should be made.

SUMMARY

1 A second case of undulant fever associated with intermittent hydrarthrosis of the knees is reported. The history is of several years' duration.

2 Repeated attempts to cultivate *Brucella abortus* or *melitensis* from the synovial fluid, the blood and the urine were unsuccessful.

3 Only slight improvement followed courses of vaccine and fever therapy.

4 It is hoped that further studies will be made to determine whether a constant relationship exists between Brucellosis and intermittent hydrarthrosis.

Addendum During the past 10 months, the patient's general condition has been unimproved. In spite of large doses of vaccine, a course of neoarsphenamine, and vigorous symptomatic treatment, the temperature continues its nocturnal rise accompanied by drenching sweats. The wrists, ankles and hip joints have become involved with pain and varying degrees of swelling. The knees continue their intermittent hydrarthrosis. The general lymphadenopathy and splenomegaly are the same, but the anemia and weight loss have become more marked. Repeated agglutinations with *Brucella melitensis* remain positive in high dilutions, but cultures of blood and synovial fluid are persistently sterile.

EDITORIAL

STUDIES ON INSULIN

EVER since its discovery almost fifteen years ago, many attempts have been made to render insulin still more effective as a clinical agent in the treatment of diabetes. These have taken two general directions: one, to find a more convenient and less difficult method of administration, and the other, to enhance its potency and to prolong the period of its physiological action. The chemical nature of this hormone, with its protein-like structure, probably renders it dependent for its physiological effects upon the molecular arrangement of its seven characteristic amino-acids. This structure also makes it vulnerable to attack by the digestive juices, so that it is unlikely that its oral administration in the present form can ever be effective. It has, indeed, been shown repeatedly that the administration of relatively huge doses of insulin by mouth will produce an irregular hypoglycemia. Some of the hormone under such circumstances is probably absorbed before it can be destroyed, but the effects upon the blood sugar are relatively so slight and inconstant as to make this method quite hopeless as a practical measure. The same objections apply to various devices employed to inactivate the digestive juices temporarily, as by alkalization, by ingestion with alcohol, by the use of anti-enzymatic preparations, or by coating the insulin with enzyme resistant materials.

Reports of many efforts directed toward the utilization of other routes of administration may be found in the literature. All eventually have been abandoned because of the uncertainty and lack of precision of the results. The quantity required for any effective action is generally several or many times larger than that required by the subcutaneous route. Rectal applications, insufflation into the naso-pharynx, instillation into the external ear, and even into the conjunctival sac, have been attempted. The writer has recently collected no less than fifteen articles which describe efforts to give insulin by skin incisions. An inconstant effect does seem to be possible with very large doses. A communication has recently appeared reporting promising results by intranasal spray. The history of these studies is always the same. A first enthusiastic report is followed by disappoint-

ment as the author discovers the impossibility of obtaining the precision and dependability of action indispensable for clinical use

Nevertheless, the cumbersomeness, inconvenience and pain of the constant hypodermic injections of insulin render any improvement highly desirable. The occurrence of fatty tumors, often disfiguring, as a result of neglect to rotate the site of subcutaneous injections is not so serious a problem as is that of the curious areas of atrophy which are seen from time to time, and which appear to be permanent scars. When one comes to consider the enormous number of hypodermic injections of insulin daily administered by untrained and often careless and dirty individuals, into diabetic tissues which are particularly susceptible to infection, the relative rarity of this complication or of any other is truly remarkable. In the course of ten years a diabetic patient who takes insulin twice daily will receive over seven thousand hypodermic injections.

A more promising line of attack has been that directed toward delaying and enhancing the hypoglycemic action of insulin. If its physiological effect is analogous to that of an enzyme, and current evidence perhaps points in this direction, such investigations may well be considered hopeful and probably eventually fruitful. Injections with various agents which delay absorption by physical means or otherwise have been extensively studied. Mechanical mixture, either of dissolved insulin, or of dry insulin powder, with semi-solid fats or oils, which are themselves absorbed slowly, or with lecithin or cholesterol, or with gum arabic or allied compounds, have not yielded very satisfactory results. Recently Clausen has reported favorable effects with mixtures of adrenalin and insulin. Promising studies upon the enhancement of insulin action by means of combination with protein precipitants, or adsorbents, as metallic salts, particularly those of iron and zinc, have recently been published by Bishoff and Maxwell, and by Scott and Fisher.

Great interest has been aroused in the report of the use of a combination of the protamines derived from the testes of certain species of fish, with insulin hydrochloride, by Hagedorn and his coworkers. These protamines, first extensively studied by Kossel, may form a loose chemical combination with insulin, perhaps analogous to that presented by aniline hydrochloride. The clinical use of this material causes an undoubted prolongation of the usual insulin effect, up to eight or ten hours. The most striking clinical

ROOT, H. F., WHITE, P., MARBLE, A., and STOTZ, E. H. Clinical experience with protamine insulinate, *Jr Am Med Assoc*, 1936, cvi, 180.

HANSEN, P. Enlargement of the liver in diabetes mellitus, *Jr Am Med Assoc*, 1936, cvi, 914.

result so far noted, aside from its influence upon the hyperglycemia and glycosuria, is the reduction of the liver enlargement sometimes observed in cases of poorly regulated diabetes especially in children. Unfortunately, the preparation of the material for injection, and its stability, present certain difficulties and render it impractical for use on an extensive scale in its present form. A flocculent precipitate is formed, and it is necessary to inject this material in an even suspension. The occurrence of insulin reactions is also somewhat disturbing, in the writer's experience. These come on, as a rule, more slowly and insidiously than do those seen with ordinary insulin, so that the danger involved in failure of recognition is possibly greater. Sweating and hunger are much less marked and the occurrence of rather severe headache is quite common.

There is no doubt that further progress along similar lines in order to secure delayed insulin action will now be rapid. It is of interest, as found in determinations of the molecular weight of insulin by the ultracentrifuge method in Svedberg's laboratory, that significant changes occur with variation in the pH value of the solution. Whereas the insulin molecule is relatively stable within the range pH 4.5 to 7.0 (molecular weight about 35,000), outside this range it dissociates into products of smaller size. This dissociation, however, is reversible. It is possible that the greatly enhanced surface area presented by the smaller dissociated particles increases their adsorption on the tissues and hence slows up their physiological utilization, as compared to that of the ordinary insulin molecule. Important developments of practical clinical value in this field may shortly be expected with considerable confidence.

REVIEWS

Physical Diagnosis By RICHARD C CABOT, M D 11th Edition 540 pages, 16 5
× 23 5 cm Williams and Wilkins, Baltimore 1934

This is the eleventh edition of this deservedly popular textbook. As usual it is notable for the clarity and force with which the material is presented. The well chosen illustrations are a distinct addition to the text. There have been new additions to and enlargements of certain sections, for example those dealing with coronary disease, latent tuberculosis, neoplasms of the lungs and bronchi and the pneumononioses. The new edition all in all is a further improvement on those preceding it and will no doubt be equally well received.

M C P

Three Philosophers (Lavoisier, Priestley and Cavendish) By W R AYKROYD
227 pages, 13 × 21 cm William Heineman Ltd, London 1935 10/6 net

Historians of medical science often are too concerned with relatively unimportant personal attributes and experiences of the great figures of medicine and too little with their ideas or their contributions. Often too they have more of the bibliophile's interest in the publications that have changed the course of scientific progress than that of the student of science. The present little volume seems to the reviewer a model of its kind. The author writes charmingly of the lives of three great scientists and of the period in which they lived. It is evident that he is thoroughly at home in the history of the late eighteenth century. On this background he develops very clearly and interestingly the story of how each contributed to our present knowledge of the composition of water and air. The significance of Lavoisier's metabolic investigations is well brought out. Toward the end of the volume the later life and death of the three philosophers is well told. To most readers the material especially on the life of Lavoisier will be new. It is a small volume which will be read by any physician with interest and profit.

M C P

Medical Tactics and Logistics By COLONEL GUSTAVUS M BLECH, M C, U S A,
and COLONEL CHARLES LYNCH, M C, U S A, Ret 201 pages, 15 5 × 23 5 cm
Charles C Thomas, Springfield, Ill 1934 Price, \$4 00

The authors have written this book to afford "medical officers, patriotic physicians and medical students a fundamental idea of the nature of their duties in the event of a national emergency." It begins with a number of short chapters on "Theory Development and Principles of War" and then proceeds to recount in considerable detail the military and medical aspects of an imaginary war, or succession of skirmishes about the borders of Maryland and Pennsylvania. All the moves in this conflict are discussed pro and con at some length and a conscientious effort is made to drive home certain elementary lessons. A folder of maps of the region accompanies the volume.

In this war everything proceeded according to regulations. Apparently orders were issued constantly and obeyed promptly, liaison was perfect, everyone knew all he should know about what was going on, maps must have been issued in abundance and medical supplies were never seriously lacking. The behavior of almost everyone was exemplary. The reviewer hopes that the next war will resemble the one here described.

Those who took part as regimental medical officers in the forward areas in the past war will find most of this volume highly theoretical and unreal. However,

there is a foundation of sound doctrine in it, and its perusal will give the battalion surgeon of the future a good general notion of how the medical corps at the front is intended to function. Following this he would do well to read "The Lost Legion" or "Chevrons" to get a more realistic conception of what a war is like.

M C P

Disorders of the Blood By LIONEL E H WHITBY and C J C BRITTON 543 pages, 16 X 24 cm P Blakiston's Son and Co, Inc, Philadelphia 1935

The authors have produced a book which may be recommended unreservedly to the attention of all physicians engaged in the practice of internal medicine. It meets in a very adequate way the need for a monograph in which the large and scattered literature of hematology of the last ten years is gathered together, added to our basic knowledge of the subject and presented as a whole. The earlier chapters deal with the origin, functions and fate of blood cells, the abnormalities of hemopoiesis, and the methods of study and of differentiation of the various formed elements of the blood. Then comes, in several chapters, an excellent discussion of the anemias. The first and second of these chapters deal with the causes of anemia and with the principles of treatment. It would be hard to find elsewhere as compact, as clearly stated and as interesting a discussion of our more recent knowledge of these topics. In the later chapters on the various types of anemia the chapter on pernicious anemia and that on anemias due to disease of the alimentary tract are of particular interest. The anemias of infancy and childhood receive notice in a separate chapter.

The purpuric and hemorrhagic states are discussed rather briefly though even rare forms are mentioned. In the chapter on aplastic diseases the data on agranulocytic angina are derived almost wholly from American sources, and there is very little expression of the authors' own opinions.

The leukemias, affections of the spleen, the blood changes in infection and infectious diseases and in miscellaneous conditions occupy the latter half of the book. Blood groups and blood transfusion are discussed.

The book is well organized and carefully written. There is a good index. References are placed at the end of the chapters. The tables, illustrations and colored plates are helpful.

The treatment of such a large field is necessarily brief, and it is perhaps inevitable that the tone should be at times dogmatic. A more critical evaluation of proposed therapeutic measures would be helpful in some sections. All in all, however, this is a very valuable book. It may be used as a reference or read through with profit as an account of the present status of knowledge concerning disorders of the blood.

M C P

Diseases of the Liver, Gall Bladder, Ducts and Pancreas By SAMUEL WEISS, M D, F A C P 1099 pages, 18 X 26.5 cm Paul B Hoeber, Inc, New York 1935 Price, \$10.00

This large, handsomely printed and illustrated volume is disappointing when put to the test of practical use as a reference volume. It is essentially a compilation of abstracts from the literature. There is a striking lack of orderly and logical sequence in the topical discussions so that the reader is left confused and unsatisfied. Important facts are often stated very briefly or omitted while pages are given to comparatively trivial details. Numerous inaccuracies further detract from the value of the book.

COMMITTEE ON FUTURE POLICY FOR THE DEVELOPMENT OF INTERNAL MEDICINE

Minutes of the Board of Regents, March 6, 1936 "RESOLVED, that a Committee on Future Policy for the Development of Internal Medicine be appointed by the President for the purpose of considering a program of possibilities for using surplus funds for the advancement of Internal Medicine This Committee shall take under consideration all matters outside that of the College Headquarters, such as fellowships, awards, postgraduate education, initiation fees of new Fellows, revolving funds for the aid of research, etc"

The personnel of this Committee, as appointed by the President, Dr Ernest B Bradley, is as follows

James Alex Miller, *Chairman*, New York, N Y
Walter L Bierring, Des Moines, Iowa
Roger I Lee, Boston, Mass
Maurice C Pincoffs, Baltimore, Md
Francis M Pottenger, Monrovia, Calif

Dr George Bachmann (Fellow), Atlanta, Ga, presented a paper on "The Gaseous Metabolism of Glucose, Fructose and a Mixture of These Two Sugars, together with Urinary Findings" at the February meeting of the Dugas Club of the University of Georgia School of Medicine

The Second Annual Postgraduate Course "Neuropsychiatry in General Practice," given by the Staff of the Menninger Clinic, Topeka, Kans, will extend from April 20 to April 25 Dr William C Menninger (Fellow) and Dr Ralph M Fellows (Fellow) are among those contributing to the course

Dr Clayton W Greene (Fellow), Buffalo, N Y, has been appointed a member of the New York Public Health Council by Governor Lehman

Dr George W McCoy (Fellow), of the U S Public Health Service, has been appointed professorial lecturer in preventive medicine at George Washington University School of Medicine

Dr Arthur C Christie (Fellow), Washington, D C, has been reelected President of the Board of Trustees of the American University

Dr Archibald Barklie Coulter (Associate), Washington, D C, has been appointed Director of the Bureau of Tuberculosis of the Health Department of the District of Columbia

Dr Frank R Menne (Fellow), Portland, Ore, and Dr Delbert H Nickson (Fellow), Seattle, Wash, have been elected President and Vice-President respectively, of the recently organized Pacific Northwest Society of Pathologists

Brig Gen Matthew A Delaney (Fellow), Assistant to the Surgeon General U S Army, has retired on his own application General Delaney graduated from the University of Pennsylvania in 1898 He also held the Certificate of Public Health from Harvard University School of Medicine He has been in the Medical Corps of the U S Army since 1901, and is retiring at the age of sixty-one He was White House physician during the administration of President Taft from 1909 to 1913 Earlier he served in the Philippines and during the World War, he was in charge of Base Hospital No 10, and was later detailed as liaison officer with the British War Office He received the Distinguished Service Medal, and was decorated by the British Government

Dr Joseph C Doane (Fellow), Medical Director of the Jewish Hospital, Philadelphia, and Dr Martha Tracy (Fellow), Dean of the Woman's Medical College of Pennsylvania, have been appointed to the Philadelphia Board of Health, to succeed Dr James M Anders (Master), resigned, and the late Dr Ellwood R Kirby

Dr William B Castle (Fellow), Associate Professor of Medicine at Harvard University Medical School, received the Procter Award on the occasion of "Professional Day" of the Philadelphia College of Pharmacy and Science, January 31

Dr Charles A Doan (Fellow), Professor of Medicine and Director of Research, Ohio State University College of Medicine, Columbus, delivered the Beaumont Lectures for 1936, sponsored by the Wayne County (Mich) Medical Society, March 23 to 24 The lectures were given on "The Histopathology of the Blood"

The Scientific Assembly of the American Medical Association decided in December to have an afternoon session at the coming meeting in Kansas City in May devoted to Tuberculosis, under the Section on Miscellaneous Topics The officers appointed for this Session were Dr James Alexander Miller (Fellow), New York City, Chairman, Dr Charles Hartwell Cocke (Fellow) Asheville, N C, Secretary The Session is to be held Wednesday afternoon, May 13, and the preliminary program will include, in addition to the Chairman's Address, papers by Drs Max Pinner, Oneonta, N Y, J Burns Amberson, Jr, New York City, LeRoy S Peters, Albuquerque, New Mex, and J J Singer, St Louis, Mo, all members of the College

MAY, 1936

NUMBER 11

THE RÔLE OF EMOTION IN DISEASE*

By WALTER B. CANNON, *Boston, Massachusetts*

WHEN your President asked me for the title of the address for this evening, I had in mind some ideas which I wished to elaborate and which could be included under the heading, "The rôle of emotion in disease." The title is so comprehensive, however, that I must set definite limits to the parts of the subject to be considered. This can be done by use of a method time-honored in the history of medicine—the statement and exposition of aphorisms. There are ten of them.

1 *In modern life infections have diminished and nervous strains have increased.* Anyone whose years allow him to survey the events of the last third of a century is aware of profound changes in the conditions of our existence. Among them is a remarkable shift in the importance of common types of illness. Diseases formerly regarded as plagues and pestilences are now largely under control or have almost disappeared. Tuberculosis is no longer "master of the kings of death", diphtheria has lost most of its terrifying character, the mortality in measles and scarlet fever has gradually been reduced to about a third that of a generation ago, and typhoid and yellow fever, once our arch enemies, may now be regarded as conquered. Release from these and other similar scourges is rightly counted among the great blessings which medicine has conferred upon mankind.

At the same time with these liberations from damaging and death-dealing infections, however, new and strange circumstances have developed in which men and women must conduct their lives. The ox-cart, the horse and buggy and the bicycle, bad losers in the race for speed, have been crowded out by the motor car. The cry for faster and faster travel has been answered by engines which now permit us to rush along the highways at 50, 60 or 70 miles an hour. Tens of thousands killed annually, and hundreds of thousands injured, measure the consequent jeopardy of life and limb. The meanings of these figures in the distress and remorse of the surviving drivers and their victims, in the pains of the crippled, and in the anguish of inconsolable loss among those who look upon their dead, are wholly immeasurable.

* Convocational Oration, Sessions of American College of Physicians, Detroit, March 4, 1936.

From the Laboratory of Physiology, Harvard Medical School.

Accompanying the development of the automobile has been an extraordinary change in the occupation of our people. From a population 60 per cent rural in 1900, we have turned into a population 60 per cent urban. The cities have gained over the farms more than 30 million inhabitants. Whatever its hazards, life in the country has admirable liberty, independence and opportunity for self-direction. Those who have chosen to live in the great cities are often confined to a routine of fixed hours and monotonous tasks. Many lead a sedentary existence, which breaks sharply the age-long racial habit of using the big muscles of the body for gaining sustenance, and the muscles, instead of keeping the body fit, become flabby and inefficient. Furthermore, as hired bookkeepers, clerks and accountants, or as hands in foundries and factories, city dwellers become entangled in the great web of dependency. Specialized work implies limited freedom. The defects of the present commercial and industrial system are not revealed so long as it operates smoothly. It is when a strike among glass molders, for example, stops tens of thousands of other workmen, or the overwhelming of an employer adds the host of his laborers to the masses of the unemployed, that helpless dependence becomes obvious. No wonder that bitter experience can lead to worry and anxiety and to fits of dark depression, and that wives and children must share the gloomy chances with the men who face the tragedy of the lost job. And illness, when it comes, adds its weight to the feeling that support is insecure.

Although reliable statistics are hard to obtain, it would appear that the intense drive and pressure of the new life, its worries and its dreads, place a strain upon men and women which often is too great to be borne. The suicide rate went steadily upward during the recent years of excitement and depression until, in 1932, in the United States it was over 50 per cent higher than during the five years after the War. That rise meant an increase of more than 6000 suicides in 1932 alone. Among diseases suggesting strain are those of the heart and blood vessels, which have nearly trebled in the last three decades. Angina pectoris, emotionally stirred if not emotionally started, now has in New York and Massachusetts three times the number of victims it had in 1900. In New York exophthalmic goiter—that picture of persistent fright—has consistently increased as a cause of death until it has doubled what it was between 1906 and 1910. But these are *mortality* figures, and as such are only indicative of the point which I wish to make. That point is that since the turn of the century an important change in the phenomena of disease has occurred—the seriousness of infection has been undergoing a remarkable decline, and strains and stresses, especially affecting the nervous system, have been on the increase. The disorders resulting therefrom may not lead directly to death and thereby affect statistics, but nevertheless they may cause an immense amount of distress and pain, both directly in the patient himself and indirectly in those bound close by family ties. I refer to the disorders due to emotional causes, fears, resentments and frustrations.

2 *The medical profession has not recognized in a practical way the recent shift in the etiology of disease* Contemporaneous with the changes which we have just reviewed there has been a development of "healing cults" in our country to a degree not seen in other lands. Persons who have had no discipline whatever in the medical sciences, and no rigorous clinical experience, have been recognized by the public, and to some degree by members of our profession, as capable of undertaking the treatment of the sick. Prominent among these cults are Christian Science and other systems of mental healing. I would add also Freudian methods as practiced by laymen, for Freud himself has argued vigorously in favor of the application of his ideas by psychologists and others who have had no medical training. The Christian Scientists deny the existence of bodily disease altogether and account for so-called illness as being the result of mental error. For the more metaphysical Freudians, likewise, the brain and its modes of government of the organism seem to be quite negligible, the id, the ego, the superego and the censor, and occasional unfortunate family quarrels among these ghostly figures, suffice to explain many of the troubles of existence.

How may this purely mentalistic attitude toward disease be interpreted? The explanation, no doubt, is complex. Fundamentally, I believe, it results from our failure to recognize the considerable rôle which emotional factors have come to play in the onset of illness, especially among people who are harassed by novel and severe demands on their nervous capacities. The medical curriculum has paid relatively little attention to this important matter. In the teaching of medical students emphasis has been laid on disease as it is manifest at the autopsy table or under the microscope. Bacterial agents, poisons, and physical trauma have been recognized as the obvious common causes of disability. In their application, through decades these notions of pathology have, to be sure, proved their worth. The immense and admirable advances of both curative and preventive medicine during the last four-score of years are properly attributed to them. But perhaps the insistence on morphological pathology and the routine attention to physical signs have led to a belittling and depreciation of human disorders so subtle that they leave no obvious trace.

Is it not true that the recent almost revolutionary transformation of the conditions of life has altered the relative importance of etiological factors? Since bacterial agencies have become less potent, and disturbances of nervous functions have become a greater liability, should not we recognize the change? It will not be easy. Fears and worries, persistent hatred and resentment—what pathology have they? Are they not manifestations of the psyche? And who knows about the psyche? Taught to deal with concrete and demonstrable bodily changes, we are likely to minimize or neglect the influence of an emotional upset, or to call the patient who complains of it "neurotic," perhaps tell him to "go home and forget it," and then be indifferent to the consequences. But emotional upsets have concrete and

demonstrable effects in the organism. It is not to be wondered at, therefore, that when a patient in trouble appeals to us for aid and finds us lacking in sympathy and interest, he turns to faith healers, or Christian Scientists, or psychoanalysts, whether they be expert or not, seeking the help which he needs.

3 *A consideration of the physiological aspects of emotional disturbance discloses a way toward understanding it.* Patients suffering from emotional strain offer to the conventionally trained physician a dilemma, he cannot put his finger on any observable lesion that would yield insight into their troubles, nor can he use his routine methods to explore that complex and mysterious realm where the strain seems to have its center. An escape from this dilemma, which avoids both the demand for palpable evidence of disease and also the vagueness and mysticism of the psychological healers, can be found, I believe, in an examination of the physiological processes which accompany profound emotional experience. As a physiologist I have good reason to regard the movement of nerve impulses along the invisible pathways of the brain as being no more associated with any permanent structural change than one would find, after I cease speaking, in the neurones which now innervate the muscles of my larynx. Yet, in the minute and intricate net of microscopic threads in the cerebral cortex, easy courses may become established which may lead to personal disaster—which may, indeed, result in conduct so intolerable that society will take away from the individual his free action. The habitual pickpocket, the incorrigible forger, the persistent incendiary are persons who exhibit such inwrought and established antisocial behavior. One would look in vain for the pathology of their neurones, yet we must admit that their repeated crimes result from repetition of the same occurrences in their brains. And similarly when typical visceral disturbances occur in regular consequence of emotional excitement—just such disturbances as can be induced by stimulating the visceral nerves—as a physiologist I have good reason to regard them as resulting from discharge of nerve impulses due to the excitement. I propose, therefore, that we try to keep out of the foggy realm of metaphysical medicine and consider emotions from the physiological point of view. Although I shall use words which designate subjective states, such as “fear,” “rage” and others, let it be understood that I use them only as convenient abbreviations for activities in the nervous system. Throughout the discussion I shall be concerned with the *physiological* aspects of affective disturbances—that is, with the nervous mechanisms which are involved. Admittedly I am laying little emphasis on the subjective states, the glow of color and warmth, or the darkness of doomsday, with which emotional states may surround simple perceptions or purely intellectual processes. Such states I do not wish to “physiologize.” Let us for the present attend to the *expressive* aspect, the “motion” part of the emotion.

From the physiological point of view an emotion is a typical reaction pattern, having in its *expressive* features characteristic facial and postural

attitudes Only a glance is needed to tell the disposition of a lost child sobbing for his mother, or a young tough who with clenched fist and gritted teeth seeks his enemy, or a thief in wild-eyed flight from an armed policeman Expressions of grief and rage and fear are ingrained in cerebral structure Just as sneezing and coughing are reflexes, provided in the congenital organization of the nervous system, so likewise is emotional behavior One does not have to take lessons in ways of showing one's feelings Place a man in danger and he is afraid, interfere with him as he satisfies some natural instinct and he becomes angered When the appropriate stimulus is applied there is commonly a prompt response So uniform is the response that among different peoples, and even in lower animals, its meaning is understood without explanation, and so persistent is it throughout life that an old man's expression of grief resembles that of a child In practically all respects the reactions of the body to emotion-provoking situations have the characteristics of simple reflexes

4 *Profound emotional disturbances are expressed in effects on viscera which are innervated by the autonomic nervous system, and especially by the sympathetic division of that system* If an emotional reaction is intense, visceral disturbances may occur which involve the entire organism The movements of the gastrointestinal tract are stopped, the digestive secretions are inhibited, the heart is made to beat more rapidly, the blood pressure is elevated by vasoconstriction in the skin and the splanchnic area the spleen is contracted so that its content of concentrated corpuscles is squeezed out, the adrenal medulla is made to secrete adrenine, blood sugar is increased by discharge from the liver, and sweat may be poured out on the body surface All these extensive alterations in the organism are displays of the functioning of the sympathetic division of the autonomic nervous system, whose outreaching filaments are distributed to every region of the body, from the hairs on the top of the head to the glands on the soles of the feet

There is evidence, also, that intense fear, for example, may involve in addition the parasympathetic control This effect seems to be more manifest in the activities of the sacral division than in those of the cranial Emptying of the bladder and rectum and cases of emotional diarrhea at times of excitement belong to this group of responses

Though there are instances of dominance of the sacral visceral nerves in emotionally disturbing conditions, the typical and more usual effects are those induced by the sympathetic Simultaneously with the discharge of sympathetic impulses, as already noted, the adrenal medulla is made to secrete Since the product, adrenine, cooperates with and reinforces sympathetic nerve impulses, we may say that a sympatho-adrenal system provides the means by which, as a rule, emotional states affect the organism

5 *Emotional stimulation of the sympatho-adrenal system is useful for immediate physical struggle, but otherwise may be deeply disturbing* The overlapping and interlacing of the preganglionic fibers as they reach up and down the lateral chains of sympathetic ganglia indicate an arrangement for

extensive discharge of nerve impulses throughout the body. The distribution of cooperative adrenine in the blood stream, which is general and indeterminate, supports the view that normally the sympatho-adrenal organization is such as to allow it to work as a whole. When there is intense excitement, that is what happens, the entire organism, as previously mentioned, may be brought under sympatho-adrenal influence, and all the bodily forces mobilized for action. It is noteworthy that the changes wrought under these conditions closely parallel the changes which occur in vigorous muscular effort. Indeed, when we consider the age-long racial association of fear with the impulse to run away or escape, and of anger with the impulse to attack, these bodily changes at critical moments may reasonably be interpreted, as I have detailed elsewhere,¹ as preparations for struggle, perhaps a supreme struggle, for existence.

There is another fundamental function of the sympatho-adrenal system, however, which is related to its emergency function and which must be regarded. That is its service in preserving constant conditions, or homeostasis, in our body fluids, the blood and lymph.² Such constancy makes possible for us uniform and consistent performance of our physiological processes. Does the temperature tend to fall and make all our motions slow? The sympathetic constricts blood vessels and increases heat production by discharging adrenine. Does the temperature tend to rise and imperil the integrity of the brain? The sympathetic relaxes surface arteries and pours out sweat for cooling. Is there danger of too little sugar in the blood, with possible convulsions and coma? The sympatho-adrenal agency steps in and liberates a supply of glucose from the hepatic stores and prevents disaster. Does vigorous muscular effort produce non-volatile acid which might overwhelm the alkaline buffer in the blood and stop all action? The sympathetic quickens the pumping of the heart, raises the general blood pressure, makes the blood flow faster through the laboring muscles, unloads extra corpuscles from the spleen, and by thus greatly augmenting the supply of oxygen in the needy parts, permits the non-volatile acid to be burned to innocuous volatile carbon dioxide and the peril is escaped.

The bodily changes in emotional excitement may be considered as anticipatory of many of these dangers. The forces of the organism are put upon a war-footing. But if there is no war to be waged, if the emotion has its natural mobilizing effects on the viscera when there is nothing to be done, obviously the very system which functions to preserve constancy of conditions within us is then employed to upset that constancy. It is not surprising, therefore, that fear and worry and hate can lead to harmful and profoundly disturbing consequences.

6 *The sympatho-adrenal system, though organized for diffuse and widespread action, may influence excessively separate organs or functions.* The evidence for this statement is derived, not from experimental data, but from clinical testimony. To what degree separate organs or functions may be influenced without attendant implication of the rest of the sympathetic has

not been determined. I suggest that here lies an interesting field for research. The indications from case reports point to the possibility that an intense emotional shock, or prolonged emotional strain, may result in one or another of the viscera becoming so subject to sympathetic impulses that even slight perturbations in the daily routine will have noteworthy effects.

Among such conditions may be noted a sensitive reaction of the heart, seen occasionally in soldiers who have been exposed to the terrors of warfare, the slightest excitement sends the pulse bounding up to 140 or 150 beats per minute. Or the vasoconstrictor center is so sensitive that the blood pressure jumps up 40 or 50 millimeters whenever an unhappy event is mentioned. Emotional "dyspepsia" so-called, including disturbances of gastric secretion and motility, due to worry or anger, spasm of the cardiac and pyloric sphincters, readily understandable because both sphincters are tightened by sympathetic impulses, vaginismus, also explained by sympathetic innervation of the encircling smooth muscle—all these are pertinent instances. Perhaps most noteworthy are cases of exophthalmic goiter, in which the striking appearance of the patient is that of chronic fright. The rapid heart, the sweating palms and the bulging eyes all tell a tale of increased activity of at least the upper portion of the sympathetic system. Friedgood's recent studies³ in the Harvard Physiological Laboratory suggest that sympathetic impulses may act primarily on the anterior lobe of the pituitary and that thyroid involvement is secondary to that. Whatever may be the way in which the disease is evolved, the evidence seems to me overwhelming that a large proportion of the cases have an emotional origin.

7 *The neural basis for emotional expression is organized in the thalamic region of the brain.* The close resemblance between emotional expressions and simple reflexes has already been emphasized. It is characteristic of simple reflexes that they have their centers in the spinal cord or in the part of the brain which is racially most ancient, the primitive brain stem. We have ample evidence to prove that the neurone patterns for the full display of the elementary emotions are organized in this part of the cerebrum. As Bard⁴ has shown, the decorticate cat, without any cerebral hemispheres, will snarl and bite when pinched, will crouch and run away when stimulated by a hissing or a loud noise, and will display characteristic mating behavior when appropriately stimulated. Here are the typical signs of rage, fear and sexual excitement, exhibited after the cerebral cortex, which associates the organism with the outer world, has been wholly removed. Characteristically the emotional expression of decorticate animals is extreme. When rage—what we called "sham rage"—occurs in such a truncated creature, the sympatho-adrenal system is supremely active, the heart rate may double, blood sugar may increase five-fold, blood pressure is markedly elevated, sweat is poured out on the toe pads, and the hair stands erect from head to tail tip. Because the display of typical emotional responses after decortication tends to be superlative, the inference is obvious that the cortex normally exerts an in-

hibitory influence on the lower centers. Decortication lifts the check and permits the display to have unlimited intensity.

The neural organization demonstrated in lower animals is present also in man. A unilateral tumor in the thalamic region—i.e., at the emotional level—may not alter a voluntary laugh or a voluntary grimace of pain, originated in the cortex. A real laugh or grimace, however, induced by proper affective stimuli, is unilateral. Or a patient with features distorted by one-sided palsy will, when he laughs or weeps because of true feeling, express his attitude with both sides of his face. In short, the muscles of expression are governed from two levels—the cortical level in the cerebral hemispheres, and the emotional level in the diencephalon.

Quite in accord with this evidence are the emotional manifestations in man when he is chemically decorticated. The primary stage of ether anesthesia, and subjection to nitrous oxide, illustrate that condition. Under ether the patient may put up a vigorous fight, and under nitrous oxide he may laugh or weep. In the circumstances voluntary or cortical government has been abolished, but the features of rage or pleasure or grief are still patterned in the emotional level.

Although there is evidence that artificial stimulation of certain parts of the cortex can influence some internal organs, the physiological significance of this fact is still unknown. We do know that as a rule we cannot directly either start or stop the motions of the stomach, for example, or the acceleration of the heart or an extra output of sugar from the liver. Thus, although cortical government may prevail over that part of emotional expression that is seen in features and posture, it is impotent in checking the effects on the viscera. A man apparently calm may be "boiling" inside.

8 *The nervous system is organized in two grand divisions operating outwardly and inwardly.* The universal distribution of the fine nervous filaments to well-nigh every minute area within us need not be emphasized. Stimulation of any point on the skin may send reverberations throughout the whole organism. By means of this intricate and elaborate net of communicating fibers the multitudes of individual parts of the body are unified and made to cooperate.

In the central organization of the nervous system two main divisions may be distinguished. There is what I have called the *exteroceptive* division, that which by means of sensory receptors is impressed by changes in the outer world and which by means of striated muscles and bony levers works outwardly to change our surroundings and our relation to them. Apart from simple reflexes this division is normally managed from the cerebral cortex. It is related to the external environment, both material and social, in a prodigious complex of impressions, memories, habitual reactions and new adjustments. Through words and pictures, as symbols for objects and acts, the exteroceptive division may become a part of an indefinitely extensive universe. And then there is the *interoceptive* division. This is the individual, personal division. It is the autonomic or involuntary system,

already detailed. It works inwardly and affects the muscles and glands of the viscera. It is primarily concerned with the internal environment, the fluid matrix of the body, and, as already noted, normally serves to maintain constancy, or homeostasis, in the watery surroundings of the living parts, inside our dermal envelope. Tendencies toward change—toward hyperthermia or hypothermia, hypoglycemia or acidosis—promptly bring this division into corrective service. In natural circumstances it works cooperatively with the exteroceptive division, keeping the conditions of the fluid matrix fit for continued activity of that division. But the interoceptive division is governed at the emotional level. Again, in natural circumstances, this division, under emotional control, cooperates with the exteroceptive division.

9 *The cerebral cortex serves to interpret the nature of outer objects and to direct emotional forces when these are liberated.* The classical experiments of Pavlov have shown that by means of its agents, the receptors on the body surface, the cerebral cortex analyzes the external environment and brings outer objects into use by the organism. Thus these objects acquire new meaning. A flash of light or the ring of a bell is quite an indifferent stimulus until, for example, it becomes associated with feeding, whereupon it acquires efficacy and is known as a conditioned stimulus. Then the flash or the ring will start the saliva flowing, an effect beyond voluntary control, in the parasympathetic realm. Experiments on man have proved that stimuli can be similarly conditioned which will cause responses, such as narrowing of the pupil and vasoconstriction—again responses beyond voluntary control, and now in the realm of sympathetic innervation. It is evident that, although the viscera are ordinarily not under direct cortical (i.e., voluntary) influence, the natural reflex response can be extended by relating an ineffective with the effective stimulus. In similar manner indifferent objects may be made into effective stimuli for emotional reactions. The banging of a door renews all the horror of a shell-burst and sends the sensitized war-victim into pitiable fright—the noise is only incidental. A visit to a grave brings back acutely the pangs of grief—the grave as such is a bit of elevated earth.

It is by associations, acquired in experience or through verbal symbols, that objects become emotion-provoking. In this category are *words*, words which have been colored by feeling. We have all heard of "fighting words," those derogatory terms which, when earnestly applied to a man, bring anger on the instant. There are also scare-words which, when carelessly applied to a patient, make him anxious and apprehensive. "Your arteries are twisted," "your heart is rather small," or "a little enlarged," "your stomach has sagged," "your blood pressure is high"—these are examples. And then there are comfort-words, expressions which, coming from a trusted physician, banish fear. By use of these symbols the nervous system can be played upon as though an instrument. The charlatan employs

them to establish conditions which he can capitalize for his own profit. The wise doctor knows how to use them as a part of his therapy.

Experimental tests show that emotion-provoking associations of objects and symbols are established in the cerebral cortex. To the decorticate dog the brandished stick is not a menace—it has no meaning. And to the intact dog the stick may mean danger or may mean play, dependent on the way it is used. If in the woods we encounter a bear we shall not be afraid on noting that it is a stuffed bear. We may be very much afraid if it proves to be a live bear and advancing toward us. The total situation is interpreted by cortical processes, and in accord with the interpretation the emotional level discharges into the viscera or not.

If the viscera are roused and the body is prepared for struggle, the cortex once more serves an interpretative function. It directs the response. Bard's decorticate cats, if stimulated by being pinched, showed signs of anger, but they did not react by biting the experimenter, instead they commonly bit their own bodies.⁴ Or consider fear of the bear in the woods. Fear is attended by the impulse to escape from danger. But how? Is it better to run or better to climb a tree? Again, in accord with the total situation, cortical operations determine the course to pursue.

10 *The nervous system, the specialized system for integration of the body, is so organized that it may itself disintegrate.* As a rule, when there is a possible antagonism between actions, the nervous controls operate in such a way that the opposed actions are made reciprocal. Thus when we contract the biceps, automatically the antagonistic triceps muscle is relaxed. This mutual adjustment is found universally in the functioning of skeletal muscles which are set to work one against another, and also in smooth muscles which are similarly arranged.

There is a part of the nervous system, however, in which these nice reciprocations may not prevail. That is where the two grand divisions of the system—the exteroceptive and the interoceptive—may come into conflict. We have already noted the evidence that the cerebral cortex, governing the exteroceptive system, exercises a check on the lower centers where the emotional level is found. The cortex provides means whereby emotional responses may be not only conditionally stimulated, but also conditionally inhibited. Thus emotions may be set in opposition to one another. Are we angry and tempted to take vengeance? The cortically associated consequence of punishment by society rouses fear in us, and our action is prevented. Is the soldier, terror-stricken when a shell tears his "buddie" to bits, tempted to desert? If he should, a shooting squad would confront him, the terror is suppressed and he sticks.

These cases illustrate a process which is going on continuously. No doubt in primitive tribes the checks on instinctive behavior are less numerous than in civilized communities. As men have gathered in larger and larger groups, more and more have traditions, codes and laws been imposed to prevent the free display of certain feelings and impulsive acts. Indeed,

the early years of life are characterized by what Myerson⁵ has called "the social conditioning of visceral activities" The impulses to defecate and urinate, the powerful sexual impulses, strongly stimulated in our aphrodisiac world, the impulses to avoid dangerous demands upon us and to punish those who have injured us—all these impulses are as natural as breathing, but in civilized society the cortex puts a rein upon them The emotional or impulsive thalamic level says "act," and the conditioning cortical level says "no," or "circumstances are not appropriate," or "wait awhile" A conflict arises between unconditioned and conditioned impulses And thus within a system arranged for the unification of the organism, there is antagonism between the portion stimulated to discharge and the portion inhibiting the discharge And so-called "tensions" develop, because the emotional level, stimulated to discharge but held back from external expression, can have its way *inside the body* The dog, restrained as he scents his bird, "quivers with excitement," we say The angry man, withholding his blow, likewise "quivers with excitement" But deeper than these surface showings are the viscera, which the cortex does not control There the impulsive emotional level, deprived of outward expression, still governs And the disturbed processes of digestion, the disorderly action of the heart, the fluctuating high pressures in the arteries, the accentuated state of diabetes and the interferences with menstrual function are among the consequences

The antagonism between nervous activity of the impulsive thalamic level and that of the conditioning and inhibitory cortical level may result in phenomena which the physiologist can explain only by an inferred blocking of neurone pathways Such blocking might explain the paralysis of the shell-shocked—the so-called "hysterical wound" of the terrified soldier, which resolves his conflict by taking him from danger and also by giving him a reason for his freedom Such blocking might likewise account for the exclusion of the memory of a painful or disagreeable experience On the assumption that, by blocking, neurone patterns may become dissociated during antagonistic activities in the brain, we could understand not only isolated "neurograms" of previous events, but their ability to influence, uncontrolled, the interoceptive apparatus and its visceral effectors How antagonism between the two grand divisions of the nervous system could result in the assumed dissociation of neurone patterns is quite unknown The fact of dissociated memories, however, is not questioned

CONCLUSION

In the foregoing exposition I have endeavored to show that a highly important change has occurred in the incidence of disease in our country—that serious infections, formerly extensive and disastrous, have markedly decreased or almost disappeared, and that meanwhile conditions involving strain in the nervous system have been greatly augmented The nervous

system is all-pervasive. It can have effects in remote and secluded portions of the body, far from any obvious lesion. Because it is universal in its effects, disorders which involve the nervous system require consideration of the organism as a whole. But well-nigh all diseases involve the nervous system, because they arouse fears and anxieties and worries, and these feelings are expressed in demonstrable bodily effects.

I have questioned whether we as members of the medical profession have been sufficiently aware of the altered emphasis of illness. Have we not insisted too strongly that only such pathology as can be heard or felt, or tested and measured in the laboratory, is true pathology? Have we not specialized our observations so intently that we do not see the organism because of the organs? Have we not institutionalized medical practice to such a degree that we think more of the disease than we do of the man as an individual and as a member of a social group? An affirmative answer, I believe, should be given to each of these questions.

The cults of mental healers, which have grown to extraordinary proportions, are probably a measure of the failure of the medical profession to consider adequately the rôle of emotion in producing bodily disorders. The practitioners of these cults, in so far as they are untrained laymen, ignorant of the methods of critical diagnosis, are a menace to society. Even if there were no other reason for us to recognize the part which these practitioners undoubtedly play in restoring the morale of the depressed and the anxious, there is the reason that by so recognizing their services and by taking over those services ourselves we should be safeguarding our fellow-men who are ill.

In the course of this discussion I have spoken as a physiologist. The ways in which fears and deep-seated hate and other intense emotional feelings can influence the organism have purposely been described in physiological terms. This was done in order to make clear the point that the bodily effects are as understandable and can be as reasonably explained as clenching the fist or lifting the foot. It was not done because I would neglect the subjective side of impressions and behavior. The organism may be regarded as a "mind-body" unity, and we may quite as appropriately speak of conflicts in the conscious realm as we would speak of opposed impulses in neurones—they may be regarded as different aspects of the same operating system. An attempt to speak of all psychic events in neurological terms is commonly called "neurologizing" or perhaps "physiologizing." But an attempt to designate as "psychic," processes which are demonstrably neural is quite as reprehensibly "psychologizing." If we agree that we are organized as a psycho-organismic unity we need not hesitate to use any convenient terms in mentioning any aspect of behavior or experience, for then we understand that these terms designate one aspect or the other of a living, systematic whole. On that basis we may consider the ways in which success is achieved in the treatment of emotional disorders. Problems of deep feeling may be settled by removing the occasions for them. Sup-

pressed and forgotten fears may be brought into remembrance and abolished by being interpreted. Or rage and hate may be overwhelmed by an inspiring and inclusive love, in the religious sense, which embraces even one's enemies. In all such conversions of turmoil and trouble into serenity and freedom from bodily disturbance, is not the common feature that of resolving conflicts, of bringing harmony where there was discord, of restoring a normal consistency to one's memories and one's attitude and behavior? Perhaps our examination of the physiological antagonism which can develop between the cortex and the thalamic area will reveal to some how internal warfare may profoundly affect the whole organism, and how a return of internal peace may bring miraculously a return of health and happiness. If this excursion into physiology may have that effect, my emotional level would be most pleasantly affected.

VIRUSES AND THE DISEASES CAUSED BY THEM

By THOMAS M RIVERS, M D , *New York, N Y*

INFECTIOUS diseases are caused by certain kinds of active agents or their toxins. For convenience, or for other reasons, such agents are divided into the following groups: protozoa, fungi, bacteria, spirochetes, rickettsia, and, finally, the viruses. The viruses and their relation to disease will be the subject of my talk at this time.

The diseases of man that are known to be caused by, or that are strongly suspected of being caused by viruses are measles, German measles, mumps, fever blisters, herpes zoster, varicella, smallpox, vaccinia, rabies, psittacosis, common colds, influenza, St. Louis type of encephalitis, Japanese B type encephalitis, epidemic encephalitis, lymphocytic choriomeningitis, poliomyelitis, lymphogranuloma inguinale, Australian X disease, louping ill, Rift Valley fever, yellow fever, papataci fever, dengue fever, warts, and molluscum contagiosum.

In addition to man, lower animals, insects, plants, and even bacteria are subject to virus maladies. Foot-and-mouth disease of cattle, hog cholera, canine distemper, sarcomata of chickens, fowl pox, polyhedral diseases of caterpillars, mosaic diseases of plants, and bacteriophagy are examples of virus maladies of hosts other than man. In fact, no form of life seems to be exempt from such diseases. Since much of our knowledge of viruses has come from the study of diseases of hosts other than man, physicians must take them into consideration. Consequently, I shall not apologize for references to work not dealing strictly with diseases of human beings.

Workers in the virus field are frequently confronted with the question, "What is there about viruses that induces investigators to set them apart from ordinary bacteria, protozoa, fungi, spirochetes, and rickettsia?" Such a question implies that all infectious diseases must be caused by agents falling into the well recognized groups just mentioned. Indeed, certain workers are loath to accept the idea that infectious diseases can be caused by active agents possessing a nature different from those already known. In any event, the viruses are smaller than ordinary bacteria, and the size of some, e.g., the viruses of poliomyelitis and foot-and-mouth disease, approximates that of certain protein molecules. Furthermore, the viruses have not been cultivated in vitro in the absence of living susceptible cells, and in that sense they are obligate parasites.

The nature¹ of no virus is definitely known. At present, however, three sets of ideas seem to cover the possibilities. (1) The smallest viruses, e.g. the viruses of foot-and-mouth disease and poliomyelitis, may be inanimate incitants of disease transmissible in series. Stanley² believes that the virus of tobacco mosaic is an autocatalytic substance and recently reported that he

* Presented before the General Sessions of the American College of Physicians, Detroit, March 2, 1936.

is able regularly to obtain it in crystalline form. His work is significant, and, if his interpretations of it are accepted, progress has been made in regard to the nature of certain viruses. (2) The medium-sized viruses, as exemplified by the etiological agents of yellow fever and fever blisters, may represent forms of life unfamiliar to us. (3) The virus of vaccinia^{3, 4, 5} might well be a minute living autonomous organism or a midget in the microbial world, provided the elementary bodies which are infectious and are composed of protein, fats, carbohydrates, and ash represent nothing but individual units of the virus.

That the viruses are exceedingly small and that they have not been shown capable of multiplication in the absence of living cells are not sufficient reasons for considering the variety of diseases caused by them as possessing pathological changes in common. Indeed, one is repeatedly asked "Why are smallpox, mosaic diseases, poliomyelitis, sarcomata of chickens, and bacteriophagy—diseases with such diverse clinical pictures—grouped together?"

It is now generally agreed that viruses, regardless of their nature, are intimately associated with the cells injured by them. In fact, they are believed to multiply or to be regenerated within such cells. Consequently, it is not surprising that the viruses exert a decided influence upon these parasitized cellular elements.

What effects⁶ are produced in cells by the action of viruses? If the action is not too rapid or explosive, and if the affected cells are capable of multiplication, the primary response is hyperplasia resulting in an overgrowth of tissue. In certain diseases this is the chief pathological change, and tumors, such as the sarcomata of fowls and the papillomata of rabbits, are formed. In other maladies, e.g., smallpox and varicella, the primary stimulation with its resulting hyperplasia is followed by a necrosis or destruction of the hyperplastic tissue which causes the formation of characteristic vesicles and pustules. Similar phenomena are also observed in bacteriophagy in which the lysis of the bacteria is preceded by a stimulation of the cells as evidenced by an increased rate of their growth. If the action of the viruses is explosive as in yellow fever and Rift Valley fever, no obvious hyperplasia occurs, and necrosis of cells is the first sign of disease. Finally, if the cells, e.g., nerve cells, attacked by viruses, even though the action of the viruses be slow, are incapable of multiplication, the first sign of infection is lysis or necrobiosis of the cells. Such is the case in poliomyelitis, rabies, and louping ill.

One might ask, "How important a rôle do inclusion bodies and inflammation play in the pathological pictures caused by viruses?" In the past, pathologists devoted most of their attention to these phenomena and considered them of prime importance. It is true that inclusion bodies are of great significance, but they do not occur in all virus maladies. Inflammation is seen in most virus diseases, but it is nothing more than a secondary phenomenon appearing in the wake of cellular destruction. While inclusions are

important and inflammation regularly occurs in virus maladies, hyperplasia, hyperplasia and sequent or accompanying necrosis, and necrosis are the primary pathological phenomena of virus diseases, are common to all, characterize them, and logically permit of their segregation, in spite of their diverse clinical pictures, into the same group of diseases

Inasmuch as it is obvious that certain viruses induce a marked hyperplasia of tissues, it is easy to understand why such agents are considered in discussions of the cause of cancer. In spite of the great amount of work that has been carried on in this field, the relation of virus tumors to cancer has not been determined

I have discussed the nature of viruses and the pathological pictures produced by them. Now I shall take up the questions of prevention and treatment of virus maladies. Inasmuch as quarantine measures are of little or no value in the control of this group of diseases, I shall omit a discussion of them and pass immediately to a consideration of prevention and treatment by means of vaccines and convalescent sera, questions of lively interest at the moment, particularly in connection with poliomyelitis

There seems to be some misunderstanding in regard to the use of the word treatment, some physicians insist that all measures instigated after exposure to an infectious agent, even though the exposed person is still well, constitute treatment, while others are in the habit of employing the word only to designate measures initiated after the onset of signs and symptoms of disease. Consequently, in order to avoid confusion, I shall, in the remainder of my talk which deals with the efficacy of vaccines and immune sera, usually indicate at what time they are administered in relation to exposure and onset of signs of disease

The principles underlying vaccinations are old and date back to variolation and vaccination against smallpox. In variolation, the infectious agent, introduced into the body in a manner not usually encountered in nature, was supposed to produce a mild disease resulting in immunity. In vaccination, an altered virus in the form of cowpox was used to induce a mild local infection that protected against the severe malady smallpox. These principles actuated Pasteur when he prepared vaccines with an altered but active bacterium or virus. The alteration of the former agent was accidentally accomplished by prolonged cultivation of the organism on an artificial medium, while in the case of the latter agent the change was brought about by repeated passages of rabic virus in rabbits which resulted in "fixed virus". Theobald Smith went one step further and showed that injections of killed bacteria resulted in evidences of immunity in animals receiving them. In spite of the excellent work that has been done, we are still faced with the problem of the proper state of activity of viruses for vaccines and the proper methods of their administration for the prevention of virus maladies

It is generally conceded that calf lymph is an efficacious means of preventing smallpox, but it appears that this, the oldest and best instrument of

vaccination, can be improved upon in the form of culture vaccine virus administered intradermally.⁷

Fifty years after the introduction of antirabic vaccination, there is no agreement regarding the type of vaccine that should be used. In certain places, the Pasteur type of vaccine is still administered, in others, the Hogyes vaccine consisting of freshly prepared active fixed virus is employed, according to the Harris method, repeated injections of dried active fixed virus are given, finally, the Semple vaccine is supposed to contain phenol-inactivated virus.

For the prevention of yellow fever, two vaccines have been employed, one a formalin-inactivated virus,⁸ the other an immune serum mixed with a virus altered by repeated passage through mice.⁹

Psittacosis in man is not likely to occur unless the virus enters by way of the upper respiratory tract. In view of this fact, repeated subcutaneous injections of fully active virus have been used for the vaccination of laboratory workers against the disease.¹⁰

Recently, poliomyelitic virus supposedly inactivated by formalin¹¹ and virus still active but "attenuated" by sodium ricinoleate¹² have been used for the vaccination of children against infantile paralysis.

Vaccines to be of value must be reasonably safe and in most instances should protect for more than a short period of time. Completely inactivated viruses certainly would be the safest form in which to use them as vaccines for human beings. However, there is no evidence that smallpox and yellow fever can be prevented with vaccines composed of inactive viruses. Furthermore, certain workers are inclined to doubt the value of some batches of Semple vaccine containing inactive rabic virus, because they do not produce protection in dogs against rabies. Indeed, some investigators¹³ question whether a serviceable amount of immunity can be produced by a completely inactivated rabic virus, and no one expects a prolonged state of immunity to follow vaccination even with active virus, as is evidenced by the fact that each time a person is bitten by a rabid animal a course of vaccination is given. There is no reliable evidence^{14, 15, 16} that either of the recently used vaccines for poliomyelitis is efficacious, while there is grave doubt concerning the safety of one and a certain amount of apprehension in regard to the use of the other.

Why do inactive viruses fail to serve as efficient vaccines? An exact answer to such a question is not available. It may be that some viruses, such as that of poliomyelitis, are very poor antigens even in an active state. Furthermore, the antigenic components¹⁷ of certain viruses may be so labile that they are altered or destroyed in the process of inactivation. Finally, viruses as a rule compose such a minute portion of the tissue emulsions containing them that it is not practical at present to obtain large amounts of them for administration as vaccines.

There is no reason to suppose that the general principles of immunity¹⁸ are not operative in virus diseases. Therefore, inasmuch as it is likely that

most viruses are proteins or are largely composed of proteins, one would expect them to be antigenic and to produce a certain degree of immunity even in an inactive state provided their antigenic properties were not destroyed by inactivation and sufficient amounts were given. In the past, it has not been possible to meet the provisos just mentioned in regard to most of the virus diseases of man. What will happen in the future no one knows.

Vaccines are usually given before exposure, but in the case of smallpox and rabies, vaccinations made after exposure may be efficacious. The incubation period of vaccinia is very short and the rapidly resulting immunity may prevent or modify the activity of the already implanted smallpox virus. The incubation period of rabies is sufficiently long, four weeks or more, to allow the administration of a complete course of vaccination after an individual has been bitten.

The efficacy of vaccines has frequently been estimated in terms of serological tests, and in the case of virus diseases the neutralization test is the one that has usually been employed. Unfortunately the results of neutralization tests made with serum from vaccinated animals may not parallel resistance. This is particularly true in the case of poliomyelitis^{19, 20} and rabies,¹⁸ i.e., vaccinated animals may possess neutralizing antibodies and still be susceptible, while others may be resistant in the absence of demonstrable antibodies. Indeed, such a state of affairs may follow an obvious infection with certain viruses. For instance, monkeys that have recovered from a systemic infection with equine encephalomyelitic virus possess neutralizing antibodies in their blood and are systemically resistant to reinfection, but their brains remain entirely susceptible to the action of the virus.²¹ Moreover, what takes place in one host as the result of a virus infection may not occur in another, e.g., the brains of monkeys systemically infected with equine encephalomyelitic virus do not become immune, while those of guinea pigs do become resistant under similar circumstances.²¹ Furthermore, the events occasioned by the activity of one virus in a host may not parallel those induced by another active agent in the same host as evidenced by the fact that a systemic infection of monkeys with vaccine virus²² results in an immunity of their central nervous system, while such is not the case, as just pointed out, in regard to a systemic infection with equine encephalomyelitic virus. Consequently, at present the only adequate test for the efficacy of a vaccine is its ability to prevent or modify the disease for which it is given in a specified host.

Before taking up the question of prevention and treatment of virus diseases by means of convalescent or immune sera, I shall describe two sets of experiments that throw considerable light upon the subject.

Several years ago it was shown in my laboratory that typical vaccinal lesions developed in normal rabbit corneas that had been removed from the animals, inoculated with vaccine virus, and cultivated in plasma clots *in vitro*.²³ It is an interesting fact that pathological lesions typical of this

virus malady can be produced *in vitro*, and use has been made of it to investigate certain immunological phenomena²⁴

Corneas were removed from normal rabbits and after inoculation with vaccine virus were embedded in plasma clots obtained from rabbits immune to vaccinia. Typical vaccinal lesions with Guarnieri bodies and an abundant amount of active virus developed in such tissues in spite of the fact that in the plasma surrounding them there were sufficient antibodies to fully neutralize the virus. This phenomenon is easily understood in the light of the fact that the activity of vaccine virus can not be materially influenced by immune substances or antibodies once it has made contact with or entered susceptible cells. In this respect our findings are in agreement with those of Rous and Jones²⁵ who showed that intracellularly situated typhoid bacilli and red blood cells are not susceptible to such injurious agents as potassium cyanide and antisera.

The other set of experiments to which I referred was conducted by Andrewes²⁶ who showed that antivaccinal serum infiltrated into the shaved skin of a rabbit prevented the development of a vaccinal lesion in the treated skin even though the virus was inoculated immediately afterwards. However, if the virus was injected into the skin five minutes prior to the time that the infiltrations of immune serum were made, no amount of serum sufficed to prevent a lesion, and, if eight hours were allowed to elapse after inoculation, not even the size of the lesion was influenced. Furthermore, it was demonstrated that large amounts of immune serum, administered intravenously shortly after the virus was inoculated intradermally, would prevent a generalized eruption but would exert no influence upon the lesion at the site of the inoculation. In this connection, it should be remembered that as a rule no evidence of infection is seen during the first 48 hours after vaccine virus is injected into the skin of a rabbit.

The results of the above experiments clearly indicate that once a virus has entered a cell its activity can not be influenced by large amounts of antiviral serum. Furthermore, such findings aid one in interpreting the results obtained in the use of immune sera for the prevention and treatment of virus diseases in man.

Convalescent measles serum given to a child just before and within six days after exposure to measles usually prevents the appearance of evidences of the disease, serum administered between the sixth and tenth days after exposure as a rule modifies the severity of the infection, serum given after the onset of signs of infection, which most frequently appear on the tenth day, is according to observant and critical workers without beneficial effects.

In attempts to interpret the significance of the results just described, let us assume that the virus of measles enters the upper respiratory tract and multiplies in some part not definitely determined. Beginning with the sixth day after exposure the virus is distributed from the primary focus to different parts of the body by way of the blood stream, and, from the course of events, it is not unreasonable to suppose that by the tenth day sufficient

virus has been distributed for the infection of most of the cells susceptible at that particular time in any given individual. If our assumptions are correct, serum administered during the first six days after exposure should not necessarily inhibit the multiplication of virus in the primary focus but should prevent its distribution and the development of illness and evidences of measles. Moreover, serum given between the sixth and tenth days should prevent the distribution of that part of the virus that has not already been distributed or should hinder its entry into susceptible cells not already involved, and, in view of this fact, should modify the severity of the infection but not prevent it. Finally, serum administered after the tenth day should not be beneficial, because most if not all the cells that are to be affected have by that time already been entered by the virus.

Those who are familiar with measles will say, "But the rash comes on the fourteenth instead of the tenth day." That is true. Viruses, however, may be in cells several days before evidences of the fact become obvious. Furthermore, according to some observers, a measles rash can be made evident by means of ultraviolet light 24 to 48 hours before it is detectable under ordinary conditions.

In the case of measles, many assumptions have been made regarding the location of the virus in the body at different times during the course of the infection. Unfortunately, a good experimental animal is not yet available for the testing of some of the assumptions. In the case of certain virus diseases of the central nervous system, however, there are suitable experimental animals from which accurate data have been obtained regarding the location and concentration of the viruses from the time that they are instilled into the nose until the animals die.

Fite and Webster²⁷ have shown that after instillation of louping ill virus into the nose of mice the active agent is present in the brain four days before the animals evidence signs of illness.

Galloway and Perdrau²⁸ found that after instillation of louping ill virus into the nose of monkeys the active agent was well distributed throughout the central nervous system several days before the animals showed signs of sickness.

Hurst²¹ instilled equine encephalomyelitic virus into the nose of monkeys, sacrificed them at different times after inoculation, tested various parts of their central nervous systems for the presence of the virus, and correlated his findings with clinical observations made on the monkeys before they were killed. According to him, all parts of the central nervous system except the cord contained virus within 30 hours after the onset of fever, and several hours later, at the time of the onset of nervous symptoms, even the lumbar cord was infectious.

Webster and Clow²⁹ dropped the virus of the St. Louis type of encephalitis into the nose of mice, sacrificed some at different times in order to test for the presence of virus in various parts of the brain and cord, killed others to determine the time of appearance and progression of lesions, and

allowed others to sicken and die in order to determine the time of onset of clinical signs and symptoms. The data obtained in this manner clearly showed that virus was present in the tissues 24 to 48 hours before the appearance of lesions detectable under the microscope, and that all parts of the brain and cord contained large amounts of virus before the animals became ill.

Fabel and Gebhardt³⁰ conducted similar experiments with monkeys that had been infected by means of intranasal instillation of poliomyelitic virus. Their findings indicate that by the fifth, sixth, or seventh day after inoculation, at which time only an occasional rise of temperature or tremor and hyperesthesia were present and before paralysis had occurred, virus was distributed throughout the central nervous system.

In view of the above mentioned results obtained by a number of workers by means of many experiments with different viruses in different hosts, it seems logical to assume that the virus of poliomyelitis by the time signs and symptoms of disease become obvious in infected human beings has already reached practically all of the nerve cells that are likely to be attacked. If such be the case, then one would expect convalescent serum given after the onset of signs of the disease to be valueless. Indeed, such expectations are in accord with the clinical findings reported by careful workers who have used the serum for therapeutic purposes under properly controlled conditions both in monkeys and in human beings.

If the factors described above as being responsible for the therapeutic failures of convalescent poliomyelitic serum are not operative in every case, there are others that enhance the likelihood that failures will regularly occur, such as the inability of antibodies to penetrate the blood-brain barrier and reach the virus in the tissues of the brain and cord. Furthermore, it is highly improbable that antibodies in potent antisera placed in the subarachnoid space are capable of reaching virus situated in the depths of the brain and cord, because drainage from the subarachnoid space is as a rule not back into the central nervous system but into the general circulation.

In the first part of the talk, I discussed problems relating to the nature of viruses and the character of lesions produced by them, while in the latter section I dealt with matters pertaining to the prevention and treatment of virus diseases by means of vaccines and convalescent or immune sera. I have presented data of a general rather than a concrete nature in the hope of initiating a train of thought that will lead to a greater appreciation of problems in the virus field and a better understanding of phenomena daily encountered in the practice of medicine.

THROMBOPENIC PURPURA, AN ANALYSIS OF 160 CASES ¹

By W M FOWLER, M D , *Iowa City, Iowa*

THE present concept of thrombopenic purpura as a definite syndrome has gradually been evolved and separated from the maze of hemorrhagic diseases. In the earliest fragmentary descriptions of purpura it was noted in association with the pestilent fevers,¹ later it was found apart from these, and still more recently was separated as a distinct entity. A proper understanding of the condition, however, awaited the discovery of the blood platelets by Donne and Arnold ² and the observation by Denys ³ and Hayem ⁵ that the platelets were diminished in certain cases of purpura. This feature was subsequently verified by numerous observers and forms the basis for the syndrome which is characterized by (1) a diminished number of platelets, (2) prolonged bleeding time but an essentially normal coagulation time, (3) a non-retractile clot, and (4) a positive constrictor or arm band test. A simple classification which is similar to that of Pratt ⁷ and Rosenthal ⁸ is as follows

- I Idiopathic Thrombopenic Purpura
 - (1) Acute
 - (2) Chronic
- II Secondary Thrombopenic Purpura
 - (1) Infections
 - (2) Toxins and drugs
 - (3) Blood dyscrasias
 - (4) Diseases of the liver
 - (5) Miscellaneous

There are many reports of hereditary hemorrhagic diseases in the literature, and among these are some cases which present the clinical and laboratory features of thrombopenic purpura ^{9, 10, 11}. Although these do not constitute a large group, they occur with sufficient frequency, so that an hereditary type of thrombopenic purpura must be acknowledged.

Since many conditions may lead to the clinical manifestations of purpura without the characteristic hematological features, and especially without a reduction of the platelets, the universal recognition of thrombopenic purpura as a distinct syndrome has been delayed, and there has been much confusion in the literature. The early classifications of purpura were based purely on the clinical features, and this has been continued in spite of more recent and improved methods of blood examination. The criteria given above for the diagnosis of thrombopenic purpura eliminate from this discussion the simple purpuras so common in youth and senility, the anaphylactoid purpura with

From the Department of Internal Medicine, State University of Iowa

abdominal and joint manifestations (Henoch-Schonlein), the purpuras due to avitaminosis (scurvy) as well as those cases of purpura associated with vascular changes which occur with many acute infections and intoxications

IDIOPATHIC THROMBOPENIC PURPURA

The pathogenesis of idiopathic thrombopenic purpura has given rise to much discussion¹² and cannot be considered as definitely settled. That the platelets originate from the megakaryocytes in the bone marrow,¹³ have a life of but a few days,¹⁴ and are destroyed by the spleen, is quite generally accepted. They accelerate coagulation,² improve the degree of syneresis,¹⁵ and perhaps play some part in combating infections and in the production of anaphylactic reactions. Their rôle in thrombopenic purpura is not clear, and some deny the existence of this syndrome as separate from those forms of purpura in which the clinical manifestations are similar, but in which the platelets are present in normal numbers.¹⁶ If we accept the syndrome as possible of recognition we must consider the cause of the platelet deficiency to determine whether it results from under-production of platelets, as originally proposed by Frank,¹⁷ or from their over-destruction by the spleen.¹⁸ We may further consider the possibilities of the actual loss of platelets through hemorrhage, the formation of defective platelets which are removed by the spleen, or the removal of platelets from the circulation in an attempt to control the capillary hemorrhage. For a further discussion of the cause and the effects of this reduction in the number of platelets the reader is referred to the work of Mackay,² Lescher and Hubble,¹⁹ and De Sanctis and Allen.²⁰ The most generally accepted theory is that a deficiency in platelets is the primary feature of the condition and that bone marrow insufficiency is responsible for this deficiency. The possibility has been advanced, however, that there are two types of thrombopenic purpura, as yet indistinguishable by clinical means, one of which is due to deficient or faulty production of platelets while the second results from their increased destruction by the spleen.

The close association of thrombopenic purpura, aplastic anemia and agranulocytosis and the similarity of many of their features have been emphasized. The three diseases have been grouped together under the term "marrow insufficiency"^{21, 22}. Their occurrence under similar conditions, their frequent association and the origin of each of the cell types within the bone marrow give credence to this correlation and, in certain cases, cause difficulty in the differential diagnosis. Although presenting distinct and separate clinical features in most instances, there are certain borderline cases with an overlapping of the hematological pictures, as might be expected when the histogenesis of the various cell types is considered.

The histologic changes in the bone marrow and spleen are varied and have tended to confuse rather than clarify our concept of the pathogenesis. Studies of the bone marrow have not been numerous in cases of idiopathic thrombopenic purpura, and in those in which they have been made, the find-

ings are divergent. Those cases in which the megakaryocytes are diminished in number or possess shrunken and pyknotic nuclei lend support to Frank's theory¹⁷. In other cases with an equally low platelet count, the megakaryocytes of the bone marrow are present in normal numbers and show no morphologic changes^{23, 24}. This group tends to support Kaznelson's theory¹⁸ that the bone marrow is not the seat of the primary disorder. Lawrence and Knutti²⁴ studied the bone marrow of six patients, four of these showed no abnormalities and two had a diminished number of megakaryocytes. They suggest, as did Lescher and Hubble,¹⁹ that in those patients with normal bone marrow the primary lesion is in the spleen with a resultant increased destruction of normally formed platelets, and that these are the patients who show improvement after splenectomy. It is interesting to note that experimental production of thrombopenic purpura by means of antiplatelet serum has led to equally divergent histological findings in the bone marrow²⁵.

Certain cases show hyperplasia of the marrow,²⁶ either diffuse or patchy, as a regenerative response to repeated hemorrhages. All the elements of the marrow may take part in the hyperplasia, even the megakaryocytes.

Examination of the spleen reveals no uniformity in the histologic picture, so that the findings are not specific or diagnostic. In many instances the spleen is essentially normal, and in others, as in two of those removed in this clinic there is a simple fibrosis. In many instances the spleen is enlarged and presents endothelial cell hyperplasia of both the sinuses and Malpighian corpuscles²⁷. The lymphoid elements may be diminished, normal, or increased, and the platelets within the spleen may be increased or entirely absent.² Thickening of the arterial walls in the vessels to the follicles has been noted in some instances.

With such a diverse histologic picture in both spleen and bone marrow, one can but conclude that there is no uniform pathological change and at present can but speculate as to the possibility of two distinct types of idiopathic thrombopenic purpura.

SECONDARY THROMBOPENIC PURPURA

An enormous number of case reports have appeared in the literature showing the association of thrombopenic purpura with a wide variety of primary disorders and intoxications. One can find no feature present in all cases to explain the diminution in platelets so that the pathogenesis is just as obscure as in the idiopathic form. In certain instances definite bone marrow pathology is present to account for the thrombopenia while in others a chemical or bacterial toxin which either destroys the platelets or inhibits their production has been hypothesized. The bone marrow may be fatty or aplastic in cases of marrow insufficiency, it may be hyperplastic with an overgrowth of myeloid or lymphatic elements in leukemia, or may show no essential histologic change in cases of infection or intoxication.

The hyperplasia of aleukemic myelosis may be found in a biopsy of the sternum or a lymph node²⁸ so that this procedure is worthy of consideration in obscure cases

CLINICAL FEATURES

The clinical features are the same in both the idiopathic and secondary types. The diagnosis of thrombopenic purpura must rest on the laboratory findings of prolonged bleeding time, positive constrictor test, non-retractile clot and lowered blood platelets rather than on the clinical picture. Hemorrhage into the skin, either as purpuric spots or as ecchymoses, is the most characteristic feature, the former frequently appearing spontaneously with successive crops of innumerable small hemorrhages on the extremities, neck and upper trunk, while the latter may occur as a result of a very minor trauma. These skin manifestations are not uniformly present and their absence may forestall the correct diagnosis. Many patients have hemorrhages from the mucous membranes of the nose, mouth, gastrointestinal or genito-urinary tracts without involvement of the skin. Painless uterine hemorrhage is a frequent manifestation of this syndrome in women, and hemoptysis, hematuria, and cerebral hemorrhage are not uncommon. These hemorrhagic manifestations are so frequently present without skin involvement that thrombopenic purpura must be considered in all cases of unexplained hemorrhage. In many of the cases which are secondary to other disease there are no hemorrhagic manifestations, and the diagnosis is made purely on the laboratory data found on routine hematological examination. In other instances the hemorrhagic features overshadow the primary condition. In the idiopathic variety, which is more common in females and usually appears early in life, there is frequently a history of having bled or bruised easily since birth.

The blood picture in the idiopathic cases is that of a post-hemorrhagic anemia, and although certain morphological changes in the platelets have been described,²⁹ they are not constant enough for diagnostic purposes. The reduction in the number of platelets varies, but Minot²² has given 60,000 per cu mm as the critical level below which hemorrhage is apt to occur. We have used the thrombocytocrit method of Van Allen³⁰ for platelet determinations, since in our hands it has been more reliable for routine use than platelet counts.

Complete hematological studies have been done in 160 cases of thrombopenic purpura. Of these, 17 were found to be of the idiopathic type, and 143 were secondary thrombopenic purpura. The further subdivision of these groups is best shown in the following tabulation. The subgroups will then be discussed separately.

ANALYSIS OF CASES

- | | | |
|---|---------------------------------|----|
| I | Idiopathic Thrombopenic Purpura | |
| | (1) Acute | 3 |
| | (2) Chronic | 14 |

Aplastic anemia		11
Familial hemolytic icterus		1
Acquired hemolytic icterus		1
Anemia of pregnancy		1
Idiopathic hypochromic anemia		1
(4) Liver disease	12	
(5) Miscellaneous	19	

SECONDARY THROMBOPENIC PURPURA

BLOOD DYSCRASIAS

Leukemia Under the heading secondary thrombopenic purpura the largest group, 81 cases, was associated with disease of the hematopoietic system, and of these leukemia was the most frequent. There were 18 cases associated with lymphatic leukemia, in four of which it appeared as a terminal event in the chronic, slowly progressing form in adults. The other 14 cases occurred in association with the more acute rapidly progressing lymphatic leukemia of childhood, nine of which were in the subleukemic state described by Abt³¹ and Hyland³². There were 15 cases of myelogenous leukemia complicated by thrombopenic purpura. In the early stage of myelogenous leukemia the platelets are not infrequently increased in number, so that the complication occurred as a terminal event in the chronic cases but appeared early in the course of the acute forms. Thrombopenic purpura was present in each of the seven cases of aleukemic myelosis which we have studied, and the resultant hemorrhagic tendencies were the predominant feature of the illness. One case of acute blast cell leukemia was accompanied by this syndrome. It is apparent that thrombopenic purpura is most apt to appear in the acute rapidly progressing forms of leukemia, but may occur as a terminal event in the more chronic forms. It very definitely adds to the gravity of the prognosis inasmuch as it signifies a more rapid course. In some instances the hemorrhagic features are the most striking part of the clinical picture, giving rise to difficulties in diagnosis, especially in the aleukemic forms in which the blood picture is not diagnostic. Examination of the bone marrow either by biopsy or sterial puncture may be necessary for a correct interpretation.

Lymphoma Thrombopenic purpura was a less frequent complication in the other forms of lymphoma than was true of lymphatic leukemia. Eleven cases were found, four of which occurred with the sclerosing type (Hodgkin's disease) and seven with the lymphoblastic and lymphocytic type without leukemia. Although not a common causative agent, these diseases

must be considered as possibilities when thrombopenic purpura appears, even though splenomegaly and lymphadenopathy are not prominent. The presence of this complication adds to the gravity of the prognosis, since it appears more commonly in the rapidly progressing forms or as a terminal feature in the chronic cases.

Pernicious Anemia In 14 patients thrombopenic purpura was found associated with pernicious anemia, a much lower incidence than with leukemia. In none of these patients were the hemorrhagic features of purpura clinically apparent except for a tendency to bruise more easily than normal or to bleed more readily from slight trauma, and the syndrome was discovered only by routine blood examinations. A reduction in the platelet count is a characteristic feature of pernicious anemia, and it is surprising that thrombopenic purpura does not occur more frequently with this disease. This complication did not influence the course nor the prognosis of pernicious anemia, and with an induced remission the platelets returned to a normal level. One case of thrombopenic purpura was found in each of the following conditions, in none of which did it produce any clinical manifestations: acquired hemolytic icterus, familial hemolytic icterus, idiopathic hypochromic anemia and anemia of pregnancy.

Aplastic Anemia There were 11 cases of idiopathic aplastic anemia, seven adults and four children, in which thrombopenic purpura was present. The clinical manifestations of purpura were present in all but one of these cases, and frequently were the predominant feature. The diagnosis of aplastic anemia was verified by necropsy in three of the patients who died in the hospital. There were certain borderline cases in which it was difficult to differentiate between idiopathic thrombopenic purpura and aplastic anemia, but in all of the above cases the anemia seemed to be the primary feature, appearing before the hemorrhagic features rather than being dependent on the loss of blood. The association of the two conditions is almost constant in the late stages of aplastic anemia, and the severe hemorrhages hasten the end in most instances.

LIVER DISEASE

Various forms of liver disease are well recognized as a cause of thrombopenic purpura, and 12 such instances were encountered in this series. The mechanism by which the platelets are affected is not known although with the seat of fibrinogen formation in the liver, it is not surprising to find changes in blood coagulation and syneresis. The clinical features of purpura were prominent in only one of these patients, and spontaneous hemorrhages did not appear in the others in spite of the presence of laboratory features of the syndrome. The appearance of the complication, regardless of the severity of its manifestations, adversely affected the prognosis. In this group there were seven cases of Banti's syndrome, one of which was syphilitic in origin, four cases of portal cirrhosis and one of syphilis of the liver.

TOXINS AND DRUGS

A review of the literature reveals that thrombopenic purpura is frequently the result of the administration of various drugs, and cases have been reported after arsphenamine,³³ bismarsen,³⁴ gold,³⁵ quinine,³⁶ bismuth,³⁷ and iodine.³⁸ In the present series only six similar instances were found. Three appeared with the administration of arsenic, two followed the application of organic hair dye, and one was associated with chronic benzol poisoning. In all of this group the associated anemia was severe and of the aplastic type.

MISCELLANEOUS

Among the miscellaneous diseases there were many entirely unrelated conditions giving rise to this complication. Included in the group were four cases of carcinoma, two of the breast and one each of the stomach and pancreas. Three of these had given rise to widespread metastasis with bone involvement, while the one arising in the pancreas had no demonstrable metastatic lesions. There was one case of extramedullary myeloblastoma without evident bone involvement and one case of melanosarcoma. One patient with myxedema presented this syndrome, as did one with Graves' disease who had not received iodine. There was one case of chronic glomerulo-nephritis. A roentgen-ray technician developed the typical laboratory features of this syndrome together with a mild degree of anemia, although there were no hemorrhagic manifestations. With greater precautions against exposure to roentgen-rays the blood returned to normal. A patient with xeroderma pigmentosum developed the typical features of aplastic anemia, agranulocytosis and thrombopenic purpura, with severe hemorrhages from the nose, mouth and gastrointestinal tract. At autopsy, however, no aplasia of the sternal or rib marrow was apparent.

There were eight cases on whom no additional information was available so that the primary lesion, if any, is unknown. No cases were found in which an allergic reaction was responsible for the thrombopenia, although such cases are numerous in the literature and it has been demonstrated that the administration of an allergen to a susceptible individual produces a distinct drop in the platelet count.³⁹

INFECTION

The importance of infection as an etiological agent in secondary thrombopenic purpura has been repeatedly emphasized, and the eradication of foci is recognized as an essential feature in the treatment of the idiopathic cases. In many instances it is difficult to evaluate with certainty the rôle which infection plays in the etiology. In the present series there were 25 patients in whom it was felt that infection was undoubtedly the cause. Only six of these occurred in adults, two of whom had subacute bacterial endocarditis and one had broncho-pneumonia. One male, aged 27, had repeated attacks of gonorrheal urethritis with a subsequent arthritis and prostatitis. Epi-

sodes of purpura and hemorrhage appeared with the acute exacerbations of urethritis, and in addition to the characteristic findings of thrombopenic purpura there was a moderate anemia and agranulocytosis. At necropsy there was no evidence of aplasia of the bone marrow. In one patient, a female aged 34, severe nasal, gingival and uterine hemorrhages, together with an extensive purpuric eruption, followed immediately an acute upper respiratory infection. On admission to the hospital the specific laboratory features of thrombopenic purpura were present, and the gums were so swollen and bloody as to suggest leukemic infiltration. Biopsy of both gums and bone marrow presented a normal histologic picture. One year later the blood was normal in every respect and there had been no recurrence of the hemorrhagic features. Another girl, aged 17, had repeated episodes of purpuric eruption for four years and more recently had two severe episodes of hemorrhage. The first appearance of purpura was immediately after diphtheria so that it was difficult to determine whether the infection was the primary etiological factor or whether the infection merely precipitated the onset in a patient with potential or latent idiopathic thrombopenic purpura.

Infection as an etiological agent plays a more important rôle in children than in adults, and 19 cases secondary to infection were found in patients under 14 years of age. In one child miliary tuberculosis not only caused the typical laboratory and clinical features of thrombopenic purpura but also a differential blood picture almost indistinguishable from lymphatic leukemia. Necropsy examination revealed a generalized miliary tuberculosis with involvement of the bone marrow. Tuberculosis appears in the literature as a frequent causative agent and has even been suggested as the responsible agent in most cases of the idiopathic form.⁴⁰ One typical example of thrombopenic purpura with severe hemorrhages occurred during the course of epidemic parotitis and one during an acute infectious enteritis. Three cases were associated with septicemia, a condition which is prone to produce not only this syndrome but also an aplastic anemia, and it is difficult at times to determine whether the septicemia was the primary factor or occurred as a terminal event. There were five cases which appeared in association with measles, either during the period of eruption or during convalescence. Acute upper respiratory infections were most common in producing this syndrome in children, and there were eight cases in which the ears, tonsils or sinuses were involved. It is more commonly associated with an acute infection but occurs also with chronic forms. Acute exacerbations of the infection may cause recurrent attacks of hemorrhage as in one six year old boy who had repeated hemorrhagic episodes over a period of a year, each accompanying an acute exacerbation of otitis media. In none of the cases secondary to infection which we have been able to follow has there been a recurrence of symptoms after eradication of the infection. This propensity of infection to cause thrombopenic purpura supports the

contention that all obvious foci should be removed even in those patients with an apparently idiopathic form

IDIOPATHIC THROMBOPENIC PURPURA

The diagnosis of idiopathic thrombopenic purpura must rest not only on the presence of the characteristic laboratory and clinical manifestations, but also on the rigid exclusion of all diseases which may cause the secondary form. Certain cases, especially in elderly patients with no preceding evidences of hemorrhage, are undoubtedly considered as idiopathic only because of our inability to locate the primary trouble. Remissions can be induced by blood transfusion in the majority of idiopathic cases and should be done as a diagnostic as well as therapeutic measure before more radical procedures are undertaken. In the acute fulminating type, which is frequently fatal in spite of blood transfusions, splenectomy is usually of no avail so that the delay for diagnostic purposes is justifiable.

Seventeen cases in this series were considered to be idiopathic in origin, nine occurring in adults and eight in children under 14 years of age. Among the adult cases, one, a female aged 24, was acutely fatal, the first episode of hemorrhage being uncontrollable by any means at our disposal. One male, aged 38, had bruised easily for many years but had no hemorrhages or purpuric spots until two years before admission to the hospital. The bleeding at this time was easily controlled by transfusion, and further therapeutic procedures were postponed so as to determine the subsequent course. There have been no recurrences as yet. One male, aged 50, had recurrent hemorrhages for 38 years, and two other elderly patients gave histories of intermittent hemorrhages and purpura of many years' duration. The same history of recurrent hemorrhages and purpura was obtained in the younger adults, so that in all cases the actual onset of symptoms was in childhood or early adult life. Splenectomy was not performed in any of this group.

The ages of the children with idiopathic thrombopenic purpura ranged from four to 14 years and were equally divided between males and females. Two of these eight cases were of the acute type. One of these died of cerebral hemorrhage soon after admission. The bleeding was controlled in the other acute case, she returned home and in the subsequent 12 months has had no recurrence except a mild epistaxis during the course of measles. The remaining six cases were of the chronic type and gave histories of hemorrhage or of bruising easily for from one to several years, and in one instance, in a boy of six, these features had been noted by the parents since birth. One chronic case, on which a splenectomy was advised, but was refused by the parents, died after returning home. Transfusions were given to all patients in this group to control the hemorrhage, and the response was good in all instances except one case that died of hemorrhage. Foci of infection were eradicated when present at

tomy was performed on three patients. Two of these three patients were subsequently followed and there has been complete disappearance of symptoms. The histologic picture in one spleen was normal while the other two showed only simple fibrosis. Two of the patients who did not have a splenectomy have had no recurrence of symptoms in the year which has elapsed since they were discharged from the hospital.

TREATMENT

The treatment of secondary thrombopenic purpura depends entirely upon the primary condition, and in those cases in which this can be eliminated the purpuric manifestations disappear. The prognosis in those cases associated with infections, pernicious anemia and other conditions responding to therapy, is good whereas little can be accomplished in the others. For immediate control of the hemorrhage transfusion of whole blood is indicated, either intramuscularly, or preferably intravenously. This is effective in many instances although in those with acute leukemia, aleukemic myelosis and aplastic anemia, it usually has but little effect. Various coagulants and hemostatics have been tried but are of little avail, and we have found no case in which these were entirely successful. Since splenectomy is acutely fatal in many of these cases and of no avail in the others, the necessity of an accurate diagnosis cannot be stressed too strongly.

There is no universal agreement as to the proper treatment of the idiopathic form of thrombopenic purpura. Since infections play so prominent a rôle in the production of the secondary forms as well as precipitating attacks in the idiopathic variety, they should be eradicated when present regardless of whether they are definitely related to the symptoms or not. Special diets,⁴¹ high vitamin intake and calcium salts have been advocated but a specific effect has not been definitely proved. Antivenin⁴² has been used with some success and snake venom has been recommended for its temporary hemostatic effect^{43, 44}. Peptone shock therapy has been advocated⁴⁵ and we have experienced some success in certain hemorrhagic diseases by sensitizing the patient to horse serum and then producing an anaphylactic reaction. The use of roentgen-rays over the spleen has been found to be of only temporary value⁴⁶ and ligation of the splenic artery has been proposed but not generally accepted.

Splenectomy should be considered in the idiopathic form only when the diagnosis has been established with absolute certainty. Many of these cases tend to improve spontaneously with advancing age, and the symptoms may completely or almost completely disappear in adult life so that removal of the spleen is unnecessary. In other cases the hemorrhage is not sufficient to warrant splenectomy, even at the onset of the illness. Since remissions induced in practically all cases of idiopathic thrombopenic purpura of transfusion, it is best to watch the patient through one or more determine the severity and frequency of the hemorrhages. If

they are severe and show no evidence of diminishing intensity, the spleen should be removed during a quiescent period. The operation carries a high mortality in the acute stages so that it is justifiable to attempt to carry the patient through this stage by transfusions. Splenectomy may produce a complete cure, an amelioration of symptoms, or the condition may recur with equal severity. At the present time there is no definite criterion on which to base the prognosis following splenectomy, although it is hoped that sternal biopsy or puncture may eventually give this information. The operation is best withheld until it has been determined whether the attacks are becoming more severe, until the effects of transfusion have been noted and until the effectiveness of eradication of focal infections has been determined. Spence,²⁷ in recording the results of splenectomy in 101 cases, found good results in 90.9 per cent of the chronic and 16.6 per cent of the acute cases. Whipple⁴⁷ collected 81 cases and found 6 deaths among 73 chronic cases and 7 deaths in 8 acute cases. Sixty-one patients were followed postoperatively and 51 had good results, 4 were fairly successful and 6 were not relieved. It has been repeatedly emphasized that protection against infections is an extremely important feature in the postoperative care of the patient.

SUMMARY

One hundred and sixty cases of thrombopenic purpura have been studied with respect to the etiology, prognosis and treatment. It was found that 143 of these cases were of the secondary type.

The importance of infection in the etiology of secondary thrombopenic purpura and its significance as a precipitating factor in the idiopathic cases have been emphasized.

The diagnostic difficulties have been mentioned, and the importance of an accurate diagnosis and of a proper period of observation prior to splenectomy in all cases is stressed.

THE THERAPEUTIC EFFECT OF SOLUTION OF POTASSIUM ARSENITE IN CHRONIC MYELOGENOUS LEUKEMIA *

By D J STEPHENS, M D , and JOHN S LAWRENCE, M D ,
Rochester, New York

For many years roentgen therapy has been the most satisfactory method of treatment of the chronic leukemias. It is generally agreed that life is not materially prolonged by irradiation, but in favorable cases symptomatic and hematologic improvement occurs for variable periods of time. Some patients experience uncomfortable reactions to treatment, others become refractory to irradiation, and occasionally an alarming depression of the red and white blood cells occurs. In the absence of specific forms of therapy for the disease, there is need of other palliative measures which may be used in place of, or in conjunction with, roentgen therapy. Interest in the use of solution of potassium arsenite was revived in 1931 by the reports of Forkner and Scott^{1 2}. These authors observed striking symptomatic and hematologic improvement in nine of ten cases of chronic myelogenous leukemia, treated for short periods of time with toxic or subtoxic doses of solution of potassium arsenite (Fowler's solution). During the past three years several reports discussing the treatment of leukemia have contained brief mention of arsenic as one of the useful drugs in the treatment of chronic myelogenous leukemia, but detailed confirmation of these observations has not appeared in the available literature.

Material for this report consists of seven patients with chronic myelogenous leukemia treated with one or more prolonged courses of solution of potassium arsenite, and observed for periods of from several months to three years. In five patients, arsenic therapy has been supplemented by roentgen treatments. In general our conclusions confirm and amplify those of Forkner and Scott.

Except for short periods of observation in the hospital, patients were followed either in the office or the Out-Patient Department, where frequent clinical and hematologic observations were made. Differential blood counts were made in films prepared on cover slips, stained with Wright-Giemsa stain. Schilling's classification of the leukocytes was used. In the figure both the myelocyte and the juvenile of this classification are included "myelocytes". Solution of potassium arsenite was given in rapidly increasing doses until toxic symptoms appeared, subsequent dosage was regulated as necessary to maintain a subtoxic level of the drug. Iron, when given, was prescribed in the form of 12 Bland's pills or six grams of ferrous

ammonium citrate daily. Roentgen-ray treatments, as indicated in roentgen units, were given over the spleen or chest. The course of each patient will be discussed briefly in relation to an accompanying chart, in which changes in the hemoglobin, the red and white blood cell counts and the differential counts are shown. Non-essential details are omitted from the case reports.

CASE REPORTS

Case 1 D S, a 58 year old salesman, was admitted to the Strong Memorial Hospital on February 2, 1934. During the previous six months he had noted fatigue, shortness of breath on exertion and loss of 15 lbs in weight. For about one month before admission to the hospital there had been intermittent abdominal pain, weakness, anorexia and pallor. Two weeks previously his physician had found a white blood cell count of 167,000, had made a diagnosis of leukemia and prescribed Fowler's solution in doses of 10 drops three times daily. The development of conjunctivitis of the right eye prompted his admission to the hospital.

In 1931 a diagnosis of coronary occlusion had been made. This was followed by thrombophlebitis in the right leg, which incapacitated him for a period of about six months. A white blood cell count of 16,000 was noted during this illness.

On examination the patient appeared chronically ill, was pale and apparently had lost weight recently. He had an acute catarrhal conjunctivitis on the right. There were several small retinal hemorrhages. The edge of the spleen was palpable 8 centimeters below the costal margin. The liver edge was felt 8 centimeters below the costal margin and was tender. There was a moderate degree of benign prostatic hypertrophy.

Laboratory findings: Blood hemoglobin 6.4 gm per 100 c c, red blood cells 1,990,000 per cu mm, white blood cells 193,000 per cu mm. The differential leukocyte formula was as follows: eosinophiles, 1 per cent, myeloblasts, 1.5 per cent, myelocytes, 37 per cent, juveniles, 2 per cent, stab neutrophiles, 2.5 per cent, segment neutrophiles, 52.5 per cent, lymphocytes, 1.5 per cent. Platelets were abundant. Blood non-protein nitrogen was 61 mg per cent, uric acid, 4.76 mg per cent, serum albumin, 4.72 gm per cent, serum globulin, 2.2 gm per cent, creatinine, 2.6 mg per cent. Basal metabolic rate was plus 31 per cent. The urine showed a small amount of albumin, an occasional granular cast and red blood cell. The electrocardiograph showed left axis deviation, without other abnormalities.

The conjunctivitis subsided within a few days. During February three doses of deep roentgen-ray therapy were given over the spleen and chest. A moderate drop in the total leukocyte count occurred but there was no change in the percentage of immature cells and no clinical improvement. Shortly after admission to the hospital the patient developed difficulty in urination, presumably due to prostatic obstruction. On February 21, the blood non-protein nitrogen was 92 mg per cent, creatinine, 6.2 mg per cent, uric acid, 8.7 mg per cent. Detailed studies of kidney function were not done because of the precarious condition of the patient.

On March 7, two weeks after the last roentgen-ray treatment, weakness, fatigue and dyspnea had increased, the total leukocyte count had risen to the previous level and the anemia had become more severe. No change had occurred in the size of the spleen or liver. The urinary symptoms had disappeared but the non-protein nitrogen was 75 mg per cent, creatinine, 5.3 mg per cent, uric acid, 7.8 mg per cent. At this time the administration of Fowler's solution was begun.

On April 13, arsenic was discontinued because of nausea and vomiting, which subsided within a few days. At this time the leukocyte count was 15,200 per cubic millimeter, of which only 9 per cent were immature cells. The strength and appetite had improved, and he had gained weight during the period of arsenic therapy. There

had been some decrease in the size of the spleen. There had been no urinary symptoms, and urinalysis showed no abnormalities. On April 23, the blood non-protein nitrogen was 48 mg per cent, uric acid, 40 mg per cent. An increase in the reticulocytes, which reached 12 per cent, was followed by striking improvement in the anemia. The administration of iron in the form of 12 Bland's pills per day was begun on April 26, and he received a blood transfusion on May 2. It should be noted that the reticulocyte response and the increase in hemoglobin and red blood cells occurred before the institution of the latter procedures.

In May, because of return of the leukocyte count and percentage of immature cells to a high level, the administration of Fowler's solution was resumed. Clinical improvement continued, he gained further weight, and there was no significant change in the level of blood non-protein nitrogen or uric acid. There was again a gradual decrease in the total white blood cell count to a value but little above normal. The decrease in percentage of immature cells was less striking. In July, Fowler's solution was again discontinued because of weakness, anorexia and diarrhea. These symptoms disappeared within a few days. There had been little change in the size of the spleen. Without therapy the leukocyte count rose again and remained high. In spite of a moderate degree of anemia, he felt quite well, without undue fatigue or weakness, during the next four months. Treatment was omitted during this period because of the satisfactory clinical condition.

In December he was again admitted to the hospital with fever and respiratory difficulty of a few days' duration. There were signs of pneumonia of the lower lobe of the left lung. The spleen was somewhat larger than it had been previously. At this time the blood non-protein nitrogen was 110 mg per cent, uric acid, 107 mg per cent, creatinine, 50 mg per cent. The patient died, apparently as the result of pneumonia, a few hours after admission to the hospital.

The autopsy findings were characteristic of chronic myeloid leukemia. All bone marrow sections showed marked myeloid hyperplasia. There were extensive myeloid infiltrations in the spleen, which weighed 2175 grams, in the liver, which weighed 3800 grams, and in the kidneys. Bronchopneumonia was present in both lungs. Canalization of an old thrombus in the right femoral vein had occurred. There was nothing to indicate that the typical pathologic picture of chronic myelogenous leukemia had been altered by the previous arsenic therapy.

Case 2 M V, a 24 year old housewife, was first seen in the Out-Patient Department October 23, 1933 complaining of abdominal pain of an indefinite nature. During the previous year she had lost about 15 pounds in weight. For about two months she had noted "weakness of the eyes" and had been unable to read or sew. There had been some fatigue on exertion but no limitation of activity.

Examination showed moderate pallor, no glandular enlargement. Ophthalmoscopic examination revealed bilateral papilledema. The retinal veins were engorged and tortuous, of irregular caliber, in some areas they were barely visible. There were several old retinal hemorrhages. The spleen was enlarged, extending to the right of the umbilicus with its lower border palpable 22 cm below the costal margin.

Blood hemoglobin was 89 gm per 100 c c, red blood cells, 2,750,000 per cu mm, white blood cells, 322,000 per cu mm. Differential formula was as follows: basophiles, 15 per cent, eosinophiles, 2 per cent, myelocytes, 46.5 per cent, juveniles, 8 per cent, stab neutrophils, 18.5 per cent, segment neutrophils, 22 per cent, lymphocytes, 15 per cent. One nucleated red blood cell per 100 leukocytes was found. Platelets were abundant.

Within two weeks after starting Fowler's solution the eyes had improved, strength had returned and the abdominal discomfort had diminished. There was gradual decrease in the total leukocyte count and percentage of immature cells. The anemia improved. The spleen gradually became smaller and in May 1934 could not

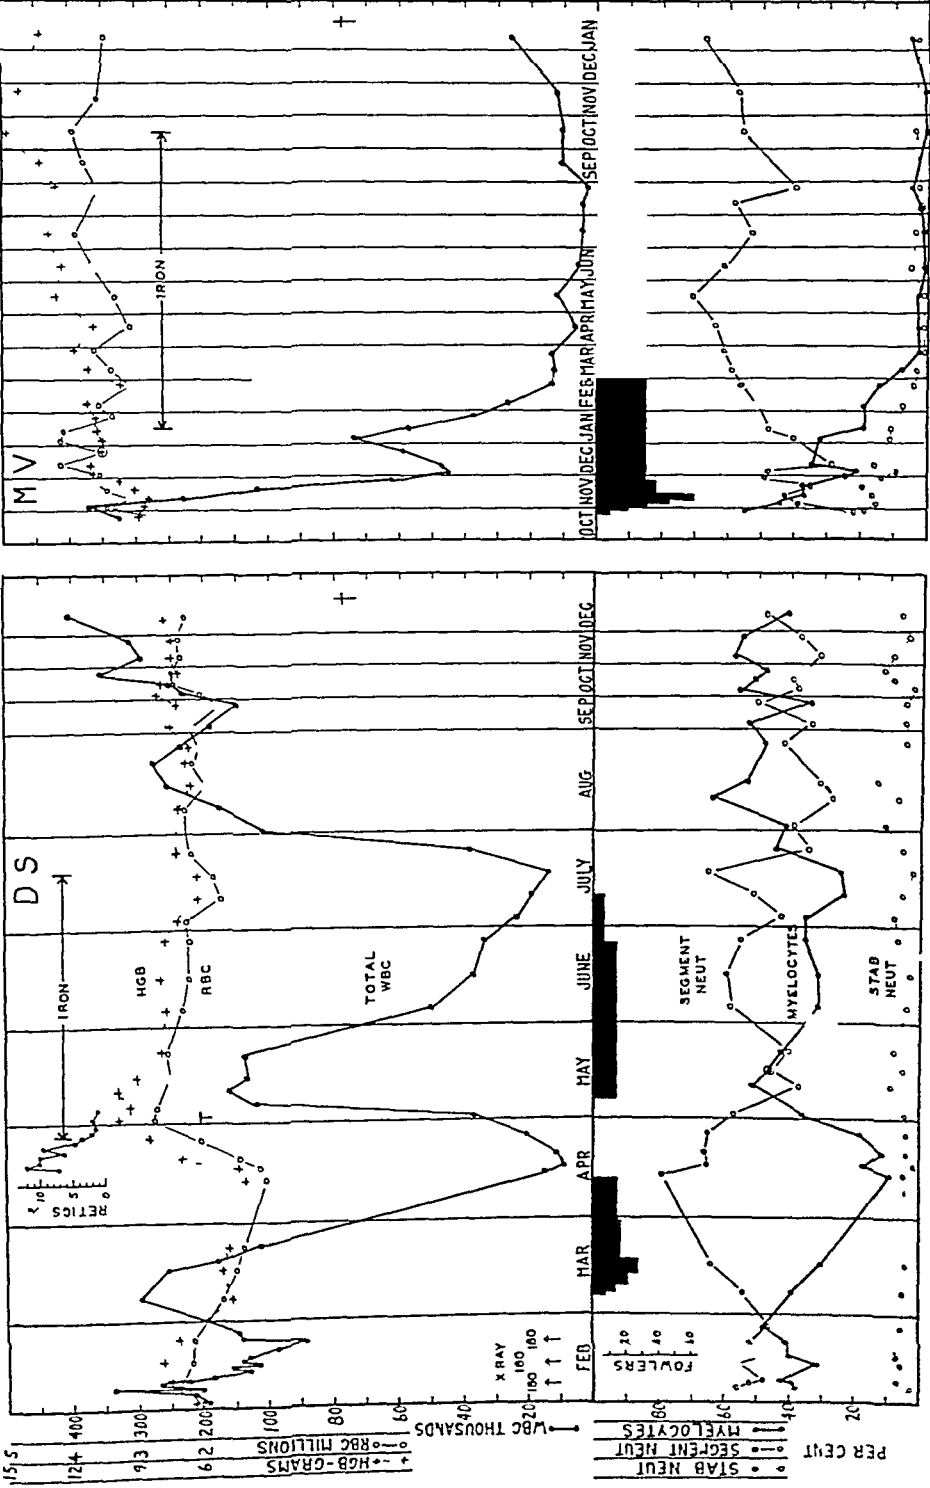

Fig. 1. Case 1 (D S), and Case 2 (M V). The daily dose of solution of potassium arsenite is indicated in drops per day. Roentgen treatments are indicated by arrows, with the dose in roentgen units. Γ indicates transfusion.

be felt The eyegrounds became normal in appearance and remained so From February 1934 until the time of her death, almost a year later, the patient was without symptoms except those attributed to mild arsenic intoxication, which occurred from time to time For a period of 10 months before death the leukocyte count was within, or slightly above normal limits and the immature cells remained below 5 per cent During the period of arsenic therapy, which was continued in subtoxic doses without interruption for 15 months, a diffuse, tan colored pigmentation with some dryness of the skin appeared and persisted over the entire body

During the latter part of January, the patient died at home, of pneumonia, after an acute illness of three days' duration Autopsy was not done

Case 3 J L, a 54 year old retired miller, was admitted to the Strong Memorial Hospital December 29, 1932 complaining of weakness and fever He had suffered from fatigue and general malaise for about six months For the past six weeks he had been weak, tired and "feverish" He had had drenching night sweats, anorexia, dyspnea on slight exertion and had lost 25 pounds in weight

On examination, the temperature was 39° C He appeared chronically ill and had evidently lost weight There were small soft lymph glands in each axilla There were small hemorrhages in each ocular fundus and one small petechial hemorrhage in the left buccal mucosa The spleen extended six centimeters below the costal margin

Blood hemoglobin was 10.5 gm per 100 c.c., red blood cell count was 3,700,000 per cu mm, white blood cell count was 91,600 per cu mm The differential leukocyte formula was as follows basophiles, 2 per cent, eosinophiles, 4 per cent, myelocytes, 30 per cent, juveniles, 12.5 per cent, stab neutrophils, 11.5 per cent, segment neutrophils, 35 per cent, lymphocytes, 4 per cent Platelets were present in normal numbers

Two doses of deep roentgen-ray therapy, totalling 350 roentgen units given over the spleen, resulted in a marked reduction in the total leukocyte count and in the percentage of immature cells There was gradual clinical improvement, with increase in strength and disappearance of fever Additional roentgen-ray therapy was given in January and February In February 1933, the administration of Fowler's solution was begun and was followed by further improvement In March the spleen was barely palpable The patient returned to work and remained symptom free for several months

In September 1933 while still taking Fowler's solution, fatigue, weakness, chills and fever, and splenomegaly returned A single roentgen treatment was followed by disappearance of the above symptoms for several months In October, toxic symptoms necessitated reduction of the dose of Fowler's solution, which was finally discontinued in January 1934 During the next four months the patient received four roentgen-ray treatments because of weakness, fatigue, fever and increase in the leukocyte count and immature cells Each treatment was followed by temporary improvement in symptoms and in the white blood cell picture The anemia became progressively more severe A temporary rise in red blood cells and hemoglobin followed a transfusion early in May 1934 The patient died at home early in June 1934 Autopsy was not done

Case 4 E G, a 51 year old housewife, was admitted to the Strong Memorial Hospital on January 22, 1935 For about 18 months she had noted increasing fatigue, slight pallor and some dyspnea on exertion Five weeks before admission to the hospital there had been an acute illness characterized by fever, malaise, sore throat and non-productive cough During this illness her physician found a white blood cell count of 80,000 and made a diagnosis of leukemia A single dose of roentgen-ray therapy had been given, followed by reduction in the white blood cell count to 41,000 Fowler's solution was prescribed in doses of 15 drops daily During the last few days before admission to the hospital an itching eruption had appeared in both inguinal regions

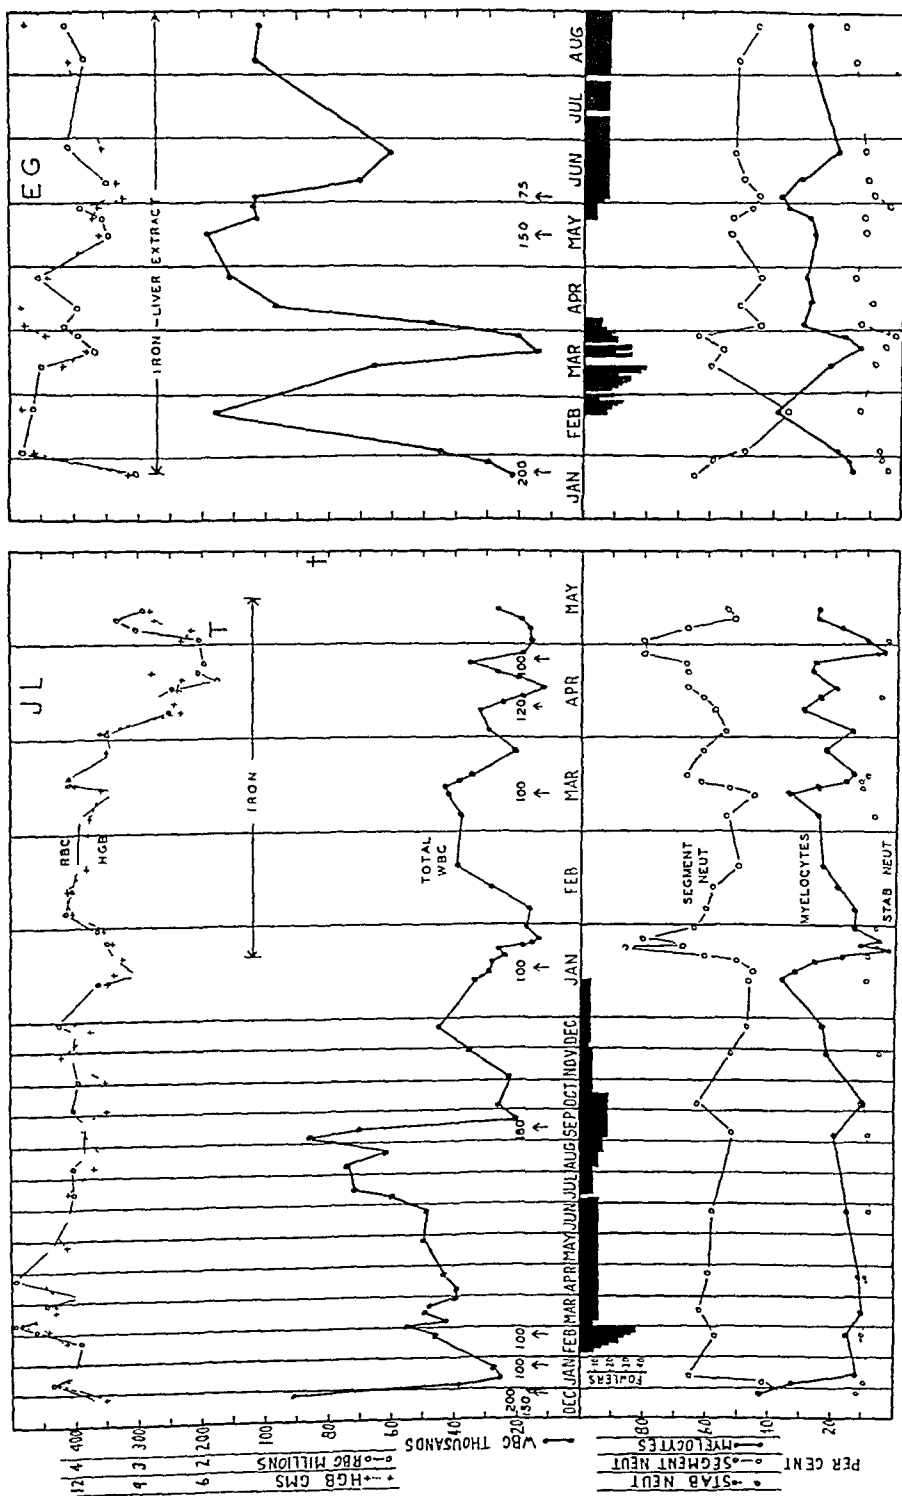

Fig. 2 Case 3 (J L), and Case 4 (E G) The daily dose of solution of potassium arsenite is indicated in drops per day. Roentgen treatments are indicated by arrows, with the dose in roentgen units. T indicates transfusion.

Physical examination showed a maculo-papular, erythematous eruption in the right axilla, in the pubic and inguinal regions, and over the labia majora. The edge of the spleen was palpable under the costal margin.

Blood hemoglobin was 9.75 gm per 100 cc, red blood cells 3,090,000 per cu mm, white blood cells 22,900 per cu mm. The differential leukocyte count was as follows: basophiles, 3 per cent, eosinophiles, 8 per cent, myelocytes, 7.5 per cent, juveniles, 7.5 per cent, stab neutrophiles, 6 per cent, segment neutrophiles 59.5 per cent, lymphocytes, 4.5 per cent. Platelets were plentiful.

A single dose of roentgen-ray therapy was given over the perineal and suprapubic regions. It was thought at the time that the skin lesions might be a form of leukemia cutis. Subsequent observations, however, indicated that the eruption was an arsenic dermatitis and that the blood picture had been favorably influenced by the previous arsenic therapy. Ison and Lilly's liver extract No. 55 were prescribed. During the following month, the skin lesions completely cleared but weakness and fatigue continued and the total leukocyte count and percentage of immature cells increased. The administration of Fowler's solution resulted in a striking diminution in the number of leukocytes and percentage of immature cells, fatigue and weakness were markedly improved. However, symptoms of arsenic toxicity appeared, and were accompanied by an itching skin eruption similar in character and location to that previously observed. This became so bothersome that Fowler's solution had to be discontinued, two weeks later the skin lesions had disappeared.

Without arsenic, the leukocyte count rose rapidly, the percentage of immature cells increased, the anemia again became more severe, and fatigue and weakness returned. A single dose of roentgen-ray therapy in May resulted in a severe reaction with prostration, increased weakness, anorexia, nausea and vomiting for several days. A smaller dose of roentgen-ray therapy two weeks later resulted in a similar but less marked reaction. The administration of Fowler's solution was again started on May 20 and continued in subtoxic amounts. Although the changes in the white blood cell picture were not striking, symptomatic relief was experienced, and improvement in the anemia was noted. At the time of writing, the clinical condition is satisfactory and the spleen is not palpable, although the total white blood cell count and the percentage of immature cells are quite high.

Case 5 N. E., a 20 year old unmarried waitress, was admitted to the Rochester Municipal Hospital September 30, 1932, with a history of chronic fatigue and loss of 20 pounds in weight during the previous year. For two days before admission there had been sharp, cramplike pains in the abdomen, without other symptoms.

Examination showed a chronically ill young woman, who appeared pale and tired. There were several ecchymoses over the legs. The spleen was markedly enlarged, extending to the right beyond the mid-line and downward to the iliac crest. A leathery friction rub was heard over the splenic area.

At the time of admission blood hemoglobin was 7.5 gm per 100 cc, red blood cells, 2,720,000 per cu mm, white blood cells 439,000 per cu mm. Differential count was as follows: basophiles, 3.5 per cent, eosinophiles, 1 per cent, myeloblasts, 1 per cent, myelocytes, 38 per cent, juveniles, 14 per cent, stab neutrophiles, 15 per cent, segment neutrophiles, 24.5 per cent, lymphocytes, 2 per cent, degenerated cells, 1 per cent. Two nucleated red blood cells were seen in counting 100 white blood cells. Platelets were abundant. Basal metabolic rate was plus 30 per cent.

The administration of Fowler's solution in increasing amounts was begun on October 2 and continued for six weeks in subtoxic doses, with occasional rest periods because of toxic symptoms. During the latter part of October there was a sharp decrease in the total white blood cell count, accompanied by a decrease in immature cells and followed by an increase in the red blood cell count and hemoglobin. These changes were accompanied by marked symptomatic improvement, disappearance of the abdominal discomfort and splenic friction rub, and diminution in size of the spleen.

On November 18, 1932 the patient was discharged to her physician in a neighboring state. She received one roentgen-ray treatment during the second week in December. When last seen on January 20, 1933 she was symptomatically well and there had been further improvement in the anemia. The total leukocyte count, however, had risen to 160,000. The further course of this patient is not known.

Case 6 M T, a 50 year old housewife, was admitted to the Strong Memorial Hospital on March 21, 1934 complaining of a mass in the abdomen. During the preceding year she had noted increasing fatigue and backache, palpitation and dyspnea on exertion and left-sided abdominal enlargement. During the past six months there had been loss of 35 pounds in weight and a chronic non-productive cough. For two months before admission there had been occasional skin hemorrhages without antecedent trauma.

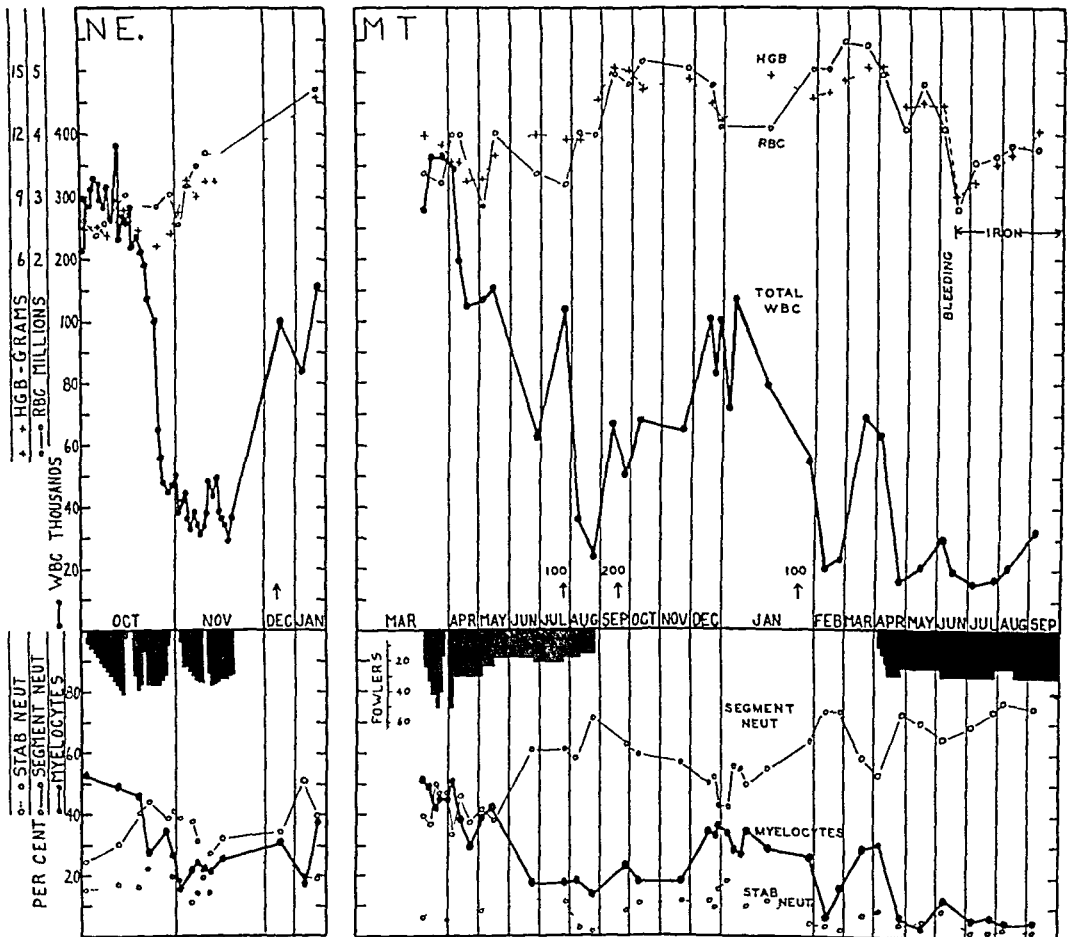

FIG 3 Case 5 (N E), and Case 6 (M T) The daily dose of solution of potassium arsenite is indicated in drops per day. Roentgen treatments are indicated by arrows, with the dose in roentgen units.

The patient was an obese woman, appearing chronically ill. The spleen extended to the right beyond the midline and downward to the iliac crest.

Blood hemoglobin was 12 gm per 100 cc, red blood cells numbered 3,800,000 per cu mm, white blood cells, 275,000 per cu mm. Differential leukocyte formula was as follows: eosinophiles, 3 per cent, myelocytes, 40 per cent, juveniles, 11 per

cent, stab neutrophils, 6 per cent, segmented neutrophils, 39 per cent, lymphocytes, 1 per cent Platelets were abundant Basal metabolic rate was plus 57 per cent

Fowler's solution was administered in subtoxic doses during the next five and a half months During this time there was a moderate decrease in the total leukocyte count and in the percentage of immature neutrophils The patient gained in weight and strength, the respiratory symptoms disappeared, the spleen decreased in size and the eyegrounds cleared In July, 100 roentgen units of roentgen-ray therapy were administered to the lateral splenic and thoracic areas, this was followed by an increase in the red blood cells and hemoglobin and by further reduction in the white blood cell count During the latter part of August, Fowler's solution was discontinued because of generalized itching and an exfoliative eruption in the pubic region Within three weeks the skin lesions had cleared A single roentgen-ray treatment in September apparently did not influence the blood picture In January 1935 the third roentgen-ray treatment was given because of fatigue and weakness This was followed by symptomatic improvement and by a sharp but temporary reduction in the total leukocyte count and the percentage of immature cells

In April 1935, the administration of Fowler's solution resulted in a precipitous decrease in the total leukocyte count and in the percentage of immature cells Since that time strength and endurance have remained good and the white blood cell count and the percentage of myelocytes in the peripheral blood have been relatively low However, the spleen, which could not be felt in April, gradually increased in size When last seen, in September, the edge of the spleen was palpable 10 cm below the costal margin, in spite of the favorable blood picture

In June 1935, tooth extraction was followed by profuse hemorrhage for a period of about 10 days Blood smears taken before and during the bleeding showed an abundance of platelets The bleeding was finally controlled by a pressure splint, but resulted in a marked increase in the degree of anemia This patient also has had occasional episodes of vaginal bleeding, controlled by gynecological measures The bleeding time and coagulation time have been normal There has been no apparent correlation of the pelvic bleeding with fluctuations in the blood picture

Case 7 J N, a 36 year old farmer, was admitted to the Strong Memorial Hospital September 9, 1932 complaining of pain in the abdomen There had been increasing weakness for the past 20 months For several weeks he had noted anorexia, fatigue, dyspnea on exertion and loss of 20 pounds in weight During the three days previous to admission there had been sharp pain in the upper left abdominal quadrant aggravated by cough, deep breathing, and changes in position

Examination showed an appearance of chronic illness, pallor, small lymph nodes in the cervical and inguinal regions There were numerous fresh and old retinal hemorrhages The spleen was enlarged, with the lower border extending downward to the level of the umbilicus A friction rub was audible over the splenic area

Blood hemoglobin was 8.6 gm per 100 cc, red blood cells numbered 2,660,000 per cu mm, white blood cells 176,000 per cu mm The differential leukocyte formula was as follows eosinophils, 1.5 per cent, myeloblasts, 2 per cent, myelocytes, 43 per cent, juveniles, 21 per cent, stab neutrophils, 8 per cent, segment neutrophils, 21 per cent, lymphocytes, 2.5 per cent Platelets were present in approximately normal numbers Basal metabolic rate was plus 29 per cent

The administration of subtoxic doses of Fowler's solution resulted in a striking diminution in the number of leukocytes and in the percentage of immature cells, but both increased rapidly when the administration of arsenic was discontinued (figure 4) The administration of Fowler's solution in amounts as large as could be tolerated again resulted in striking hematologic improvement which persisted for about three weeks after discontinuing the drug The leukocyte count was reduced to a normal value and immature cells almost entirely disappeared from the peripheral circulation Meanwhile there had been steady clinical improvement Symptoms present on ad-

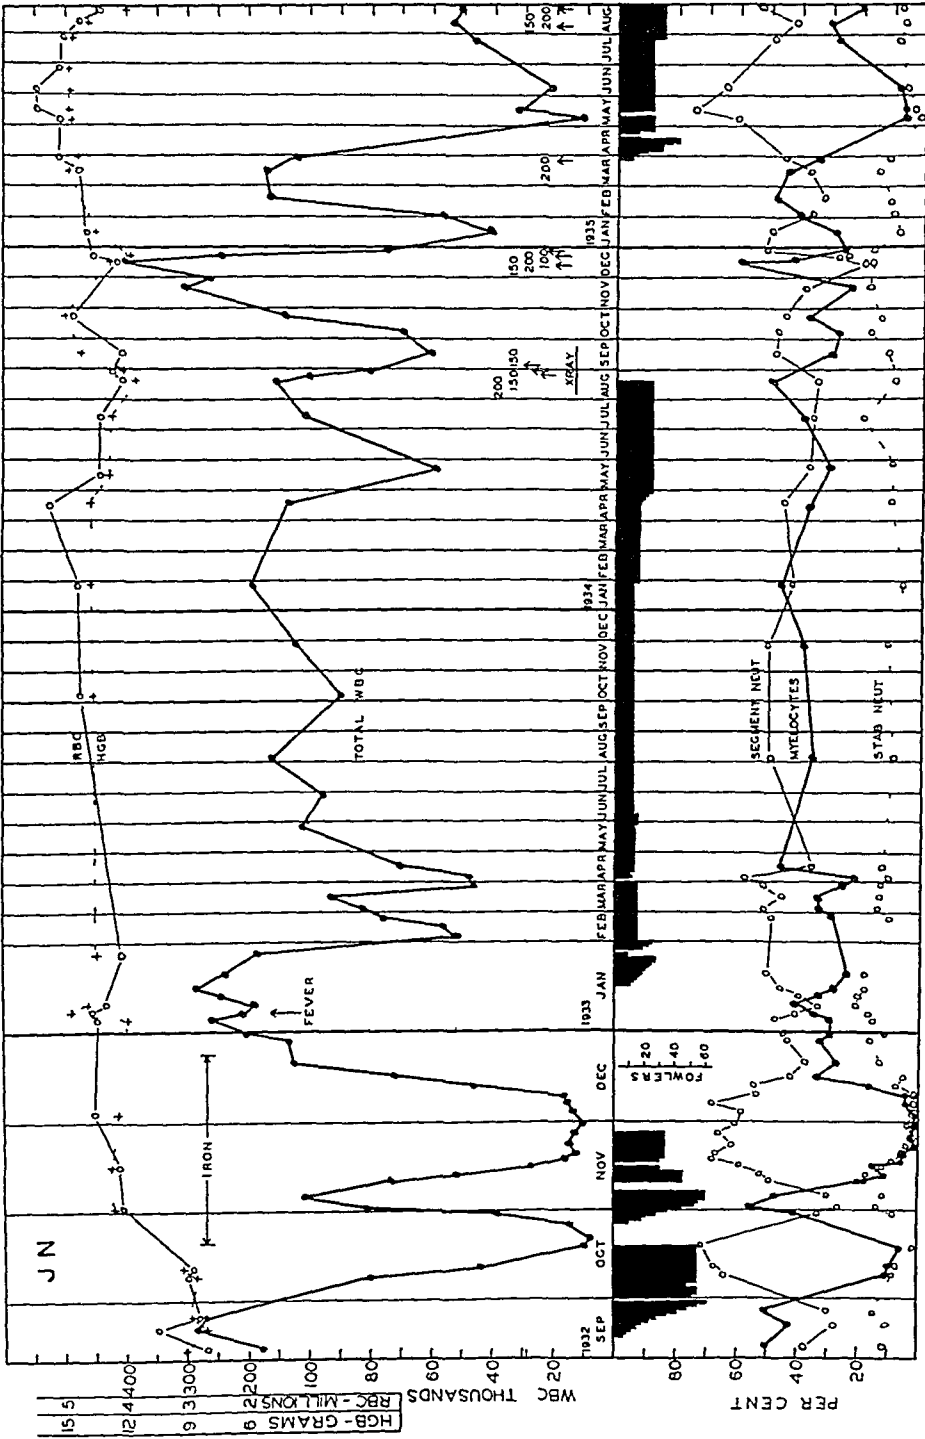

FIG 4 Case 7 (J N) The daily dose of solution of potassium arsenite is indicated in drops per day Roentgen treatments are indicated by arrows, with the dose in roentgen units

mission disappeared. The patient gained 20 pounds in weight and returned to work. In December 1932, the spleen was palpable under the costal margin.

Without therapy the total leukocyte count and the percentage of immature cells rapidly increased. On January 6, 1933, the patient submitted to 4 hours of artificial fever at a temperature of 40.5 to 41.0° C as an experimental procedure. Except for a temporary increase in hemoglobin, there was no significant change in the hematologic or clinical picture.

On January 15, 1933, the administration of Fowler's solution was again begun and was continued in subtoxic doses without interruption for 19 months. During this period the total leukocyte count and the percentage of immature cells remained relatively high. However, a satisfactory red blood cell and hemoglobin level was maintained, the splenic edge remained at the costal margin, the patient worked regularly as a laborer and was symptom-free except for intermittent, mild manifestations of arsenic toxicity.

During the month of August 1934, there was rapid increase in the size of the spleen to the level of the umbilicus and return of fatigue and weakness, shortness of breath and abdominal fullness. Arsenic was temporarily discontinued. During the next six months two courses of roentgen-ray therapy were given over the spleen. Each of these resulted in temporary clinical improvement, slight reduction in the size of the spleen, and a moderate decrease in the total leukocyte count and the number of immature cells.

In April 1935, the administration of Fowler's solution was again resumed and resulted in striking hematologic and clinical improvement. He again became symptom-free and was able to return to work regularly as a laborer in a gravel pit. The spleen was reduced in size so that the edge was palpable at the costal margin. Solution of potassium arsenite was continued, but within a few months the leukocyte count and the percentage of immature cells again began to rise and nucleated red blood cells appeared in the peripheral blood. The spleen gradually increased in size and the patient developed fatigue, non-productive cough and night sweats. In August, roentgen therapy was again begun.

DISCUSSION

It is apparent from the above case reports and charts that solution of potassium arsenite is an effective palliative agent in the treatment of chronic myelogenous leukemia. Symptomatic improvement was reported by the majority of patients soon after the administration of the drug was begun. In several instances, symptoms referable to the leukemia completely (but temporarily) disappeared. As a rule symptomatic improvement was accompanied by gain in weight, reduction in the size of the spleen and by improvement in the blood picture.

The hematologic changes in each patient are presented in detail in the charts. Soon after the toxic dose of arsenic was reached, in the characteristic response, the total leukocyte count began to fall sharply and in many instances approached the normal value. Decrease in the total white blood cell count was accompanied by a diminution in the percentage of immature cells, so that the white blood cell picture as a whole approached normal. The most striking response was observed in M V, for a period of several months the only abnormality present in the leukocyte counts was the presence of less than 5 per cent of myelocytes. The degree of hematologic improve-

ment varied from patient to patient, and in the same patient with successive courses of the drug. For example, J. N. experienced two striking hematologic and symptomatic remissions. The third course of Fowler's solution resulted in no significant change in the total or the differential leukocyte counts, but he remained symptom free for a period of 18 months, during which administration of the drug was continued. After a rest period during which roentgen therapy was used, arsenic again resulted in a striking, but temporary, hematologic and clinical remission. A similar variability in response was observed in M. T. and in E. G. with successive courses of the drug.

Anemia, which was present to some degree in all cases, was favorably affected. As a rule, increase in the red blood cell count and hemoglobin did not occur until a significant reduction in the total white blood cell count had taken place. In one patient (D. S.) a reticulocyte response was observed, followed by a sharp increase in the red blood cells and hemoglobin. It should be noted in the chart that the maximum reticulocyte response occurred before the administration of iron. It is possible that improvement in the anemia was dependent on the changes in the white blood cell picture, rather than constituting a direct effect of the arsenic. When nucleated red blood cells were present in the smears before the administration of Fowler's solution, they disappeared from the peripheral blood as the white blood cell picture and the anemia improved. Although there was originally no significant decrease in platelets in any of the patients studied, a favorable response to the arsenic therapy was usually accompanied by an increase in the platelets, easily detected in the smears.

Omission of the drug resulted, in a few weeks, in return of symptoms, increase in the size of the spleen and increase in both the total leukocyte count and the percentage of immature cells.

In attempting to maintain the dose of solution of potassium arsenite as near as possible to the minimum toxic level, each patient experienced repeated toxic symptoms. These included diarrhea, anorexia, nausea and vomiting, itching and puffiness of the eyelids, lacrimation and generalized itching of the skin. Three patients developed localized skin eruptions, characterized by small areas of erythema, dryness, scaling and itching. Three patients complained of tingling in the fingers and toes. In one individual, the soles of the feet became diffusely reddened, tender and slightly swollen. In one instance, herpes zoster of the ophthalmic division of the fifth nerve appeared while Fowler's solution was being administered. It is of interest that herpes zoster appeared in one of Forkner's patients under similar circumstances. Symptoms of arsenic toxicity disappeared within a few days after reduction in dose or omission of the drug. No alarming or serious reactions were encountered. Evidence of hepatic, renal or serious skin lesions was not observed. One patient (M. V.) developed a generalized pigmentation of the skin after taking large amounts of the drug for several months,

the continued administration of arsenic resulted only in very gradual intensification of the pigmentation

Serious bone marrow depression has occasionally occurred due to the arsphenamines but has been described only after the use of those arsenic preparations which contain the benzene ring. Aplastic anemia, agranulocytosis, and thrombocytopenic purpura are not mentioned either in the literature or in the pharmacologic texts, even as rare manifestations of inorganic arsenic poisoning. Hydrogen arsenide causes a severe anemia in both man and the experimental animal, but here the anemia is due to the markedly hemolytic action of this particular compound.³ Although there is apparently no danger of inducing bone marrow aplasia, the danger of other serious manifestations of arsenic poisoning must be continually kept in mind in giving, over long periods of time, the large doses of Fowler's solution necessary to induce symptomatic and hematologic remissions in leukemia. Unless frequent and careful clinical observations can be made, this form of therapy should not be used. The prolonged use of such a potentially dangerous drug, under the above conditions, is considered justified in view of the uniformly serious prognosis of the disease.

The mechanism of the action of solution of potassium arsenite in chronic myelogenous leukemia is not clear. Wichels and Hofer⁴ observed a reticulocyte response in normal individuals after the administration of toxic doses of the drug. Isaacs,⁵ working with white mice, concluded that arsenic solutions had a depressing effect on the bone marrow resulting in a decrease in the production of red blood cells. The effect of inorganic arsenic on the granulopoietic apparatus apparently has not been studied. The beneficial results observed in leukemia are apparently due in large measure to an inhibitory effect on the abnormal process of granulopoietic activity, resulting temporarily in a tendency for the involved structures to return to normal. This view is strengthened by the observation by Forkner and Scott¹ of return to red marrow in one patient in whom bone marrow biopsy was done after arsenic therapy. This inhibitory effect is apparently incomplete and temporary, symptomatic and hematologic relapse occurs after prolonged administration of the drug in adequate dosage. Further study of the effect of inorganic arsenic preparations on the blood and bone marrow of the human and of the experimental animal is needed.

Although roentgen therapy has been used in the treatment of several of the patients reported, conclusions as to the relative merits of roentgen and arsenic therapy are not justified. The number of cases is small, and in many instances less than the optimum amount of roentgen-ray therapy was given. However, the response in individual patients treated with Fowler's solution compares favorably with the reported symptomatic and hematologic response of patients adequately treated with roentgen therapy.⁶ This similarity in response of the patient with chronic myeloid leukemia to arsenic and to irradiation has been previously noted.¹ In considering the relative

merits of the two therapeutic procedures, several points should be borne in mind. Solution of potassium arsenite is relatively cheap, is readily available and does not require complicated and expensive equipment, or special technical experience on the part of the attending physician. Frequent clinical and hematological observations are essential, regardless of the method of therapy employed. While by no means all patients who receive roentgen-ray therapy have reactions, patients who have experienced both much prefer the repeated but usually mild symptoms of arsenic toxicity to the more severe and frequently incapacitating reactions which sometimes follow roentgen therapy. The alarming and frequently fatal bone marrow depression which may follow the irradiation therapy of chronic leukemia has not been reported in the small number of patients treated with Fowler's solution. A more extensive experience with the drug may reveal equally serious manifestations in unfavorable cases. It is apparent that arsenic is merely a palliative measure, with temporary effect, as is the case with roentgen therapy. However, an apparently effective agent is available for trial in those patients who become refractory to the effect of roentgen-rays. It is probable that arsenic may be most advantageously used in conjunction with or alternating with irradiation. Apparently the development of refractoriness to one or the other does not preclude the effective use of the alternative agent or a subsequent response to the original therapeutic measure. The question as to whether arsenic, used alone or in conjunction with irradiation, will appreciably prolong the life of the patient with chronic myeloid leukemia cannot be answered at the present time.

SUMMARY

1 Seven patients with chronic myelogenous leukemia, who have received one or more prolonged courses of solution of potassium arsenite, are described.

2 Solution of potassium arsenite is apparently an effective palliative agent in the treatment of chronic myelogenous leukemia.

3 In our experience, the drug is most effective if given in rapidly increasing doses until toxic symptoms appear and then continued in amounts as large as tolerated. Such a regime has been maintained for periods in excess of one year without serious reactions.

4 Solution of potassium arsenite administered in toxic or subtoxic doses to patients with chronic myelogenous leukemia usually results in (a) symptomatic improvement, (b) reduction in the size of the spleen, (c) decrease in the total white blood cell count, (d) decrease in the number of immature cells and in the number of nucleated red blood cells in the peripheral blood, (e) improvement in the anemia, (f) increase in platelets. Such evidences of improvement vary in degree and duration. Symptomatic and hematologic relapse may occur during the continued administration of the drug.

5 It appears that solution of potassium arsenite may be most advantageously used in the treatment of chronic myelogenous leukemia in conjunction with, or alternating with, courses of roentgen therapy

ADOLESCENT DISTURBANCES OF ENDOCRINE FUNCTION, THE IMPORTANCE OF THEIR RECOGNITION AND TREATMENT^{*}

By CHARLES H. LAWRENCE, M D , F A C P , *Boston, Massachusetts*

It is manifestly impossible to discuss in a single article all the disturbances of endocrine function that may be encountered during the period of adolescence. I have, therefore, selected one type of dysfunction which is peculiarly related to that period, hypofunction of the anterior lobe of the pituitary gland.

It has long been known that the pituitary was a factor in the abnormalities of skeletal growth which are responsible for gigantism and dwarfism, but its responsibility for disturbances of maturation has been established more recently, and is still imperfectly understood. We have surmised that aberrations of that process were caused by functional disturbances of one or another of the endocrine glands, but have been unable until recently to identify the specific factors responsible for them. This fact, coupled with the observation that not a few of these disturbances of growth and development apparently corrected themselves completely by the time the age of maturity was reached, has resulted in our adopting an attitude of optimistic expectancy in regard to them. The ability of the individual to "outgrow" an adolescent arrest of development has been observed so frequently that it has been depended upon to meet the situation until its failure to do so was demonstrated after the growth impulse ceased. If the failure affects bodily growth markedly, its result is obvious, but if, as more commonly occurs, it results only, or chiefly, in incomplete maturity of the reproductive system, the condition often escapes notice, until symptoms referable to the genital organs direct attention to their incomplete development—too late, as a rule, to correct the defect.

Although no statistics are available concerning the frequency with which significant hypofunctional pituitary disturbances occur during adolescence, evidence is accumulating that they do so more often than has been realized, and that they are successfully "outgrown," or spontaneously normalized, less frequently than we have supposed, so that at present the physician finds himself in a dilemma when confronted by an adolescent patient with definite evidence of genital hypoplasia. Will the underlying pituitary hypofunction correct itself early enough and completely enough to achieve normal adult genital development, or does it require help, and if so, is effective help available?

In an effort to find the answer to these questions I have analyzed the records of two groups of patients. The first is composed of 97 couples

^{*} Presented before the General Sessions of the American College of Physicians, Detroit, March 5, 1936.

The several foci involved are indicated by T for thyroid, P for pituitary, G for gonad, and A for adrenal The minus sign (-) indicates a depression of function, the plus sign (+) a hyperactivity

whose marriages were sterile, and in whom a complete study of the causes of sterility was made¹ From such a study some idea of the incidence of genital hypoplasia and the disturbances associated with it is obtained The second group is composed of patients who have been treated for hypofunction of the anterior pituitary lobe and the resulting genital hypoplasia, and offers evidence from which a working hypothesis concerning the value of treatment can be constructed

Table I shows the incidence of normal and hypoplastic genital development in the women of this series, and the association of existing or pre-existing endocrinopathies in the two subgroups The diagnosis of pelvic hypoplasia was made by vaginal examination and the determination of the uterine index by an independent observer¹ Among the patients with normal genital development there were 12 who showed clinical and laboratory evidence of co-existing endocrine disturbance, as contrasted with 34 women with genital hypoplasia who showed, by the same criteria, evidence of active endocrine disturbances In both groups, the anterior pituitary was the gland most frequently at fault, with ovarian hypofunction of the primary type, next Adolescent endocrine disturbances, which had spontaneously corrected themselves, were found in two patients with normal genital development, and in 10 with genital hypoplasia

A similar analysis of the males, using spermatogenesis as the criterion of normal gonadal development, is shown in table 2 Again the preponder-

* The examinations of these patients were made by Dr S. N. Vose

† Six patients showed testicular hypoplasia Six showed cryptorchidism These conditions are probably the result of adolescent pituitary hypofunction, now compensated

ance of endocrinopathies, and in particular anterior pituitary hypofunction, in the group with defective spermatogenesis is striking, in contrast to their relatively low incidence in the group with normal gonadal function None of the normal group shows convincing evidence suggesting adolescent endocrine disturbance, while unmistakable stigmata of that condition, without metabolic disturbance at the time of examination, were found in 12 of the patients in the defective group The figures show a surprisingly high incidence of defective spermatogenesis among the males In part this may be due to an exacting standard of normality which included not only the number of spermatozoa, but their morphology, duration of motility, and percentage of abnormal forms as criteria However, the figures of Bland and

his associates,² which show more than 50 per cent of deficient spermatogenesis in the males of his series, agree essentially with ours in indicating that whatever the actual percentage may be, there is a very high incidence of defective spermatogenesis in males whose marriages are sterile. Such subnormal function, according to the work of Evans and his associates,³ is produced when the normal gonad stimulating hormone of the anterior pituitary is lacking, and its high incidence in these patients indicates a correspondingly frequent occurrence of hypofunctional pituitary disturbances, beginning probably during adolescence. The considerable number of patients with thyroid hypofunction serves as a warning, however, that pituitary hypofunction cannot be taken for granted whenever defective spermatogenesis is discovered.

Table 3 shows the incidence of normal and abnormal menstruation in the women composing our series. The correlation between normal genital development and normal menstruation, on the one hand, and genital hypoplasia and oligomenorrhea on the other, indicates that a definite relation between normal development and normal menstrual function exists, and that extremely short, scant, or infrequent menstrual periods are an indication of either genital hypoplasia or, in its absence, of ovarian pathology.

TABLE III
Genital Development and Menstrual Function in 97 Females (Sterile Marriages)

Genital Development	Menstruation Normal	Polymenorrhea	Oligomenorrhea	Dysmenorrhea
Normal (49 patients)	29 patients	1 patient	18 patients (7 = cystic ovaries) (1 = premenopausal)	1 patient
Hypoplastic (44 patients)	4 patients	4 patients	32 patients (2 = cystic ovaries)	*13 patients
Atrophic (1 patient)	0 patients	0 patients	1 patient	0 patients
Condition undetermined (organic pathology) (3 patients)	3 patients	0 patients	0 patients	0 patients

* Nine patients had both oligomenorrhea and dysmenorrhea.

There is at present some disagreement concerning what is normal menstruation. Boynton,⁴ King,⁵ and Allen⁶ have investigated the menstrual rhythm in healthy women, and have reached the conclusion that irregular menstruation is not uncommon among them, and Anspach and Hoffman⁷ have questioned the truth of the idea that most healthy women menstruate regularly and at 28 day intervals. Much of the significance of their findings depends upon what they mean by the word "health." It is obvious that perfect health, as the term is usually understood, can and does exist without complete development of the genital organs, and without their normal function. In our own series, none of the patients complained of ill health, nor

was organic disease, other than focal infection or moderate anemia, demonstrated in them, yet in those whose periods were abnormal by conventional standards, genital hypoplasia or polycystic ovaries existed in a significant majority. It is quite possible that undetected hypoplasia was the cause of the "abnormal" menstrual periods in the women investigated by the writers just cited.

In contrast to the differences of opinion concerning so-called normal menstruation, there is fairly general agreement concerning the normal age of menarche. Englemann⁸ in a study of 10,000 patients, found that the average age of menarche in American born women living in this country was 13.9 years. Meaker's¹ figures, from over 2,000 patients, show that menarche occurred in 80 per cent before the fifteenth birthday, so that it seems justifiable to regard the event as delayed when it takes place after that age has been reached.

An analysis of our own series (table 4) shows that there was a definite lag in the age of menarche in those patients who had reached adult life with-

TABLE IV

Age of Menarche in Patients with Normal and Hypoplastic Genital Development

out achieving complete sexual maturity. It likewise suggests that early menarche, before the eleventh year, does not insure normal developmental progress throughout adolescence.

The percentage figures for the "normal" group agree essentially with those given by Englemann⁸ and Meaker,¹ while those of the "hypoplastic group" show retardation of the onset of menstruation. From the point of view of diagnosis and treatment, it seems justifiable to conclude that if regular menstrual rhythm has not been established by the middle of the fourteenth year, an investigation of the patient's organic and metabolic condition is justified, and that if it is still absent at the beginning of her fifteenth year, appropriate treatment of the associated defect, again determined by careful and complete study, should be instituted if it is available.

In contrast to the female, the male exhibits no sharply defined events characteristic of adolescence which can be accurately timed. There is, however, some less dramatic evidence to indicate that similar retardation of development occurs in males. The most definite is delay or failure of testicular descent which, if it persists beyond the normal age of puberty, is generally believed to result in permanent depression or even total failure of spermatogenetic function. It is impossible to determine the incidence of cryptorchidism in civil life, but the records of the United States Army Medical Department⁹ showed that among the troops in the late war it occurred in three per thousand individuals. In our series of men whose marriages were sterile, it was found 12 times among 97 patients, associated with defective spermatogenesis in every instance.

From the evidence assembled in the foregoing analysis, it seems justifiable to draw certain conclusions, which if not completely proved, afford at least a fair working hypothesis for further investigation. These conclusions are: First, that in both males and females hypoplastic genital development is more common than has been supposed. Second, that such hypoplastic development is generally the result of a hypofunctional disturbance of the anterior pituitary gland, which in all probability begins during adolescence, and in the majority of individuals persists, if untreated, into adult years. Third, whether the pituitary hypofunction does so persist, or as may occur in a minority of cases normalizes spontaneously, the defect of genital development tends to be permanent throughout the reproductive period. It therefore, seems clear that treatment, if it is to be effective in preventing these developmental defects, should be applied before the end of the normal period of development.

There is, however, a lack of agreement concerning the value of treatment arising from the conflicting results of animal experimentation and clinical experience. Only lately has it become clear that many of these conflicts are due to species variations. These variations have been recently emphasized by Loeb and his associates¹⁰ who have shown that the effects observed in any experiment depend not only on the species of the test animal, but also

upon the species from which the extract employed was derived. It must be clear, therefore, that many of the apparently conflicting reports in the literature are not truly conflicting, since the experiments upon which they are based are not identical. It must also be equally clear that the effect of a given endocrine extract upon human beings cannot be accurately predicted from results observed in any other species. Such observations furnish the clinician with a general conception of the response to be expected, but its exact nature can be determined only by the study of patients before, during, and for a sufficient time after treatment to determine its permanent effect. Such studies are difficult to carry out in adolescent patients for obvious reasons. One cannot do vaginal examinations and endometrial biopsies, nor determine the uterine index, in adolescent girls, nor can one study the spermatogenetic function in adolescent boys. However, by using all the methods that can be fairly applied to each patient, it is possible gradually to accumulate a series in which the condition before treatment, and the response to it, can be established with reasonable certainty.

Table 5 shows the results of treatment in two groups of women so studied who exhibited, before treatment, definite evidence of anterior pituitary hypofunction and associated genital hypoplasia. The latter condition was determined by rectal pelvic examination in the adolescent patients, by

TABLE V
Results of Treatment

End Result	29 Adolescents		21 Adults	
	Amenorrhea	Menorrhagia	Amenorrhea	Menorrhagia
Well	71+%	62+%	30%	27+%
Mod improvement	14+%	0	10%	18+%
Slow improvement	0	0	10%	36+%
No improvement	14+%	37+%	50%	18+%

vaginal examination in the adults. The diagnosis of pituitary hypofunction was based upon history, physical examination, and metabolic studies. For convenience in tabulation, the patients have been grouped according to the type of menstrual disturbance which constituted their chief complaint. The term "end result" is used to indicate the condition existing six to 12 months after treatment had been omitted, and applies specifically to the menstrual disturbance and its associated genital hypoplasia. Each patient was treated with the same preparation of the anterior pituitary-like hormone derived from pregnancy urine.* The only variable factor was the duration of treat-

* The specific preparation used was Antutrin S (Parke, Davis Co.)

ment, which ranged between three and 12 months, according to the promptness of the response obtained

The number of patients on whom it has been possible to carry out these controlled observations is small, and hard and fast conclusions cannot be drawn from the series. The obvious difference in the results of treatment in the two groups, however, is larger than chance would account for, and suggests that the age factor may be an important one in determining the response. This idea receives support from observations on animals. Hertz and Hisaw¹¹ have shown that the female chinchilla rabbit four weeks old shows no response to a dosage of pituitary extract ample to elicit a maximal response in a rabbit of the same breed when 12 or 13 weeks old. Smith,¹² commenting on this fact, observes "From conditions found in women it may be surmised that after a certain degree of aging the reproductive organs lose their capacity to respond to the gonad stimulating hormone, for after the menopause, follicle stimulating hormone may be present in large amounts, yet reproductive cycles cease." "It is evident," he continues, "that the response elicited by injections of the pituitary or any other hormone is dependent on at least two factors—namely, the stimulating capacity or potency of the dosage given and the responsive capacity of the receptor tissue or organs." The results presented in table 5 suggest at least that the responsive capacity of the human ovary reaches its maximum during adolescence.

Just when this responsive capacity of the human gonads is initiated is not known, but certain clinical evidence shows that it is present, in some degree, before puberty, at least in the male. This evidence is derived from the treatment of cryptorchidism with pregnancy urine extract, concerning which there are numerous reports in the literature. Rubenstein¹³ has reported the results of treatment of a patient ten and a half years old who had dystrophia adiposo-genitalis and intra-abdominal testes. The left testis entered the inguinal canal and could be pushed into the scrotum after six injections, totalling 250 rat units. After five months' treatment it had descended completely, the right one partially, and both had increased in size. In contrast, Brosius¹⁴ reports no effect from similar treatment in a pituitary dwarf 38 years old. Dorff¹⁵ has recently published a careful study of 14 (?) male children with maldevelopment and maldescent of the testes. He calls attention to the fact that response is slow, but that it was most rapid in the patients who were close to puberty. Sexton¹⁶ has reported satisfactory response to treatment in a boy 18 years old with double cryptorchidism. It seems apparent from these results that the treatment of genital hypoplasia is about equally effective in both sexes, and that its effectiveness is influenced to a considerable degree by the age of the patient, reaching its maximum at or about puberty, and showing a decided diminution in adult life.

As a corollary, treatment for that condition should be begun in time to

take advantage of the capacity for response. Doing so may involve the occasional treatment of a patient who would have achieved normal development without help, but failure to do so means the acceptance of an unjustifiable handicap. I wish to emphasize again, however, my statement that treatment should not be instituted until a painstaking and complete study has identified the causative factor or factors responsible for the individual patient's developmental delay.

CONCLUSION

In conclusion, I wish to restate briefly the working hypothesis which seems to be justified by the evidence presented.

Genital hypoplasia, anatomical or physiological, is more common than is generally appreciated. It is caused, in the majority of individuals, by a functional depression of the activity of the anterior lobe of the hypophysis, developing during the pubertal or adolescent periods, but other possible causes, endocrine and non-endocrine, must be recognized. In the female, its existence is suggested by any significant abnormality of the menarche or menstrual rhythm, and can be proved by appropriate examinations. Its causative factors can also be demonstrated by careful study. In the male, the diagnosis is often more difficult to establish before adult age is reached except when physiological hypoplasia is accompanied by obvious anatomical stigmata.

Treatment, to be most effective, must be instituted during the pre-pubertal or adolescent period.

OXYGEN TREATMENT AND THYROID ABLATION IN THE TREATMENT OF HEART DISEASE ~

By ALVAN L. BARACH, M.D., F.A.C.P., DICKINSON W. RICHARDS, M.D.,
and W. BARCLAY PARSONS, M.D., *New York, N. Y.*

THE primary function of the lungs is to transmit to the arterial blood coursing through them an adequate supply of oxygen from the inhaled atmospheric air. During expiration carbon dioxide and water vapor are eliminated. The delivery to the tissues of the oxygen absorbed by the arterial blood is dependent upon the heart, the peripheral circulation, the amount of functioning hemoglobin, the blood volume and other factors. If the heart action is sufficiently impaired it is unable to maintain adequate blood flow, and the oxygen is supplied to the tissues at a tension less than that needed for proper functioning of the various organs in the body.

In this clinic, an attempt to treat heart failure was made by increasing the amount of oxygen carried by the arterial blood, through the inhalation of high oxygen atmospheres.¹ An added increment of oxygen was provided for the arterial blood with less ventilatory effort, oxygen reached the tissues (including the heart) at higher tensions, oxygen transport was thus more effective, and in certain patients, circulatory compensation was thereby restored.

A more radical therapeutic measure than the provision of an increased arterial oxygen supply is the reduction of the oxygen requirement of the patient through total ablation of the thyroid gland (Blumgart, et al.²). In decreasing the needs of the body for oxygen by 25 to 35 per cent, the work required of the heart is so much less than it was that a slowed blood flow becomes adequate to the metabolic demands of the patient. It has, of course, been recognized that the full pursuits of life's activities may be threatened by such a marked reduction in oxygen consumption, approximately to two-thirds of the normal metabolism. The development of hypothyroid states of varying degree, however, is requisite for a significant decrease in the work of the heart.

In each type of therapeutic approach an adequate amount and tension of oxygen in the tissues of the organism are striven for.

Since we had employed oxygen treatment as a method of facilitating the recovery of patients with cardiac insufficiency, it seemed reasonable to extend it to the procedure of thyroidectomy in heart disease. Twelve patients with heart disease, in whom thyroid ablation was performed with the aid of oxygen treatment, will be presented in this communication.

* Received for publication February 17, 1936.

From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, New York City.

HISTORICAL

The rationale for the removal of the thyroid gland which Blumgart and his collaborators have carried out in various types of heart failure was derived by them from investigations concerning the effect of the hypothyroid state on blood velocity.³ According to their reports, the blood velocity varies with the metabolic demands of the body, it is increased in hyperthyroidism and decreased in myxedema. In patients with congestive heart failure, the blood velocity was found to be considerably retarded, in general in proportion to the degree of failure, although the metabolic needs of the body were not lessened. By lowering the basal metabolic rate, i.e., by thyroidectomy, the work the circulation had to do was conspicuously lessened. Equilibrium between the metabolic rate and the blood velocity thus effected was found to restore compensation.

When thyroid ablation was contemplated in our clinic, we proposed to treat these cardiac patients with oxygen prior to operation for a period sufficient to remove as far as possible the signs of cardiac insufficiency, and to employ oxygen during the operation itself and for a period following it. The operative mortality in patients subjected to this operation in various clinics warranted in our minds not only a careful selection of cases but every aid that might be found to lessen the chances of death due to the operation. In a recent series reported by Blumgart et al.,⁴ of 50 cases of congestive heart failure, six patients died as a result of the operation. In 25 cases of angina pectoris, none died. In some of these severe cases, our suggestion of preoperative as well as postoperative oxygen treatment was adopted.⁵ Since the use of oxygen as an accessory to the procedure of thyroid ablation has appeared to result in a specially smooth postoperative course, so far without operative mortality, the basis for its employment will be reviewed.

It has long been known that the rate of normal heart is especially responsive to changes in the oxygen tension of the inspired air, slowing when pure oxygen is breathed and becoming regularly elevated when the atmosphere has either a diminished concentration or pressure of oxygen. In addition to an increased rate, dilatation of the heart occurs as a result of oxygen-want in normal men at high altitudes (Campbell⁶). In small animals Campbell reported degenerative changes in the myocardium as a result of prolonged exposure to low oxygen atmospheres.⁶ Katz and Long,⁷ using mammalian heart preparations, have shown that by reducing the oxygen supply to the heart there was rapid dilatation and failure of function, the contractions becoming progressively feebler and conduction slower. When the lactic acid accumulated, as a result of anoxemia, to 2.5 times the normal level, they found complete exhaustion took place, whereas skeletal muscle could withstand up to 4.5 times the normal level, revealing the greater intolerance of the heart to oxygen debt. In experiments on the effect of diphtheria toxin in circulatory failure, G. T. Evans⁸ found that the striking feature was sud-

den death and that this could be prevented by artificial pulmonary ventilation. When artificial pulmonary ventilation was not carried out, the heart was found to be almost completely depleted of glycogen. In other words, as Meakins⁹ has said, the sudden deaths appeared to be due to a respiratory failure with progressive anoxemia, producing a conspicuous reduction in cardiac glycogen. Under no conditions of severe physical exercise was it possible to lower cardiac glycogen below the normal levels, whereas marked anoxemia depleted cardiac glycogen within a minute or two. Animals breathing atmospheres containing 7 to 6 per cent oxygen gave up as much as two-thirds of their cardiac glycogen.

The heart, therefore, appears to be especially sensitive to oxygen-want. When it is failing it shows its dependence upon the amount of oxygen furnished to it by improving in its function when high concentrations of oxygen are inhaled. Beddard and Pembrey¹⁰ in 1908 observed that the inhalation of oxygen resulted in a decreased pulmonary ventilation in a patient with cardiac insufficiency, which was confirmed subsequently by Campbell, Hunt and Poulton¹¹ and by Barach and Richards^{10, 10}. Means and Newburgh¹² in 1915 found a diminished oxygen saturation of the venous blood in cases of cardiac decompensation. Harrop¹³ showed that a diminished arterial oxygen saturation was also frequently present. Barach and Woodwell¹⁴ administered 40 to 60 per cent oxygen to cases of cardiac insufficiency for short periods and observed an increase in the arterial saturation and a corresponding elevation of the venous oxygen saturation. In addition, they noticed a definite slowing of the pulse incident to inhalation of high oxygen atmospheres but did not discover alleviation of cardiac dyspnea, due to the brevity of the periods of oxygen administration and the use of a mask or mouthpiece.

In 1927 Campbell and Poulton¹⁵ reported beneficial effects of continuous residence in an oxygen chamber on subjects with dyspnea, especially when related to chronic bronchitis and emphysema, but including also one case of arteriosclerotic myocardial failure. Barach and Richards¹ (1930 to 1935) have presented investigations which reveal in a more detailed manner the special effects of oxygen treatment in congestive heart failure. Their results may be briefly reviewed as follows. Subjective improvement, relief of dyspnea and cough, begins generally in about three hours after entrance to the oxygen chamber and becomes well-marked on the following day. Between the third and sixth days of residence in a high oxygen environment, a diuresis sets in, in the favorable cases, which progresses until the patient is edema-free. This diuresis has been shown to be specifically dependent upon oxygen inhalation and not upon rest in bed, by withdrawal of oxygen in certain instances with cessation of diuresis and recurrence of edema. Objective changes are an increased oxygen saturation of the arterial blood, decreased pulse rate, lowered pulmonary ventilation, fall in blood lactic acid, gradual increase in vital capacity and a characteristic rise in the arterial CO_2 .

content The CO_2 curve of the arterial blood may increase from 50 to 100 per cent of the normal level as a response to inhalation of 50 per cent oxygen, representing a mechanism for the elimination of greater amounts of CO_2 in a decreased volume of breathing, which the provision of increased atmospheric oxygen makes possible This cardio-respiratory rest which oxygen therapy makes possible may be of significance not only as providing relief of symptoms but also as an important factor in the restoration of compensation When the lungs move more freely, as pulmonary congestion diminishes, the CO_2 curve falls, even in the presence of a high oxygen environment Deeper ventilation is then employed by the patient for CO_2 elimination rather than the shallow breathing which oxygen therapy makes possible when passive pulmonary congestion is present

The relief of dyspnea which oxygen therapy induces is sometimes almost immediate as in certain cases of Cheyne-Stokes breathing, sometimes delayed In a period of several hours, however, the patient will usually notice some relief The delay is probably due in part to the time required for readjustment of CO_2 level of the blood This has been discussed in a previous paper It is evident that a diminished oxygen saturation of the arterial or venous blood is not felt directly as the sensation of dyspnea through its nervous pathways The relief obtained by oxygen therapy is produced by lessening the effort requirement by enabling not only a lessened total pulmonary ventilation but a shallower type of breathing The lungs are less locally harassed, the respiratory musculature is relieved of some of its burdensome labored action Decreased dyspnea results Peabody and his co-workers¹⁶ emphasized the rôle of lung stiffening in congestive failure (the theory first put forward by von Basch¹⁷), also the reduction of vital capacity and the mechanical limitations of chest movement Recently, Harrison¹⁸ has presented elaborate investigations in support of the reflex cause of cardiac dyspnea, minimizing the importance of chemical factors He states "As regards the dyspnea produced by mild exertion in patients with congestive heart failure (1) It cannot be due to inability to increase the cardiac output (2) It cannot be due to diminished cerebral blood flow

(3) It is evident that the dyspnea of mild exertion is not related to alterations in the oxygen, carbon dioxide, or reaction of the blood, either arterial or venous" He later remarks that attacks of cardiac asthma, when unaccompanied by pulmonary edema, are not likely to be associated with abnormalities in the composition of the arterial blood, and relief of the attack occurs *independently of the changes in the composition of the arterial blood*

We would criticize the conclusions of Harrison on two grounds, one of fact and one of logic As to the first, in the tables presented by Harrison, purporting to show the lack of alteration in blood gases in cardiac asthma, one finds that the majority of patients showed a definite lowering of arterial oxygen saturation, sometimes as low as 86 per cent (see reference 17, pp 172-173)

On the ground of logic, we believe, as Harrison does, that the primary and immediate cause of the *sensation* of dyspnea, not only in cardiac cases, but in all other instances as well, is to be looked for in the nature of the proprioceptive impulses streaming into the central nervous system from the air passages, lungs and moving framework of the chest. The difficulty with Harrison's point of view, as we see it, is his failure to give due importance to the subject's *breathing requirement*, as distinct from his *breathing capacity*. It is in most instances just as effective, in relieving dyspnea, to reduce the breathing requirement, as it is to increase the breathing capacity. Reduction in breathing requirement, as abundantly shown by Campbell and Poulton, by Richards and Barach, and others, is just what is accomplished by oxygen inhalation in cases of congestive heart failure.

(a) Total ventilation is less

(b) Breathing is light and shallow, instead of relatively deep and labored

(c) Oxygen saturation of the arterial blood becomes normal or greater than normal

(d) Arterial CO_2 tension increases, but CO_2 combining capacity increases as well, and pH changes little

In the accompanying chart (chart 1), a patient with cardio-nephritic disease recorded his tidal volume while breathing air, 100 per cent oxygen, air again and 40 per cent oxygen. It can be seen that the relief of paroxysmal dyspnea, or cardiac asthma, took place immediately after the inhalation of oxygen and that the dyspnea recurred immediately when oxygen was withdrawn. In this case, there was no time for the pathology of the lung itself to change, the dyspnea was *chemically* relieved due to an alteration of the state of the blood gases in the patient which changed the type of respiration as well as decreased total ventilatory requirement.

There is an important aspect to this argument since it has been insufficiently recognized that oxygen therapy in heart disease is based on an actual need of the failing heart muscle for oxygen. In the investigations referred to by Richards and Barach,¹ clinical improvement in patients with congestive heart failure took place both in those in whom arterial anoxemia was present and to a degree in those in whom it was very slightly present or absent. Even without arterial anoxemia, many apparently compensated cardiac patients are in chronic oxygen debt (Uhlenbruck,¹⁹ Knipping²⁰), the measurement of which has been used as a criterion for oxygen therapy. There is therefore reason to believe that cardiac patients may make sufficiently severe efforts to cause distress in breathing in order to maintain their blood gases in a normal range, to fulfill oxygen requirement and be released from oxygen debt. Thus, one cannot conclude because the arterial oxygen saturation is normal or only slightly lowered that the threat of anoxemia is not burdensome to the patient.

CHART 1 Effect of Oxygen on Cheyne-Stokes Breathing

The effect of increased atmospheric oxygen is three-fold (1) The arterial blood contains an increase in the oxygen in physical solution and in that combined with hemoglobin, both of which afford a greater tension of oxygen and a greater delivery of oxygen per unit of blood flow. In other words, a diminished blood flow is made more efficient. In a converse way a small blood flow is made more efficient by a reduction of the oxygen consumption.² The second effect of increased atmospheric oxygen is an extension of the first, namely, that an increased delivery of oxygen per unit of blood flow supplies the heart muscle with increased oxygen, upon which it is peculiarly dependent, as noted above. A better contraction of the heart muscle in turn inaugurates a more efficient blood flow, and a virtuous cycle of increased oxygen supply replaces a vicious cycle of oxygen deficit, in which decreasing arterial oxygen tension makes for lessened ability of the heart to contract which in turn lessens blood flow, with an augmentation of the secondary results of cardiac failure, dyspnea and edema.³ In the third place, as indicated above, increased atmospheric oxygen enables pulmonary ventilation to proceed more efficiently and with actually less effort.

METHODS

When a patient was selected for thyroid ablation, he was transferred to the oxygen chamber, oxygen concentration 50 per cent. The chamber was of the thermal circulation type described by one of us.²¹ In cases of congestive failure, treatment was continued for two to three weeks or until evidence of decompensation receded. In patients with angina pectoris without congestive failure, a period of four to seven days of oxygen treatment generally preceded operation. The patient on the morning of operation was given a small dose of nembutal, 0.1 to 0.2 gm. A nasal catheter was inserted into the nasopharynx in the chamber and a flow of 5 liters of oxygen per minute begun before the door of the chamber was opened. He was then taken up the elevator and wheeled to the operating room without discontinuance of oxygen, the 220 cu. ft. tank being wheeled behind the patient. Oxygen was continued throughout the operation, which was done under local anesthesia, and the patient returned in a similar manner to the oxygen room. When the concentration was brought up to 50 per cent, the nasal catheter was withdrawn. Generally, a period of four days in the chamber followed, when the oxygen concentration was lowered to 40 per cent for 12 to 24 hours, then to 35 per cent for 12 to 24 hours, when he was removed to a ward or room. If lowering the oxygen concentration provoked too great a rise in pulse rate, i.e., over 10 beats per minute, the oxygen concentration in the chamber was elevated for two or three days and then again gradually lowered. If the patient had been withdrawn from the chamber, a nasal catheter was used for several days if the pulse became unduly increased.

The gas analysis was done by the method of Van Slyke and Neill. The blood volume was determined by the dye method, using brilliant vital red

(of Peters and Van Slyke) The venous pressure was measured by the direct method of Moitz and Tabora

RESULTS

Of 12 patients upon whom thyroid ablation was performed, five had rheumatic disease with congestive failure, two had arteriosclerotic disease with congestive failure, two had congestive failure with associated coronary sclerosis and anginal pain, and three had coronary arteriosclerosis with anginal pain without congestive failure. All the patients except one had a normal basal metabolism and experienced a complete ablation of the thyroid. One patient had hyperthyroidism with arteriosclerotic heart disease and congestive failure and was treated with oxygen and a partial thyroidectomy. In summary, nine of 12 cases had congestive heart failure prior to treatment.

CASE REPORTS

Case 1 N G, female, aged 34

Family History One daughter had rheumatic fever. *Personal History* No rheumatic fever but occasional sore throats as a child. Malaria at 14. *P I* Heart lesion first noted 17 years ago during first pregnancy. Six years ago, patient noticed dyspnea on climbing stairs, and for past five years has been practically incapacitated. During the last 18 months she has been confined to bed, with palpitation on the slightest exertion, intermittent edema and recurring ascites which finally necessitated paracentesis at three-week intervals.

Physical Examination A poorly developed, emaciated, cyanotic, adult woman, not dyspneic at rest. Neck veins dilated. Pupils react to light. Lungs contain râles at both bases. Heart enlarged in all diameters, systolic and diastolic murmurs at apex, blowing diastolic at the base, pulse totally irregular, exceptionally small volume. Blood pressure 80/40 mm of Hg. Abdomen distended with fluid. Liver hard, felt 7 cm below costal margin. Slight sacral edema without ankle edema.

Laboratory Findings Hgb 84 per cent, rbc 3.8 millions, wbc 4,600, polynuclears 83 per cent. Urine albumin, heavy trace. Serum protein 7.8 per cent. Electrocardiogram auricular fibrillation, R_2 and R_3 notched, T_1 diphasic, T_2 and T_3 inverted.

Course A paracentesis was done the day after admission with considerable relief. She was put in the oxygen chamber (concentration of oxygen 50 per cent), for two weeks when thyroid ablation was performed. A nasal catheter was inserted while the patient was in the chamber and 5 liters of oxygen administered during the transport of patient to and from the operating room and during the operation. Local anesthesia was used. The operation was performed without any signs of cardiac embarrassment. She was kept in the oxygen chamber for one week after operation, the oxygen concentration being gradually lowered the last three days, and then removed to the ward. As shown in chart 1, she had a slight increase in temperature with little change in her cardiac and pulse rates after operation. During the next 10 weeks, her basal metabolism gradually dropped from minus 13 to minus 43 per cent. Eight weeks after operation, she developed enough ascites to require tapping, 2,200 cc fluid were removed. She was discharged 14 weeks after operation, unmistakably improved, able to walk the length of the hospital floor without palpitation or dyspnea.

Before operation, her venous pressure varied between 130 and 153, after operation, between 135 and 225. Blood velocity before operation, 25-35, after, 38, 41, 48, 52 (table 1 and chart 2).

CHART 2 Clinical chart before and after thyroid ablation with patient in 50 per cent oxygen atmosphere

TABLE I

Case 1	Before Operation	After Operation	Remarks
Date	10-17-33 to 11-7-33	11-7-33 to 8-1-35	
Arterial oxygen saturation	94%	93%	Patient had been confined to bed for 18 months prior to operation. She was in oxygen chamber 14 days before and 6 days after operation. Arterial oxygen saturation in oxygen chamber 99 per cent. Ascites recurred for 1 year following operation. Since 10-17-34, no paracentesis necessary.
Hemoglobin	84%	72 to 85%	
Basal metabolism	-13	-18 to -43	
R B C millions per cu mm	3.8	3.6 to 4.2	
Vital capacity	900 to 1100	1200 to 1750	
Blood velocity (seconds)	25-35	38, 41, 48, 52	
Venous pressure	130-153	135 to 225	
Arterial pressure	100/60	95/50 to 120/70	
Sedimentation rate		45 mm / 1 hr	
Arterial CO ₂ vol per cent	53.6	55.4	
Blood cholesterol		194 to 205	
Wt kg	44	45.8	
Pulse	48-120	40 to 64	

Following her operation, December 7, 1933, patient was able to do more without heart consciousness or dyspnea than she had at any time during the previous five years. She required paracentesis at long intervals for one year and since that time has had no re-accumulation of fluid in her abdomen (from December 17, 1934, to the present time, December 7, 1935). She is up and about the house, does a small amount of shopping, walks in her garden, and has had no break in compensation. She has been kept on 0.1 gm digitalis daily. Her vital capacity before operation was between 900 and 1,100 c.c. Since operation, it has varied between 1,200 and 1,750 c.c. The electrocardiogram has not altered essentially. The blood velocity is slower, the venous pressure not appreciably different. The blood cholesterol reached a high of 205 mg per 100 c.c.

The patient was an intelligent Armenian, a writer, with marked emotional instability. For a year after operation, she believed that her writing was impaired by her lowered metabolism, this opinion being shared by an editor to whom she was accustomed to submit material. When her basal metabolism was raised to a level of minus 30 per cent she resumed her writing and the editor referred to said she wrote one of her best stories. It may also be said that her interest in her husband was revived as a result of her better physical health. She regards herself as having been strikingly benefited physically but believes she has been somewhat handicapped in her ability to write. She is on a maintenance dose of $\frac{1}{4}$ gr thyroid daily.

The follow-up results in this patient have been remarkably good. Bed-ridden for 18 months prior to operation, requiring paracenteses finally every three weeks,

conscious of her heart beat on the slightest movement, she became a woman able to carry on ambulatory activity without discomfort, being up five to eight hours daily. The signs of facial myxedema have been slight and the mental reaction to her operation has largely subsided. However, she has complained of pains in legs and feet for the past eight months. Noticeable crepitus on movement of the left knee-joint has appeared in the past four months.

Case 2 M M, female, aged 56

Personal History No rheumatic or luetic history. *P I* Ten years ago the patient was in the hospital for four months for cardiac insufficiency, she was discharged on digitalis, able to carry on ambulatory activity. Six weeks before the present admission, her abdomen began to swell, she became dyspneic and during the last three weeks before admission was confined to bed.

Physical Examination A slight, undernourished and pale cyanotic woman. Pitting edema over sacrum but not in legs. Lungs showed evidence of fluid at right base and moist râles over lower two-thirds of both lungs. Heart enlarged to left and right. Loud systolic and diastolic murmurs at apex. Heart fibrillating. Blood pressure 135/90 mm of Hg. Abdomen distended with fluid, and liver palpated below the umbilicus.

Laboratory Findings Hgb 82 per cent, rbc 4.2 millions, wbc 8,000, polynuclears 79 per cent. Serum protein 7.13 per cent. Electrocardiogram Auricular fibrillation, R_1 notched, T_1 inverted, T_2 and T_3 upright. Blood urea 32 mg per cent. Course After five months of routine hospital treatment, the patient was still bed-ridden, unable to regain sufficient compensation to be about in a chair. She was treated for three weeks in the oxygen chamber (oxygen concentration 50 per cent), and became free from dyspnea, orthopnea and heart consciousness. She was operated on while receiving oxygen through a nasal catheter, as outlined. She had scarcely any postoperative reaction (chart 3). She was removed from the chamber seven days after operation.

Basal metabolism dropped from minus 3 per cent before operation to minus 30 per cent one month later, finally falling to minus 42 per cent. Two months after operation the patient was able to walk slowly without dyspnea or heart consciousness. The liver was still palpable 8 cm below costal margin but there was no evidence of fluid or other sign of cardiac insufficiency. The venous pressure varied before operation from 260 to 53, after, from 175 to 57. The arterial oxygen saturation before operation was 93 per cent, after, 97 per cent. Vital capacity 1,375 before operation, after, 1,050 to 1,675 cc. Blood cholesterol increased to 264 mg per 100 cc blood. The blood volume was 4,600 before, 4,000 to 4,200 after operation (table 2).

The follow-up results in this patient were very good. She was able to go about, live in an apartment where she had to climb two flights of stairs, and felt comfortable and happy. Despite a basal metabolism that was approximately minus 40 per cent, she had little evidence of facial myxedema except an increased pallor and no distressing symptoms. Small doses of thyroid were given for a short time only, as they resulted in heart consciousness. She was nevertheless mentally alert. She was operated upon December 16, 1933. Except for a brief stay in the hospital in April 1935, for mild symptoms of cardiac insufficiency of five days' duration which quickly responded to rest in bed, she has been quite well. At the present writing (August 1935) she is ambulatory. Without thyroid medication her basal metabolism is minus 37 per cent.

Case 3 A S, female, aged 22

Personal History Patient had rheumatic fever with valvular heart lesion before age of ten. *P I* Four years ago, the patient developed symptoms of acute decompensation in the sixth month of pregnancy. After a rest period, Caesarian sec-

TABLE II

Case 2	Before Operation	After Operation	Remarks
Date	7-3-33 to 12-16-33	12-16-33 to 8-1-35	
Arterial oxygen saturation	93%	97%	Oxygen treatment in chamber, 50 per cent oxygen, was carried out for 3 weeks. Patient lost sensation of dyspnea while in oxygen chamber and was generally improved. Liver was still much enlarged. No fluid in pleural cavities. Data before operation obtained in 3 separate admissions for congestive failure, dyspnea being outstanding symptom. Nasal oxygen, 5 liters per minute, was given during operation. She was in oxygen chamber for 7 days following operation.
Hemoglobin	73 to 86%	74 to 95%	
Basal metabolism	-3%	-20 to -42%	
R B C millions per cu mm	4 0 to 5 0	4 0 to 4 8	
Vital capacity	1375	1050 to 1675	
Blood volume	4600	4000 to 4200	
Blood velocity (seconds)	49, 43, 34	41, 52, 25 5	
Venous pressure	260 to 53	175 to 57	
Arterial pressure	104/60 to 150/100	145/70 to 108/65	
Sedimentation rate	20 mm /1 hr		
Arterial CO ₂ vol per cent	47 0	42 4	
Blood cholesterol mg per cent		264	
Wt kg	42 7 to 48 2	44 to 47	
Pulse	42	60	

tion and sterilization were performed. Since that time she has been admitted to the hospital five times for cardiac insufficiency. Her present attack began two weeks before this admission with edema of ankles, tachycardia, and dyspnea. Eight days ago, coughing and orthopnea appeared.

Physical Examination A well-developed girl with a hacking cough, without dyspnea or cyanosis. Lungs contain a few râles at the bases. Heart greatly enlarged. Rhythm totally irregular. Systolic thrill and double murmur at apex, diastolic murmur at aortic area. Blood pressure 160/70 mm of Hg. Liver palpable 7 cm below costal margin. Edema of feet, ankles and sacrum.

Laboratory Findings Hgb 85 per cent, rbc 45 millions, wbc 7,600, polynuclears 72 per cent. Electrocardiogram Auricular fibrillation, T₁ and T₂ upright, T₃ diphasic.

Course At the end of two months in the hospital, the patient was compensated in bed. She was treated in the oxygen chamber (oxygen concentration 50 per cent) for seven days prior to operation and eight days after under the usual technic. The operation was attended by a minimal reaction. Her basal metabolism, which was plus 6 to minus 10 before operation, was minus 13 per cent on discharge four weeks later, ultimately declining to minus 25 per cent. Vital capacity varied between 1,200 and 1,800 before operation, 1,300 after (table 3).

TABLE III

Case 3	Before Operation	After Operation	Remarks
Date	1-30-34 to 4-3-34	4-3-34 to 12-12-35	
Arterial oxygen saturation	95%	96%	Patient in oxygen chamber, 50 per cent oxygen, 7 days before operation and 8 days after operation. She had 5 admissions for cardiac insufficiency during previous 4 years
Hemoglobin	74 to 90	65 to 86	
Basal metabolism	+6 to -10	-13 to -25	
R B C millions per cu mm	3 8 to 4 8	2 8 to 4 7	
Vital capacity	1200 to 1800	1300	
Blood velocity (seconds)	25	35	
Venous pressure	28	45	
Arterial pressure	105/70 to 160/70	105/65	
Sedimentation rate mm /1 hr	16 to 57	58	
Arterial CO ₂ vol per cent	55 1	48 5	
Blood cholesterol		217	
Wt kg	47 to 49	55	
Pulse	80 to 84	82 to 92	

For three months after operation the patient did well, when palpitation, dyspnea and pain over her heart recurred. Symptoms persisted for seven weeks when she entered the hospital. At this time her hemoglobin was 66 per cent, r b c 2 8 millions with numerous macrocytes. During the nine weeks in the hospital thyroid was first administered and subsequently liver and iron, the hemoglobin rising to 81 per cent and the r b c to 4 0 millions. Six months after discharge, she said she felt "fine" on ambulatory activity. Her basal metabolism was then minus 13 per cent on 1 grain of thyroid daily. She took 0 1 gm digitalis daily.

Symptoms of cardiac insufficiency recurred seven months later, necessitating readmission to the hospital. However, her basal metabolism had become elevated to plus 5 per cent, which obviously counteracted the effect of thyroidectomy. After four months' hospitalization, during which time thyroid administration was stopped, the basal metabolism dropped to minus 20 per cent and she gradually regained compensation (December 1935).

Although the results in her case were complicated by high thyroid dosage, the amount of work she was capable of performing in her periods of compensation outside the hospital was greater than that she was able to do prior to operation.

Case 4 J P, male, aged 51 years

Family History and Personal History Irrelevant. *P I* Patient began to have recurrent attacks of precordial pain radiating down left arm and dyspnea on exertion five years ago. Three years before the present admission he entered the hospital for alcohol injection. This resulted in a somewhat wider spacing of attacks but was followed by spinal pain and recurrence of anginal attacks. During this

period, he manifested considerable anxiety and depression, so that it was difficult to form a confident appraisal of the etiology of all his complaints

Physical Examination An obese, whispering, uncomfortable man sitting in bed, orthopneic and slightly cyanotic Pupils slightly irregular but reacted to light Heart greatly enlarged with P M I in sixth space, 15 cm from mid-sternum Sounds of poor quality Blood pressure 150/120 mm of Hg Radial artery thickened Lungs contained moist râles at both bases Abdomen Dullness in both flanks but no fluid wave or shifting dullness

Laboratory Findings Hgb 95 per cent, r b c 5 19 millions, w b c 8,600, polynuclears 75 per cent Urine, few granular casts Serum protein 7 per cent, non-protein nitrogen 36.4 Electrocardiogram sinus rhythm, R₁, R₂ notched, T₁, T₂ inverted, T₃ upright Indication of incomplete bundle branch block

Course After four weeks on the ward, thyroidectomy was performed He was in the oxygen chamber for eight days prior to operation and five days afterwards On removal from the chamber, he had a recurrence of chest pain, relieved by nasal catheter which was continued for three days His pain thereafter seemed to be definitely diminished However, the patient has done poorly Operated upon February 8, 1934, he was admitted twice during the following year, with slight congestive failure but mainly because of a depressed hopeless attitude He has spent all of his time in bed, both in the hospital and at home, complaining of weakness and recurrent chest pain Basal metabolism one year after operation was minus 28 per cent

It must be admitted that the operation did not justify itself in his case His anxiety state with persistent depression made it impossible to evaluate the results of the operation As seen in the table (table 4), the measurements recorded failed to give any evidence of improvement The venous pressure and blood volume tended to be higher after thyroidectomy, the arterial oxygen saturation only 1 per cent higher

TABLE IV

Case 4	Before Operation	After Operation	Remarks
Date	1-16-34 to 2-8-34	2-8-34 to 5-1-35	
Arterial oxygen saturation	92%	93%	Patient was in oxygen chamber 8 days before and 5 days after operation Recurrence of pain after removal from chamber was treated by nasal catheter for 3 days
Hemoglobin	103 to 113	85 to 115	
Basal metabolism	-2%	-14 to -27%	
R B C millions per cu mm	5.5 to 6.0	4.8 to 5.8	
Vital capacity	2400	2000 to 2700	
Blood volume	4144	5155	
Blood velocity		32 to 52	
Venous pressure	68	83 to 130	
Arterial pressure	152/100	136/92 to 178/128	
Arterial CO ₂ vol per cent	52.0	55.1	
Wt kg	73	72 to 74.3	
Pulse	80	74 to 80	

Case 5 W H, male, aged 51 years

Family History and Personal History Irrelevant *P I* For three years the patient has suffered from recurring, sharp, substernal and epigastric pain, radiating to back and down left arm, increasing steadily in severity and in the frequency of attacks. He had no orthopnea or ankle edema, but his illness prevented him from working for the past year and a half.

Physical Examination A well-developed pale man of 51. Fundi show slight narrowing of arteries. P M I 11.5 cm from midsternal line in fifth space. Sinus arrhythmia with numerous extra-systoles. Sounds distant. Soft, blowing systolic murmur at apex, loud rough systolic at aortic area. Radial arteries thickened. Blood pressure 145/90 mm of Hg. Liver edge felt 4 cm below costal margin.

Laboratory Findings Hgb 77 per cent, rbc 4.4 millions, wbc 6,100, polynuclears 67 per cent. Blood urea 46 mg per cent. Electrocardiogram. Ventricular premature beats, R_s notched, T inverted in all leads.

Course Patient was treated with 50 per cent oxygen in the oxygen chamber for nine days prior to operation and for 16 days after. The length of the postoperative oxygen treatment was due to the fact that the first attempt at lowering the oxygen concentration, on the fourth to the fifth day after the operation, was followed by rise in the pulse rate and recurrence of substernal pain. The second lowering of the oxygen concentration was uneventful. The operation resulted in a minimal reaction (chart 4 and table 5).

TABLE V

Case 5	Before Operation	After Operation	Remarks
Date	4-14-34 to 4-28-34	4-28-34 to 6-29-34	
Arterial oxygen saturation	96%	97%	Patient was in oxygen chamber 9 days before and 16 days after operation. First attempt at lowering oxygen concentration precipitated rise in pulse rate and recurrence of pain in chest, which was promptly relieved by raising oxygen concentration again to 50 per cent. Second lowering of oxygen concentration was borne without symptoms.
Hemoglobin	77 to 85%	83 to 85%	
Basal metabolism	+24%	-2 to -20%	
R B C millions per cu mm	4.5	4.1 to 4.7	
Vital capacity	2950	2500 to 2850	
Blood volume	5700	5000	
Blood velocity	25	25	
Venous pressure	10	25	
Arterial pressure	140/95	138/88 to 152/90	
Arterial CO ₂ vol per cent	48	55.3	
Pulse	108	68 to 100	

Before operation his basal metabolism was plus 24 per cent, during the five weeks after operation, his lowest basal metabolism was minus 11 per cent. During the last week he began to show improvement, with practically no discomfort on walking the hospital corridor. For one month after leaving the hospital, the patient did well, being able to walk 10 blocks without pain. Symptoms then returned worse than ever, and he reentered the hospital seven weeks after discharge. On this admission, his

CHART 4 Clinical chart showing reduction of pulse rate due to oxygen treatment, minimal postoperative reaction and elevation of pulse on first attempt to lower oxygen concentration

OPERATIVE PERIOD
CHART 4—Continued

POST-OPERATIVE PERIOD
 CURVE 4—Continued

blood count was lower, Hgb 70 per cent, rbc 3.5 millions. The electrocardiogram showed definite changes, the T waves in Leads I and II were more deeply inverted, T_1 diphasic, R_2 more notched. Blood cholesterol 208 mg per 100 cc. The lowest basal metabolism obtained was minus 20 per cent. Radiotherapy to the thyroid gland was begun. Four weeks after admission he began to have severe precordial pain at rest, unrelieved by nitroglycerine. His heart sounds became weak and he was placed in an oxygen tent, oxygen concentration 60 per cent. The next day he felt fairly well when suddenly he had a severe precordial pain and died almost instantly.

It was evident that thyroidectomy did not alter the progressive course of coronary sclerosis in this patient. Such improvement as took place was very temporary. At autopsy, a small nodule of hyperplastic thyroid was found, which accounted for the basal metabolism not reaching lower levels. However, since his preoperative reading was plus 24 per cent, a relative lowering of oxygen consumption did take place. Post-mortem examination revealed marked aortic stenosis with slight generalized coronary sclerosis.

Case 6 S S, male aged 57 years

Personal History Four years ago, the patient developed difficulties in urinating, and was treated two years later by supra-pubic prostatectomy. *P I* Three years ago, he began to be short of breath on exertion. Five months ago, he developed precordial pain on exertion. For four months he has suffered intermittent claudication in the legs. Three and one-half months ago, he went to bed for six weeks because of dyspnea and edema. Precordial oppression has frequently occurred while at rest, walking three blocks brought on pain in chest.

Physical Examination A plethoric, well-developed man of 57, somewhat orthopneic and dyspneic. Slight arterial tortuosity noted in fundi. Lungs, sibilant râles scattered throughout, with slight dullness at left base. Heart slightly enlarged. Systolic blow at apex. Radial artery sclerotic. No pulsation in dorsalis pedis or posterior tibial arteries. Blood pressure 160/90 mm of Hg. Varicose veins of legs. Liver edge palpable 3 cm below costal margin.

Course He was placed in an oxygen tent (oxygen concentration 50 per cent) and five hours later precordial oppression subsided. During a week in 50 per cent oxygen he had two minor attacks of upper precordial pain. On discharge his liver was not palpable and his lungs were clear.

One year later he was again admitted. In the intervening year symptoms of precordial pain had continued, brought on by walking one block, accompanied by dyspnea during the preceding three months. Lungs contained subcrepitant râles at both bases. The electrocardiogram now showed auricular fibrillation, T_1 and T_2 upright, S_3 notched. Heart little changed from previous admission. Blood pressure 170/100 mm of Hg. Liver 3 cm below costal margin. Blood urea 51 mg per 100 cc. He was kept in the oxygen chamber for one week prior to operation and six days after. His postoperative course after thyroidectomy was uneventful. His heart rate returned to sinus rhythm. He returned home three weeks after operation free from pain on mild exercise. Seven months later his electrocardiogram showed sinus rhythm, P_2 notched, S_2 notched, S_3 notched, T_1 and T_2 inverted and T_3 upright. Since the record taken on the previous admission, the T waves in Leads I and II had increased in amplitude and T_3 had become inverted.

His clinical course was characterized by severe facial myxedema which was uncomfortable enough for the patient to require thyroid extract, gr $\frac{3}{4}$ daily. When the thyroid dosage was raised to 1 grain daily, walking 15 blocks precipitated an attack of precordial pain for which he went to bed for two days. On his present dose of $\frac{3}{4}$ gr thyroid daily, he is able to walk 15 to 20 blocks without pain or dyspnea 16 months after operation. He does not feel strong enough to work. On limited ambulatory activity, he is comfortable. His face appears mildly swollen but

CHART 5 Clinical chart showing reduction of pulse rate due to oxygen treatment and elevation of pulse when oxygen was withdrawn

Citari 5—Continued

CHART 5—Continued

does not distress him. His blood pressure during the first two months after the operation was lower, 145/70 mm of Hg, but since then it has gradually become more elevated, from 195/125 to 200/130 mm of Hg. The laboratory data shown in table 6 reveal a slight increase in vital capacity, from 2,000 to 2,650 c c. The basal metabolism has been kept mainly at minus 35 per cent.

TABLE VI

Case 6	Before Operation	After Operation	Remarks
Date	8-9-34 to 8-21-34	8-21-34 to 10-1-35	
Arterial oxygen saturation	95%	98%	Patient was in oxygen chamber 7 days before and 6 days after operation
Hemoglobin	118		
Basal metabolism	+3%	-22 to -35%	
R B C millions per cu mm	6.8		
Vital capacity	2000	2650	
Blood volume	6180	6780	
Blood velocity	19	11	
Venous pressure	12		
Arterial pressure	180/100	136/58 to 200/130	
Arterial CO ₂ vol per cent	55.2	50.6	
Blood cholesterol		250	
Wt kg	66.8	66.4	
Pulse	72	44 to 80	

The patient feels much improved. He is quite philosophic about his inability to work, being content with a life of mild activity, supported by his son. The elevation of his blood pressure, particularly the diastolic, indicates that thyroidectomy has not arrested a pathologic circulatory process. On the other hand, it has made possible a comfortable existence. As a by-product of the operation, the symptoms of intermittent claudication have disappeared.

Case 7. Female, 43 years old

Past History. Irrelevant. *P. I.* Patient was well until six months ago when she began to have cough and shortness of breath on exertion. Her symptoms increased until she was confined to bed, one month after the onset of symptoms. In spite of digitalis and complete bed rest, she became progressively worse. Weakness and dyspnea continued with attacks of nocturnal dyspnea for which morphine was used. After four weeks of bed rest she was removed to the hospital and placed in the oxygen room at an oxygen concentration of 50 per cent.

Physical Examination. She was a chronically ill-looking woman sitting propped up in bed, pale without discernible cyanosis. Neck veins were moderately distended. There were dullness and diminished breath sounds and fremitus over the right lower lobe. Heart was enlarged 13 cm to the left and 5 cm to the right. A systolic murmur was heard at the apex. There were frequent premature beats. Blood pressure

130/80 mm of Hg The liver could be percussed as far as the umbilicus There was pitting edema over the sacrum and ankles

Laboratory Findings Hgb 90 per cent, rbc 4,500,000, wbc 7,400, polynuclears 76 per cent Blood NPN 35 mg per cent Electrocardiogram showed sinus rhythm, ventricular premature beats, P-R interval 0.16 sec, left preponderance, P notched in all leads, T_1 and T_2 inverted, T_3 upright Urine showed a heavy trace of albumin with an occasional hyaline cast Venous pressure 135

Course After entrance to the oxygen chamber the patient had no more attacks of paroxysmal dyspnea, and while at rest breathing was comfortable She was kept in the oxygen room for three and one-half weeks and then put on nasal oxygen for 10 days This was gradually reduced from five to one liter per minute before it was discontinued She lost approximately 15 pounds of edema She was allowed home and for a period of two months pursued mild ambulatory activities Then orthopnea, indigestion and slight shortness of breath recurred and she was admitted to the hospital to the oxygen room as a preparation for thyroidectomy Her vital capacity was 2,000 cc Basal metabolism plus 19 per cent Blood cholesterol 177 mg per cent Venous pressure 135 Blood pressure 140/100 mm of Hg On examination she had dullness and diminished breath sounds over the right lower lobe and pitting edema over the sacrum At the end of one week she was again entirely comfortable She was kept in the chamber for two more weeks, and after she was entirely free from symptoms of decompensation, she was operated on under nasal oxygen and returned to the chamber for one week She was given oxygen through nasal catheter for one more week, and left the hospital two weeks later She had a minimal postoperative reaction

Vital capacity on discharge was 2,800 cc Basal metabolism plus 1 per cent four and one-half weeks after operation and minus 8 per cent six months after operation Venous pressure before discharge, 45

This patient on her first admission showed a striking improvement on transfer to the oxygen chamber, especially characterized by prompt disappearance of paroxysmal dyspnea That improvement was not longer maintained seemed unusual in a case of arteriosclerotic heart disease When she was again put in the oxygen chamber, compensation was rapidly regained In the six months that have elapsed since operation, she has been very comfortable on mild activity, and says she feels like a new woman She has appeared definitely to benefit from the thyroidectomy, although the basal metabolism has only been reduced from plus 19 per cent to minus 8 per cent

An abductor paralysis of both vocal cords has, however, given her a husky voice which has persisted since operation

Case 8 Female, aged 46

Family History Two members of the family have had rheumatism *Personal History* Irrelevant *P I* At age of 33 the patient had her first attack of rheumatism Six years later she had a second attack at which time she developed cardiac symptoms For the past three years she has had shortness of breath, orthopnea, rapidly recurring ascites, finally requiring paracentesis every few weeks, frequent hydrothorax and persistent ankle edema

Physical Examination A chronically ill negress with edema of ankles and sacrum Chest shows right hydrothorax and moist râles at both bases Heart is markedly enlarged both to right and left with signs of mitral stenosis and insufficiency and aortic and tricuspid insufficiency Blood pressure 120/60 mm of Hg Abdomen distended with fluid Liver down 4 cm below costal margin

Laboratory Findings Hgb 92 per cent, rbc 5 millions, wbc 8,900, polynuclears, 62 per cent Venous pressure 278 Vital capacity 750 Serum protein 63 per cent NPN 32 mg per cent Electrocardiogram shows auricular fibrillation, left preponderance, R_1 and R_2 notched, T_1 and T_2 isoelectric, T_3 upright

Course She was put in the oxygen chamber for one week prior to operation and for three days after operation. She had a minimal postoperative reaction. Basal metabolism plus 5 per cent before operation, minus 23 per cent 23 days after operation, minus 35 per cent eight months after operation. Venous pressure 278 on admission, and 158 twenty-three days after operation. During the following eight months the patient has felt better and able to do definitely more than formerly, but recurring ascites has required paracenteses at intervals of 10 days to three weeks.

Case 9 Male, 60 years old

Past History Spontaneous pneumothorax 18 years ago. Questionable history of coronary occlusion 12 years ago. *P I* Hypertension discovered 10 years ago. Four years later he began to have paroxysmal difficulty in breathing at night, gradually increasing in frequency and severity. Three months ago patient had a severe attack of nocturnal dyspnea, and examination at that time showed definite heart failure. Apex rate 90, blood pressure 170/100 mm of Hg, many premature beats. Liver palpable below the costal margin. Lungs showed moist râles at both bases. Two months ago dyspnea increased, and he complained of severe pain in the left arm. Electrocardiogram showed right bundle branch block, marked slurring and notching of QRS complexes, diphasic T waves and many premature ventricular beats. Blood urea 62 mg per cent. Basal metabolic rate plus 12.

Physical Examination The patient showed marked dyspnea, at times gasping. His breathing was distinctly more comfortable while he was in the oxygen chamber (oxygen concentration 50 per cent). He spent 19 days in the chamber, and for 11 days after this was given oxygen by nasal catheter. Thoracenteses were repeatedly necessary, 1,800 c c of fluid being aspirated during this period from the right chest. Salyrgan was given at frequent intervals without restoring compensation. The patient was replaced in the oxygen chamber for three days and then operated on, remaining in the oxygen chamber for eight days after operation. He had a slight postoperative reaction.

The vital capacity was 800 to 900 before oxygen treatment, rose to a high of 1,350 before operation and was 1,150 after operation. Venous pressure before operation was 45, velocity of blood flow 45 seconds (Decholin). Salyrgan and thoracenteses continued to be necessary after operation and the patient showed no improvement. Four weeks after the operation, he died of bronchopneumonia.

In this patient with maximal cardiac failure, thyroidectomy appeared to be of no benefit. The progressive nature of the pathologic process was uninterrupted by the attempt made to lessen the work of the heart.

Case 10 Female, aged 65

Family History and Past History Irrelevant. *P I* Sixteen years ago, the patient began to suffer from attacks of pain in left arm, shoulder and precordium, at first induced by walking, later by changing from a warm to a cold room, and finally occurring at rest. During the week of admission, she had one severe attack with marked air-hunger and tachycardia.

Physical Examination The patient was a well-developed, well-nourished woman of 65, sitting quietly in bed, without dyspnea, cyanosis or orthopnea. Her heart was slightly enlarged, and the aortic arch on roentgen-ray appeared to be moderately dilated. No peripheral edema. Blood pressure 200/108 mm of Hg.

Laboratory Findings Electrocardiogram T_1 and T_2 inverted, T_3 upright, left preponderance. Basal metabolism minus 9 per cent. Vital capacity 2,200 c c. Arterial oxygen saturation 95 per cent.

Course She was placed in the oxygen chamber for six days before operation and six days after. As indicated by chart 4, her pulse rate was substantially reduced during the period following admission to the oxygen chamber. She had a minimal postoperative reaction. There was an elevation of the pulse rate when oxygen was

discontinued Three days after leaving the chamber she was anxious to be out of bed She was discharged, free from pain, one week later She has been well since operation

In this patient, freedom from precordial pain was secured following thyroidectomy Despite her long history and her age, she withstood the operation extremely well She is in apparently good condition 13 months after the operation, except for the development of severe joint pains having the appearance of chronic arthritis

Case 11 Male, aged 59

Family History and Past History Irrelevant *P I* Nervousness and dyspnea began two and one-half years ago A diagnosis of hyperthyroidism was made but the patient refused operation Since that time, dyspnea has become worse, with increasing palpitation and ankle edema Two weeks prior to admission, following a sore throat, the patient became orthopneic and was confined to bed

Physical Examination Acutely ill man of 59 years, orthopneic and cyanotic, with massive edema of extremities Thyroid diffusely enlarged Lungs contained moist râles at both bases Heart greatly enlarged to left, sounds rapid, systolic murmur at apex Blood pressure 110/60 mm of Hg Liver felt 5 cm below costal margin

Laboratory Findings Hgb 92 per cent, rbc 5.3 millions, wbc 10,000, polynuclears 74 per cent Non-protein nitrogen 40 mg per cent Venous pressure 265 Electrocardiogram Auricular fibrillation, left preponderance

Course On rest in bed, nasal oxygen, morphine and digitalis he improved rapidly The basal metabolic rate was found to be plus 50 per cent On Lugol's solution for one week, the basal metabolic rate dropped to plus 17 per cent A partial thyroidectomy was performed under the same conditions as in the previous cases, with nasal oxygen and local anesthesia, the patient having been kept in the oxygen chamber for five days before and five days after operation He had very little postoperative reaction The basal metabolic rate 18 days after operation was plus 1 per cent He was discharged, ambulatory and improved Fibrillation with a slow ventricular rate was present

This was the only patient in the series in whom a partial thyroidectomy was done The symptoms of cardiac failure were precipitated by hyperthyroidism and it was felt that reduction to a normal oxygen consumption would be adequate to restore compensation The smooth postoperative course in this type of case, cardiac failure with hyperthyroidism, was not dissimilar to that seen in the cases of heart disease recited above

Case 12 Female, aged 30

Family History Grandmother had rheumatism *Past History* Pneumonia at four years, scarlet fever at six years, no rheumatic fever, chorea at six years *P I* At the age of 15, patient first noticed palpitation of the heart on exertion, accompanied by shortness of breath Four years ago increasing dyspnea took place, and one year later she entered the hospital because of cardiac insufficiency Patient improved but never became free from edema, dyspnea on slight exertion and a swollen abdomen A second admission became necessary on June 18, 1935, because of increasing orthopnea and swelling of the legs and abdomen

Physical Examination A thin, poorly developed negress, moderate orthopnea and dyspnea, doubtful cyanosis Lungs Dullness and diminished breath and voice sounds, with moist râles at both bases posteriorly Heart Greatly enlarged, dullness at base 8 cm, in the fourth interspace to the right 5 cm, 13.5 cm to the left in the fifth interspace, rhythm totally irregular, systolic and diastolic murmurs at the apex, a diastolic and rough systolic murmur at the aortic area, blood pressure 130/60 mm of Hg Abdomen tense and full with a fluid wave, liver palpable at the level of the umbilicus, spleen felt at the costal margin

Laboratory Findings Hgb 75 per cent, rbc 4.2 millions, wbc 8,700, polynuclears 75 per cent Non-protein nitrogen, 26 mg per cent, serum protein 5.9 per

cent Venous pressure 270 to 310 Electrocardiogram Auricular fibrillation, ventricular rate 50, left preponderance, T_1 upright, T_2 and T_3 inverted Basal metabolic rate plus 8 per cent

Course Patient was treated in the hospital with rest in bed, digitalis and salyrgan for four months, when thyroid ablation was decided upon At this time her vital capacity was 1,150 c c , pulmonary ventilation 62 liters per minute, arterial oxygen saturation 91 per cent, circulation time 40 seconds (by sodium cyanide method) Patient was placed in the oxygen chamber for two and one-half weeks prior to operation, which was done under oxygen and local anesthesia In this patient, the only one of the series, a postoperative reaction took place, the temperature rising to 103.6° F and pulse from 62 to 96 on the day following the operation, returning to normal on the third day postoperatively The patient was removed from the oxygen chamber six days after operation

Four weeks after operation the patient no longer experienced any heart consciousness However, she began to accumulate fluid in the abdomen again and required salyrgan The basal metabolic rate at that time was minus 21 per cent

This patient represents a case of cardiac insufficiency that was not compensated by rest in bed Although she had a febrile postoperative reaction, the behavior of her heart was at no time embarrassed The patient did not make any substantial improvement and died six months later of congestive failure

DISCUSSION OF RESULTS

In presenting 12 cases of thyroid ablation in patients suffering from heart disease, we wish to formulate no general conclusions concerning the value of the procedure nor of the special use of oxygen therapy in conjunction with it Our intention is rather to discuss the results of our experience as a guide to further work in the treatment of cardiac disorders

That no mortality occurred as a result of operation cannot in such a small series be ascribed to the use of oxygen or to the skill of the surgeon However, in some instances maximally severe cases of congestive heart failure were chosen, patients who had been bed-ridden five to 18 months, who were brought to an operable stage without manifestations of cardiac insufficiency by residences in a 50 per cent oxygen atmosphere The severity of congestive failure may be estimated by the marked reduction of the vital capacity in five of our patients who at some time before operation showed the following readings case 1, 900 c c , case 2, 1,100 c c , case 8, 750 c c , case 9, 800 c c , case 12, 1,100 c c In the series of Blumgart and his collaborators, the lowest vital capacity among 31 cases tested preoperatively was 1,350 c c * In their review of 18 months' experience with thyroid ablation, they report that in 60 cases of congestive failure six have died since operation and six died operative deaths, i e , within the first three days after operation Their operative mortality was then 10 per cent They state that all deaths occurred in patients in congestive failure at the time of operation Our own series is too small to make statistical comparison with theirs We wish merely to point out that our interest has centered chiefly in cases in whom compensation in room air under conditions of ambulatory activity could not be obtained, the severity of whose condition is in some instances revealed by the low level of their vital capacities (table 7) We

* Personal communication

TABLE VII
Summary of Clinical Data in 12 Patients with Cardiac Insufficiency on Whom Thyroid Ablation Was Performed

Case	Age	Sex	Diagnosis	Arterial Oxygen Saturation	Vital Capacity	Venous Pressure	Basal Metabolism	Con-gestive Failure	Car-diac Pain	Outcome
1	34	F	Rheumatic valvular heart disease, cardiac insufficiency, ascites	94	900-1100	130-153	-13	4+	0	Marked improvement
2	56	F	Rheumatic valvular heart disease, cardiac insufficiency, ascites	93	1100-1375	260	-3	4+	0	Marked improvement
3	22	F	Rheumatic valvular heart disease, cardiac insufficiency	95	1200-1800	28	-10	3+	0	Moderate improvement
4	51	M	Arteriosclerosis, coronary sclerosis	92	2400	68	-2	2+	3+	No improvement
5	51	M	Arteriosclerosis, coronary sclerosis, aortic stenosis	96	2950	10	+24	0	4+	No improvement, death four months postop
6	57	M	Arteriosclerosis, coronary sclerosis, hypertension	95	2000	12	+3	1+	3+	Moderate improvement
7	43	F	Arteriosclerotic heart disease, cardiac insufficiency	—	2000	135	+19	2+	0	Moderate improvement
8	46	F	Rheumatic valvular heart disease, cardiac insufficiency, ascites	—	750	278	+5	4+	0	Moderate improvement
9	61	M	Arteriosclerosis, coronary sclerosis, hypertension, emphysema, cardiac insufficiency	—	800-900	45	+12	4+	2+	No improvement, death one month postop
10	65	F	Arteriosclerotic heart disease, coronary sclerosis	95	2200	—	-9	0	4+	Moderate improvement
11	59	M	Hyperthyroid heart, cardiac insufficiency	—	—	265	+50 to +17	3+	0	Moderate improvement
12	30	F	Rheumatic valvular heart disease, cardiac insufficiency, ascites	91	1150	310	+8	4+	0	Minimal improvement, died 6 months later

wish to draw attention to the fact that preoperative oxygen treatment was employed to increase the efficiency of the circulation, that oxygen was used during and after the operation to prevent anoxemic shock, and finally that under these circumstances there was little or no postoperative reaction, as revealed by the clinical condition of the patients and the charts of their pulse, respiration and temperature. It seemed likely to us, as a result of an experience with an admittedly small number of patients, that the very severe case of congestive failure in whom an operative mortality of some degree might otherwise be expected could with the employment of this program of preoperative and postoperative treatment be more safely conducted through the procedure of thyroid ablation. Furthermore, our impulse to utilize thyroidectomy was in the main directed toward this type of case. In two instances, in which prolonged oxygen treatment did not achieve a satisfactory state of compensation, the majority opinion decided against thyroidectomy. In most of the cases, the favorable effect of oxygen treatment was apparent, especially by the lowering of the pulse rate before operation and its elevation when oxygen treatment was discontinued after the operation, examples of which occur in the charts presented. In addition, the scarcity of the symptoms of postoperative reaction impressed us.

The beneficial effect of oxygen therapy immediately following major surgical operations has been reported by Boothby and Haines,²² Binger, Judd, Moore and Wilder.²³ Judd²⁴ has already observed, "We feel there can be no question that the use of oxygen postoperatively has a definitely favorable effect on the prevention and treatment of pulmonary edema and congestion. In our opinion, we have materially reduced the incidence of postoperative pneumonia since using oxygen therapy freely following major surgical procedures."

In presenting this communication, we wish to record mainly the clinical data which we observed, the opinions we derived from them are tentative and must await a longer period of trial before we can accept them as established conclusions.

In viewing the results of thyroidectomy itself, we have been especially struck by the improvement in two maximally severe cases of congestive failure, numbers 1 and 2, both due to rheumatic heart disease. In these cases, the change from a bed-ridden existence to one of ambulatory activity was striking and could be distinctly ascribed to thyroid ablation. In neither of the patients was clinical myxedema a troublesome feature. In another case of severe congestive failure, number 8, the time interval has been too short to permit prediction of her ultimate improvement. She is subjectively considerably improved. The vital capacity has increased from 750 c c to 1,200 c c. The venous pressure has fallen from 250 to 97. Paracentesis of the abdomen has been reduced from once a week to once in two weeks. The result in case number 3, one of congestive failure of more

moderate degree than the three above mentioned, is not striking, but it can be safely said that some improvement in the function of her circulation has occurred and that subjectively she is better than prior to operation. The patient whose congestive failure was associated with hyperthyroidism, number 11, is much improved, as might be expected. He was included in the series because he was subjected to the same program of oxygen treatment in association with thyroidectomy. The case of congestive failure, number 9, in whom coronary arteriosclerosis was at the basis of his heart disease, was unimproved, and died one month after operation. His failure was progressive from the time of entrance to the hospital and was uninfluenced by thyroid ablation. The sixth case of congestive failure, number 7, was one of moderate severity. She has been subjectively improved and is able to carry on distinctly increased ambulatory activity since the operation, but the time interval that has elapsed is too small for more to be said than this. The seventh case of congestive failure, number 12, became free from heart consciousness but no substantial improvement took place and the patient died six months later of congestive failure.

There remain four cases in which operation was performed for cardiac pain in the absence of congestive failure. In two, cases 6 and 10, relief from pain was definite, the patients themselves were pleased with the results of the operation and the procedure could be said to have justified itself. The occurrence of severe facial myxedema in one, case 6, ultimately ameliorated by thyroid extract, for a time clouded the patient's satisfaction with the relief of his heart pain. In the remaining two cases, an unsuccessful result was obtained. In one of them, case 4, the patient had a psychoneurosis sufficiently severe as to obscure any benefit he might have received. He did not appear to be subjectively or objectively improved. In the other, case 5, a temporary period of improvement was followed by a progressively severe course ending in death. It should be mentioned in his case that the basal metabolism did not go below minus 20 per cent, and that at autopsy a nodule of hyperplastic thyroid tissue was found. In addition to arteriosclerosis he had a marked aortic stenosis. The other three cases of cardiac pain were presumably cases of coronary arteriosclerosis.

The laboratory data submitted in the tables do not require detailed comment. The blood cholesterol was elevated after thyroidectomy, which is in accord with the careful studies on this point by the original authors²⁵. The oxygen saturation of the arterial blood in the cases studied was either slightly lowered or normal. The venous pressure and vital capacity measurements indicate the severity of congestive failure in the individual cases. The blood volume in two cases was reduced after thyroidectomy, suggesting lessened work for the heart. The vital capacity was moderately increased in some cases, although this was not a marked or consistent outcome. The red blood cells tended to show a decrease of a half million to a million cells, with pro-

portionate decrease in hemoglobin, as previously mentioned by Blumgart and his collaborators. The venous pressure was definitely decreased in some patients, uninfluenced in others.

COMMENT

We are unable to formulate any firm indications for thyroid ablation in the treatment of heart disease, our own experience is too limited and the total lapse of time since the procedure was inaugurated is too brief to permit of final judgment. Nevertheless, we did select the cases that make up the present report with certain principles in mind.

The patient with congestive failure who was bed-ridden all the time, or most of the time, became a potential candidate for thyroidectomy. Also, when the periods of compensation in a patient were very brief, such as a matter of a few months, we regarded these recurring attacks of cardiac insufficiency as indicating a very small cardiac reserve. In other words, the procedure seemed justified when little expectation of comfort could be expected without it.

In the cases with cardiac pain, the existence of unrelieved, severe, frequent pain over the heart raised the question of thyroidectomy. In both groups of cases, the presence of a stationary lesion, rheumatic or arteriosclerotic, increased the indication for operation. Cases that appeared to regain a somewhat stable compensation on oxygen therapy alone were not subjected to thyroidectomy.

We accepted certain contraindications such as a basal metabolism under minus 15 per cent, the presence of nephritis, advanced age—over 75 years—or too youthful an age, such as before puberty. Also, we have avoided choosing patients with syphilitic heart disease, since the pathological process in these cases might be expected to advance despite the production of a lowered oxygen consumption. In addition, we believe the patient should be brought into a state of relative cardiac sufficiency before operation. Oxygen therapy was specially used for this purpose. It was not demanded that these patients should be able to be compensated in room air. Our belief was that if they could be brought to a state of relative cardiac sufficiency in an oxygen chamber, the operation could then be performed with the patients compensated, even if the inhalation of oxygen-enriched atmospheres was necessary for the maintenance of compensation, the fact that the operation was done while oxygen inhalation was still being continued removed the danger of anoxic shock. It is true that a sudden removal from a high oxygen environment to that of atmospheric air may precipitate cardiac collapse in severely ill patients. However, the method here pursued was to avoid any interruption of oxygen therapy until a safe period following the operation appeared. The subsequent reduction in cardiac work then

allowed the patient to pursue an ambulatory existence without the help of oxygen therapy, as was illustrated by the two severe rheumatic cases of congestive failure in our series

In the case of angina pectoris, we would now feel doubtful about selecting patients who had such severe coronary artery disease as to suggest an advancing process. The clinical course of these patients is difficult to predict, but in so far as it is possible to do so, the patient with very troublesome pain but with little evidence of progressive coronary disease, would appear a more justifiable candidate than one with very marked and probably advancing coronary changes. In this group, the danger of cardiac failure attending the operation is less real than in the congestive failure patient who is unable to be compensated out of a bed, although postoperative deaths have been reported in this group (Cutler²⁶). We adopted a practice of employing oxygen in these cases also, using a smaller preliminary period of treatment. Doubtless, many of these patients would have gone through the operation without reaction. However, anginal pain is itself a result of anoxemia of the heart muscle, and in many cases can be relieved by inhalation of oxygen^{1d}. In two of our cases, anginal pain and increased pulse rate recurred four days after the operation when the oxygen concentration of the chamber was lowered and disappeared with elevation of the oxygen concentration. The presence of anemia increases the indication for oxygen treatment in this group*. During a period of stress which an operation induces, the inhalation of oxygen would tend to counteract the development of oxygen debt and therefore tend to maintain the efficiency of the circulation. In patients with anginal pain without congestive failure, the use of oxygen treatment according to the program outlined would therefore appear to be helpful, although not as valuable a procedure as in the patient whose cardiac insufficiency is an immediate problem.

SUMMARY

In 12 patients a program of preoperative, operative and postoperative oxygen treatment has been employed as an adjuvant to ablation of the thyroid gland in cases of heart disease. In patients with congestive failure, their circulation efficiency was improved by the preoperative period of residence in an oxygen chamber. During the operation itself and for a time following it, oxygen therapy tended to prevent the development of oxygen debt and anoxic shock. Charts showing the effect of oxygen treatment and the absence of severe postoperative reactions have been drawn up. There were no operative deaths.

* Pickering and Wayne²⁷ reported observations on a series of 25 patients with anemia, eight of whom complained of pain over the sternum induced only by exercise and relieved by rest, in which this pain was no longer experienced after the anemia had been cured, while in two it persisted. The authors concluded from their experiments that the essential factor in the production of anginal pain in anemic patients is a diminished supply of oxygen to the working cardiac muscle and not an inadequate flow of blood.

The physiological effects of oxygen therapy in cardiac decompensation have been reviewed. Its helpfulness in this condition has added further evidence in support of our belief in the value of this form of therapy.

The results of thyroidectomy have been commented upon individually in this study without attempting to formulate firm conclusions. Our interest has been aroused chiefly in severe cases of congestive heart failure of rheumatic etiology in the absence of an active rheumatic process. In two cases of this type followed for a period of over two years, the gain of cardiac efficiency has been striking. The treatment of angina pectoris by thyroidectomy seems to us more wisely restricted to those patients who have troublesome anginal pain in the absence of clinical and electrocardiographic evidence of an advancing sclerosis of the coronary artery. In two cases of this type the clinical betterment which ensued completely justified the operation. Three patients, two with cardiac pain and one with congestive failure and cardiac pain, were not helped. One case of congestive heart failure was not improved and died six months later. The remaining four were improved, the time elapsing since operation being insufficient to permit giving a reliable estimate of the degree of benefit.

THE THERAPEUTIC ACTION OF THE NUCLEOTIDES, THE TREATMENT OF THE WHOLE BLOOD PIC- TURE WITH FERROUS ADENYLATE*

By SIMON L. RUSKIN, M D , and ELIHU KATZ, M D , *New York, N Y*

SINCE Rothmann, in 1931, showed that the hemoglobin percentage and the red cell count in a series of patients suffering from widely different diseases bore a fairly constant relationship to the amount of adenylic nucleotide in the blood, there has been a progressively increasing interest in the physiologic rôle of adenylic acid. The *Annual Review of Biochemistry* lists 114 separate papers in one bibliography. In the light of recent investigation, this study has become all the more interesting because of the general enthusiasm which first greeted nucleic acid therapy twenty years ago, and its subsequent failure to materialize. The explanation for this, apparently, lies in the fact that nucleic acid is composed of two groups of nucleotides representing physiologic antagonists in equal amounts and is thus relatively inactive. The prediction of our former teacher, Prof. John Mandel, that the unlocking of nucleic acid would usher in a new era of physiologic chemistry, appears to be approaching realization.

It is well for us to consider, briefly, the formation of nucleic acid before studying the characteristics of the nucleotides which form it.

Nucleic acid when conjugated with albumin or globulin forms a nucleoprotein. As a rule the protein elements may change with the different tissues where the nucleoprotein is formed but the nucleic acid radicals are relatively constant.

Nucleic acid is composed of four nucleotides, two of which are purines, having as the nitrogen containing base adenine and guanine respectively. The other two nucleotides are pyrimidines having the nitrogen containing bases thymine and cytosine. In plant nucleic acid instead of thymine we have uracil.

All four nucleotides have a common structure, thus, the base is united with a glucoside which, in animal nucleic acid is D-ribose, as well as to phosphoric acid.

Thus a picture of nucleic acid, according to Dr. P. A. Levene, is as follows:

* Read in part at the American Chemical Society Meeting at St. Petersburg, Florida, 1933. Received for publication November 27, 1935.

If we group the nucleotides in respect to their physiologic action, we get a schematic arrangement as follows

ANALYSIS OF NUCLEOTIDE ACTION

NUCLEIC ACID

Adenine Nucleotide

Guanine Nucleotide

Purine structure resembling
caffeine, etc

Stimulative

- 1 Stimulates reticulo-endothelial system, and induces leukocytosis
- 2 Increases coronary circulation
- 3 Participates in carbohydrate metabolism
- 4 Participates in muscle metabolism
- 5 Acts as a coenzyme
- 6 Is a glandular stimulant

Cytidilic Nucleotide

Uridylic Nucleotide

Pyrimidine structure
resembling phenobarbital

Depressive

- 1 Precipitates toxins and binds toxalbumin
- 2 Induces leukopenia on injection
- 3 Inhibits bacterial growth
- 4 Is antiseptic in stronger dilutions
- 5 Acts like barbiturates on metabolism

It can therefore be readily seen that, in dealing with the individual nucleotides, we are working with substances radically different from the larger molecule, the nucleic acid. The situation may be considered as analogous to the relationship which coal tar bears to its various physiologically active fractions. This fractionation of nucleic acid has made available a new series of physiologic agents. The isolation of the nucleotides is both costly and difficult, but the value of separating these constituents of nucleic

acid was well pointed out by Doan who states that, "The definite and usually considerable leukocytosis that followed the intravenous injections of relatively large doses (1 gm of sodium nucleinate), in their series of normal rabbits, was proved to be of unquestionable bone marrow origin. However, a preliminary leukopenia occurred, sometimes lasting for a number of hours before the peripheral leukocytosis was observed, an obviously undesirable phase in the reaction

It was then determined to see whether this 'active principle,' affecting the myeloid foci in bone marrow, might not be contained in some of the degradation products of nucleic acid, as distinct from the accompanying leukopenia producing factor of the larger molecule. Chemically pure crystalline adenylic and guanylic acid were later tested. These products all gave an immediate neutrophilic response without preliminary leukopenia which recommended them as preferable to the larger nucleinate molecule for clinical use."

Of the four nucleotides, the adenine nucleotide, adenylic acid, has received the greatest amount of attention. Rothmann has shown that there is a direct correlation between the adenine nucleotides and the erythrocyte count and the hemoglobin percentage. This correlation holds in the various conditions ranging from severe anemia to polycythemia. The influence of adenylic acid on the circulation is further shown by the work of De Caro who demonstrated that adenylic acid isolated from yeast nucleic acid (1) lowers the blood pressure, (2) abolishes motility of the intestine, and (3) produces bradycardia. These effects are independent of the sympathetic and para-sympathetic innervation since they are observed in the same degree after the administration of atropine or ergotamine. Similar observations were made by Bennet and Drury whose investigations revealed that adenylic acid is a constituent of many tissues, being found in great amount in striated and heart muscle. It is apparently liberated from injured tissues and may be a contributing factor in inflammations and traumatic shock. The biologic effects of adenylic acid have been found to be identical with those of adenosine, in that (1) the blood pressure is lowered, (2) the vessels of the perfused rabbit lung are constricted, (3) the isolated virgin guinea pig uterus is caused to contract and (4) in that a general leukocytosis may be produced. Drury, furthermore, found that in the perfused rabbit heart, the addition of either guanylic or adenylic acid leads to a brief primary decrease followed by a prolonged increase in the amplitude of the mechanogram. He did not find adenine or guanine to have such influence and concluded, therefore, that the nucleic acid derivatives which contain a phosphoric acid grouping were capable of producing the change.

This is, however, somewhat at variance with the observations of Drury and Weeds on the influence of adenosine in dilating the coronary arteries of the heart. They showed that yeast or muscle adenylic acid have about 66 per cent of the effect of adenosine, whereas inosinic acid, adenine, guanosine,

and sodium nitrate were about 33 per cent as effective as adenosine. Thymus and yeast nucleic acid have an inconstant effect. A slight constriction is occasionally produced. These conclusions are further corroborated by Weld, who found that adenosine caused marked dilation of the coronary vessels, being twenty times as powerful as sodium nitrate. Adenylic acid (yeast or muscle), adenine, or guanosine also dilated the coronary vessels but were not as effective as adenosine.

Among the earlier investigations of the nucleotides, adenylic and guanylic acid, is that of Rosenfeld who found, upon the injection of these acids in the form of the sodium salts, an increase in the uric acid and total nitrogen of the urine. This increase in total nitrogen was greater than the nitrogen contained in the injected substances, while the increase in uric acid was only 10 per cent of the value calculated for the complete conversion of the purine. It is not unlikely, therefore, that the effect on the composition of the urine is explained, in part at least, as due to an increased metabolism and increased glandular activity.

The occurrence of adenylic acid and its isolation from the blood were demonstrated by Hoffman, Jackson, Buell and Perkins. Its presence in and isolation from milk has been proved by Kay, from brain by Pohle, from muscle by Ostern and from kidney by Embden.

How significant a rôle adenylic acid plays in the normal metabolism is gleaned from its relationship to carbohydrate metabolism. The investigations of Myrbock and Euler have shown that cozymase activity is associated with a nucleotide which, in certain respects, resembles muscle adenylic acid. It has not been obtained in crystalline form, nor has a crystalline salt been prepared from it. Studies of the rate of hydrolysis show that this nucleotide belongs to the same group as inosic acid and muscle adenylic acid, but it is clearly distinguished from the adenosine phosphoric acid obtained from yeast nucleic acid.

That adenylic acid plays an important rôle in metabolism is further substantiated by the observations of Lehmann who showed that the esterification with trihydrogen phosphate through the lactic acid enzyme system proceeds only in the presence of adenylyl-pyrophosphate plus magnesium. He showed that frog muscle extract loses its ability to hydrolyze glycogen after standing at 20° for two to three hours. Adenylyl-pyrophosphate isolated from a fresh muscle can completely restore this lactic acid forming ability to the inoculated extract. Myerhof, Lohmann and Meyer have also demonstrated that the lactic acid forming system of muscle or muscle extracts consists of the thermolabile enzyme and the thermostable coenzyme. The coenzyme must consist of an autolysable and non-autolysable fraction. The former is the adenylyl-pyrophosphate. The complement of the coenzyme present in autolyzed boiled juice is the magnesium. Therefore, the magnesium salt must be added besides the adenylyl-pyrophosphate to completely

restore its lactic acid forming ability From these considerations it is concluded that the system,

- (1) inorganic phosphate,
- (2) adenylypyrophosphate,
- (3) and the magnesium,

constitutes the coenzyme of lactic acid formation

Jacobson has in addition shown that an enzyme liberating trihydrogen phosphate from adenylypyrophosphate is present abundantly in the liver and to lesser extent in the kidney Evidence is presented for considering this enzyme as distinct from other phosphatases

Euler and Myrbock define cozymase as that substance which brings about the typical carbohydrate cleavage in an otherwise inactive mixture of sugar, phosphate, zymphosphate, apozymase, and magnesium salts They found that the purest preparations of this consisted almost entirely of a substance closely related to adenylic acid (muscle) The close relationship of cozymase to adenylic acid was also demonstrated in an interesting manner by Svengard who showed that injections of cozymase into the jugular vein of rabbits under Wrettan narcosis caused a lowering of blood pressure This effect was independent of the specific action of the cozymase, since inactivation of the coenzyme by heating did not interfere with the lowering of the blood pressure Pure adenylic acid of yeast is somewhat more active in this respect, possibly because of the fact that the cozymase is not an entirely pure adenylic acid The introduction of the thio-methyl group into the adenosine molecule apparently does not diminish this special action The action of cozymase in lowering the blood pressure is a non-specific effect of the adenylic acid or the homologous adenosine derivatives This is further corroborated by Zipf in his observations with muscle adenylic acid

Not only do we find adenylic acid playing an important rôle in carbohydrate metabolism, but it is no less significant in its influence on muscle metabolism Thus, Schmidt showed that it undergoes enzymic deamination when treated with the pulp or press juice from rabbit muscle The free purine on the other hand remains practically unaltered when subjected to this treatment Likewise, Embden and Wassermeyer performed experiments which proved that the source of the ammonia in muscle contraction is from the NH_2 group in adenosine phosphoric acid The influence of adenylic acid during muscle contraction has been carefully studied by Embden and Lehnartz who found the amounts of free pentose and pentoside in muscle increased following contraction, which indicated that the increased phosphate regularly observed was liberated from an adenylic acid complex Many authors further suggest that in the recovery period of muscle contraction the pyrophosphoric acid is resynthesized both from the free trihydrogen phosphate and the split off product of adenylic acid For confirmation, they point to the increase of free pentose during the two hour recovery period of fatigued muscle

These studies of the purine nucleotides thus reveal the beginning of an analytic break-up of nucleic acid into a series of substances possessing independent properties in balanced systems not yet completely revealed. From the physiologic standpoint the separation of the purine from the pyrimidine nucleotides makes a radical difference in availability, for, the purine nucleotides possess valuable stimulative action on the reticulo-endothelial system and form a valuable vehicle for metal salt therapy while the pyrimidines, because of their depressing action on the reticulo-endothelial system, are undesirable for injection. On the other hand, the increased solubility of the pyrimidines makes them available for salts such as the silver salts, that are used in topical application. The interesting disclosure of Williams, that vitamin B is a pyrimidine thiazole compound, lends added interest to these substances.

One of us, Dr. Simon L. Ruskin, has therefore synthesized all the metal and metalloids salts of adenylic and guanylic acid as well as the metal and metalloids salts of cytidilic and uridylic acids.

In studying these preparations, it is interesting to note that ferrous adenyate provides a non-toxic iron for intramuscular or intravenous use that is stable, readily soluble, and non-irritating on injection, having a pH close to neutral. How valuable the combination of iron with a physiologically occurring radical may be can be seen from Rothmann's study showing that the average value of this nucleotide in blood is from 15 to 18 mg per cent. He finds that there is a distinct correlation between adenylic acid and the erythrocyte count. In anemia the lowest values are found, in polycythemia the highest. The daily destruction of erythrocytes explains the relatively large amount of adenylic acid excreted in the bile. The injection of this nucleotide leads to a rise in excretion of uric acid in the urine. Rothmann believes that adenylic acid plays an important rôle in the endogenous metabolism of uric acid. Engelhardt regards the adenylic pyro-nucleotide as a component of the coenzyme system of respiration. Thus, in employing ferrous adenyate we have a therapeutic agent in a more potent form not only for stimulating erythrocyte and leukocyte formation, but also for enhancing the respiratory coenzyme system in which the iron also plays a rôle.

In approaching the clinical study of the therapeutic action of the nucleotides, we selected, for this investigation, the influence of the nucleotides on the blood picture, leaving for later study the other aspects discussed in this paper. The relationship between hemoglobin, erythrocyte count and leukopenia has hitherto received but little study. Even though the proverbial tonic has always been directed toward hemoglobin and red cell formation, nevertheless, it appears that the white cell should really be the objective. Roberts and Kracke, in a comprehensive study analyzing the accumulated data in terms of white cell level and symptomatology, reviewed 8000 cases of private clinic patients. One of every four was found to have had a mild granulopenia. One of each two women patients, between the ages of 40 and 60, was neutropenic, and complaints of weakness, exhaustion and

fatigue, with a tendency to sleep, were twice as frequent in the granulopenic individuals as in those showing a normal white cell count. Eighteen per cent of the granulopenic group gave a chief complaint of nervousness. Furthermore, the severity of the symptoms paralleled, to a remarkable extent, the degree of granulopenia found.

In our own cases, cited below, the feeling of well being was far in excess of the rise in hemoglobin and erythrocytes, even though the latter increase was in itself considerable.

The relationship between leukopenia and anemia was further emphasized by Roberts and Kracke who say that, in the attack of pernicious anemia the granulocytes often decrease with the normocytes, and the characteristic granulocytes of pernicious anemia seem to be the first blood evidence of the attack and the last after remission has begun. If one could explain agranulosis, he might also be able to explain pernicious anemia.

The first extensive series of clinical tests was conducted with ferrous adenyate, prepared in half and one grain doses with the assistance of the Merck Research Laboratory. The clinical aspects were carefully followed by one of us, Dr. Elihu Katz, in selected cases. Although over 1,000 injections were administered in a wide variety of patients, no untoward local or general reaction was observed at any time. The case reports present several of those controlled by Dr. Katz (table 1).

Since the ferrous adenyate is the salt which has been selected for clinical trial, it is well to point out several of the factors relative to iron therapy. Since ferrous adenyate is soluble without the addition of ammonium, it is non-irritating and available for intravenous as well as intramuscular use. The Heath, Strauss and Castle report, that the parenteral administration of iron resulted in 100 per cent iron utilization, has established the value of parenteral iron medication and made possible a precise determination of iron need and supply. According to Fullerton, blood iron corresponding to 100 per cent hemoglobin (Haldane scale) is equal to 48 mg. per 100 c.c. Assuming blood volume to be 5 liters, a rise of 1 per cent hemoglobin is equivalent to a gain of $48/100 \times 50$ equals 24 mg. Fe as hemoglobin. Since a 1 per cent rise of hemoglobin may be considered as a satisfactory result from iron salt therapy, 24 mg. can be considered the essential therapeutic dose. This amount of iron is found in $1\frac{1}{2}$ grains of ferrous adenyate. When one compares this with the oral administration of 90 grains to supply the utilized amount of less than half a grain, one gets a better perspective of the relative merits of oral and parenteral therapy. The discomfort of daily use of large amounts of ferric ammonium citrate may be obviated by the parenteral route.

The immediate hormonal action of the adenyate radical on the circulation was apparent in all of the cases observed. During several hours following the injection, the patients would, as a rule, experience a sensation of exhilaration and a mild flushing of the skin. Several children showed a marked improvement in facial color. One of the patients showed an initial

TABLE I

drop in blood pressure with slight sweating and vertigo Some of the patients had slight tingling sensation in the extremities The sensation of well being and feeling of increased energy were in excess of those ordinarily experienced from iron therapy alone

Another noteworthy point was the fact that, although one and one-half grains of ferrous adenylyate was the calculated amount of daily iron needed, nevertheless, the dosage employed on the reported cases was only one-half gram of ferrous adenylyate This, in terms of iron alone, would represent only 6 mg The pronounced hemoglobin response is definitely out of all proportion to this quantity of iron and must represent the supporting action of the adenylic acid, either through its stimulation of the bone marrow, directly, or the improvement of the utilization of iron in the food In this respect adenylic acid may be looked upon as one of the effective substances so stimulating to blood regeneration found in the various tissue extracts, such as liver, beef, and stomach There are many factors pointing to this First, that these tissues are a rich source of adenylic acid, second, that Williams has shown vitamin B to have a pyrimidine nucleus, thus relating this to the adenylic acid structure, and third, the findings of P Karrer and H V Euler, who showed in their paper, on the water soluble growth vitamins of the B group, that the active substance obtained through the physical and chemical treatment of an aqueous liver extract showed spectroscopically a maximum absorption band at 260 mμ which agreed with that of cozymase and the adenylyl nucleotide When one adds to this the findings of Rothmann, that the hemoglobin per cent and erythrocyte count bear a direct relationship to the amount of adenylic acid of the blood, one gets a striking view of the important relationship of the adenylic nucleotide to blood formation

It is now commonly accepted, as shown by Bethell, "that the retarded rate of hemoglobin formation is most often due to a lack of iron, although such deficiency may possibly be associated with insufficient available protein, pigment complex, and certain vitamins"

Minot has strongly pointed out "that the term iron deficiency does not adequately describe all cases placed under this heading. The withdrawal from the tissues of material to make hemoglobin, the influence of substances on physiologic mechanisms for the utilization of iron and hemoglobin building substances must be studied further before there is final knowledge concerning iron deficiency anemias"

It thus becomes apparent that the use of simple iron compounds such as ferrous sulphate, ferric ammonium citrate, or reduced iron, such as have been used as far back as antiquity, may now be supplanted by the iron compounds of physiologically related radicals and supplemented specific active agents

The stimulation of bone marrow function, by the continued action of iron and nucleotide, was demonstrated in our cases by the elevation of the whole blood picture in every instance. The feeling of well being experienced by the patient could be compared with the sensation produced by the physiologic leukocytosis following ingestion of food, stimulation of a cold shower or massage. Also, the elevation of a white cell count from three thousand to five or six thousand lessens the danger of approach to the more malignant forms of neutropenia

HEPATIC COMPLICATIONS IN THE TREATMENT OF SYPHILIS

II INCIDENCE OF HEPATIC DISEASE IN PATIENTS WITH UNTREATED SYPHILIS AND DURING THEIR SUBSEQUENT TREATMENT

By FREDERICK KELLOGG, M D,† NORMAN N EPSTEIN, M D, and WM J KERR, M D, F A C P, *San Francisco, California*

HEPATITIS as a complication of anti-syphilitic therapy is not an uncommon occurrence. The injury thus suffered by the liver may be transient or it may be permanent, resulting in cirrhosis. Thus Baldrige¹ reported that, of a series of 36 patients with definite portal cirrhosis, one-third had histories of treatment for syphilis. During the past 10 years the value of controlling the arsphenamine treatment of syphilis by functional tests of the liver has been repeatedly emphasized. Such tests are indicated especially for patients with histories of hepatic disease or with evidence of disturbance of the liver developing during the course of treatment. Previous studies² have also shown that liver-function tests may reveal hepatic disease in a number of patients who present no clinical signs of liver dysfunction.

Consequently, it seemed desirable to survey a group of patients with untreated syphilis, and to follow these patients with repeated functional tests of the liver during their subsequent treatment. In this way it was hoped to determine (1) the incidence of hepatic disease in patients with untreated syphilis, (2) the effect of anti-syphilitic treatment on the liver, and (3) the possible relationship of diminished liver-function to untoward reactions resulting from treatment.

Method of Study The patients with syphilis who were selected for this study had received little or no antisyphilitic treatment. Some of these patients had received a few treatments with bismuth or mercury and a few had received one or two treatments with an arsphenamine. Thorough physical examinations were done on all patients, and complete histories were taken with special reference to antecedent disease of the liver. The liver-function of these patients was checked routinely with the Rose Bengal dye test at the onset of treatment, and at intervals during the course of therapy. This test has been used in the University of California Hospital the past 12 years, and has proved a reliable and satisfactory method of determining hepatic function. Details of the technic have been recently described,³ and will not be repeated here. A retention of over 55 per cent of the dye in the blood stream at the end of eight minutes, and of over 35 per cent of the dye at the end of 16 minutes, is considered to indicate abnormal hepatic func-

* Received for publication March 18, 1936

From the Division of Medicine and the Department of Dermatology, University of California Medical School, San Francisco

† Research Fellow, American College of Physicians

tion For the purposes of this study more stringent criteria were selected, and only patients with a retention of the dye of over 60 per cent at the end of eight minutes, and of over 40 per cent at the end of 16 minutes were considered to have abnormal hepatic function

Some of the patients with abnormal hepatic function were further tested for disease of the liver by the modified glucose tolerance test,⁴ and by determination of urobilin in the urine

Observations A total of 90 patients, on whom a total of 200 Rose Bengal tests were performed, was studied Unfortunately a large percentage of patients treated at this clinic are transient, so there were 39 patients on each of whom we were able to make only one test The remaining 51 patients had two to six tests each during the course of their treatment

Of the entire group, 57 were males and 33 were females The age distribution, shown in table 1, indicates that the greater number were between

TABLE I
Distribution of Patients According to Age and Sex

Entire Series							
Age	10-19	20-29	30-39	40-49	50-59	60-69	Total
Male	3	17	14	17	5	1	57
Female	2	9	10	7	4	1	33
Total	5	26	24	24	9	2	90

Group with Abnormal Hepatic Function before Treatment							
Male	0	1	2	8	3	0	14
Female	0	0	4	1	0	1	6
Total	0	1	6	9	3	1	20

20 and 50 years of age When grouped according to the diagnosis made at entry, 15 were in the primary stage, 23 were in the secondary stage, 35 were classified as latent, and 17 were classified as late—four of these latter having syphilis of the central nervous system

The incidence of abnormal liver function as indicated by the Rose Bengal test was surprisingly high Of the 90 patients in our series, 20 had abnormal liver-function before antisyphilitic treatment was given As shown in table 1, there was a tendency for this group to be of an older age than the group as a whole, but there was no definite correlation between the liver-function and the stage of the disease in these patients

Group with Repeated Tests, Normal Liver Function before Treatment Of the patients with normal hepatic function before antisyphilitic treatment, 33 had repeated tests during the course of therapy Five of these (table 2) were shown to have an abnormal test of liver-function while under treatment In two patients (numbers 2 and 5), the hepatic function was still

				9-24-34	88	53	Moderate	Maphars 0.40 gm	
				5-6-35	67	43	Slight	Maphars 0.60 gm	

abnormal at the time of the last examination, antisyphilitic treatment apparently having led to permanent hepatic damage. In the other three patients the abnormality was transient, and subsequent arsphenamine therapy was tolerated without mishap, though one patient (number 4) had had an attack of jaundice and glomerular nephritis.

Group with Repeated Tests, Abnormal Hepatic Function before Treatment There were 18 patients in this group, which can suitably be divided into a sub-group of 9 (table 3) in whom the function returned to normal following antisyphilitic therapy, and the remaining 9 (table 4) in whom the function of the liver continued to be abnormal.

In table 3 we have included a group of patients who may have had syphilitic involvement of the liver, inasmuch as the hepatic function improved with antisyphilitic therapy, although one patient (number 6) showed further impairment of liver-function before improvement occurred. Three patients (numbers 6, 9 and 11) had transitory attacks of dermatitis, probably related to antisyphilitic therapy. In one patient (number 8), an abnormal reading was obtained when the Rose Bengal test was performed a few hours after an injection of neoarsphenamine. This may represent only a temporary toxic effect on the liver, for in the course of our study on other patients a similar relationship has not infrequently been noted.

Table 4 represents a group of patients with an abnormal hepatic function which persisted after a period of one to two years of antisyphilitic treatment. It is highly significant that an increased impairment of hepatic function occurred in four (numbers 19, 20, 21, and 22) of this group during the course of arsphenamine therapy. In one patient (number 19) who had developed icterus, a marked improvement in liver-function followed the cessation of arsenical treatment. One patient (number 22) developed purpura after each administration of neoarsphenamine but tolerated mapharsen without ill effect.

Group with Only One Rose Bengal Test As stated before, there were 39 patients on whom only one Rose Bengal test was done. No reactions to arsphenamine therapy occurred in these patients while attending the clinic. Two patients (table 5) had definitely abnormal hepatic function. One of these (number 24) had a decompensated cirrhosis of the liver. This patient was lost sight of before antisyphilitic treatment was given.

Relation of Abnormal Hepatic Function to Untoward Reactions of Therapy Eighty patients received treatment with the arsphenamines. Sixty-two of these patients had initially a normal liver-function, and 18 had abnormal function.

Table 6 shows the untoward reactions which occurred. Approximately one-fifth (12 patients) of the group with initial normal function manifested some degree of intolerance to arsenic at one time or another. The only serious reaction occurring was the jaundice and glomerular nephritis which one patient developed. Subsequently, this patient tolerated arsenical therapy without untoward effects.

TABLE III
Patients with Abnormal Retention of Rose Bengal Dye Initially, but with Normal Function following Specific Therapy

Case No	Age	Sex	Diagnosis	Date	Rose Bengal		Degree of Abnormality	Preceding Arsenical Treatment	Remarks

TABLE VI
Reactions during Course of Antisyphilitic Therapy

	Abnormal Rose Bengal Test before Treatment	Normal Rose Bengal Test before Treatment	Total
Total number receiving the arsphenamines	18	62	80
Reactions			
Dermatitis (mild)	3	4	7
Malaise	2	7	9
Jaundice	1	1	2
Purpura	1	0	1
Enlarged liver before treatment	3	7	10

Seven (approximately one-third) of the group with initial abnormal function developed untoward reactions. Two had serious reactions, one having jaundice and the other purpura. Although the series is not large enough to be statistically significant, it would appear that patients with abnormal hepatic function are more apt to develop untoward reactions than are patients with normally functioning livers.

Comment. The findings presented demonstrate that latent hepatic disease is not uncommon in patients with untreated syphilis. Of the entire series of 90 patients, 20 were found to have abnormal liver-function as shown by protracted retention of Rose Bengal dye in the circulation. Two of these patients had other clinical evidence indicative of cirrhosis of the liver, and a third patient had a history of jaundice. The remainder, 17 in number, had impaired liver-function which was detected only by the Rose Bengal test. In 10 of these 17 patients improvement in hepatic function followed specific therapy, while in the remaining seven, the liver-function remained abnormal in spite of long continued antisyphilitic therapy. Improvement in the patient's syphilitic condition probably accounts for the improvement in the liver-function in the first 10 while in the other seven the liver disease was probably so advanced that the function could not be restored. It is in this group where extreme caution must be exercised in the administration of the arsphenamines as irreparable harm may be done by these drugs.

Only one patient (table 4, number 19) with clinically recognizable cirrhosis of the liver received arsenical therapy. This was tolerated poorly, and jaundice developed which subsequently disappeared only after treatment with arsphenamine was discontinued. The patient (table 4, number 16) with a history of jaundice suffered no untoward effects from treatment. Six of the seven patients with presumably latent cirrhosis were given the arsphenamines cautiously. This was well tolerated except for one patient (table 4, number 22) who developed purpura following neoarsphenamine. In two other patients (table 4, numbers 20 and 21), antisyphilitic therapy led to increased hepatic damage as shown by the Rose Bengal test.

Of the 29 patients with an initial normal hepatic function test, five developed hepatic injury as shown by the Rose Bengal test. This damage was slight to moderate, and relatively transient. One patient (table 2, number 4) developed jaundice and glomerular nephritis temporarily, but subsequently tolerated arsenical treatment without reaction. Since the development of cirrhosis is a relatively slow process, a further study of these patients is indicated to determine the possible relationship of anti-syphilitic therapy to the future course and end result.

An analysis of the untoward reactions occurring during antisyphilitic therapy suggests that patients with an abnormal hepatic function are more apt to suffer ill effects than those with normal liver-function. If this is borne out by further observations, it would be advisable to perform routine liver-function tests on all patients with syphilis before instituting therapy. Every effort should be exerted to protect the liver from the harmful effects of antisyphilitic remedies. We would suggest the taking of carbohydrates by mouth a few hours before the administration of an injection of arsphenamine and caution the patient against the taking of alcohol or an excess of fat in his diet.

SUMMARY

1 A high incidence (19 per cent) of abnormal liver-function, as shown by the Rose Bengal test, was found in a group of 90 patients with untreated syphilis.

2 Antisyphilitic therapy caused transitory disturbances in liver-function in five of 29 patients originally having a normal function, and caused further impairment in four of 18 patients with initial abnormal function.

3 Patients with initially abnormal liver-function had an increased tendency to have untoward reactions to antisyphilitic therapy.

NEUROLOGICAL SYMPTOMS IN POSTHEMORRHAGIC SECONDARY ANEMIA⁴

By SAMUEL B. HADDEN, M D , F A C P , *Philadelphia, Pennsylvania*

IN 1878 the pathological picture of postero-lateral-sclerosis was described by Kahler and Pick,¹ and in 1887 Lichtheim² pointed out the frequency of the relationship of this neurological condition to pernicious anemia. At the present time the symptom complex of postero-lateral-sclerosis is regarded as most commonly the result of primary pernicious anemia. The relationship of secondary anemias to changes in the nervous system, however, is less well known. Changes in the cord occurring in secondary anemia have been reported, but not all these cases can be accepted as authentic.

Oppenheim³ believed that in all cases of postero-lateral-sclerosis the anemia need not be pernicious, and he reports one case in which the postero-lateral-sclerosis was the result of the cachexia due to a malignant tumor, one occurring during the anemia of lactation, and three cases in persons in the sixth and seventh decade of life who had an anemia he attributed to chronic malaria which was contracted in early life. These cases were reported before our present knowledge of pernicious anemia and cannot be accepted as due to secondary anemia without question, although many German neurologists in the past have likewise held the opinion that secondary anemia may cause changes in the nervous system.

Sargent⁴ reports cases of simple achlorhydric anemia where symptoms of postero-lateral-sclerosis existed and in whom marked improvement of both the blood picture and nervous symptoms occurred from the use of iron, but not from liver therapy. This worker believes that in all types of anemia, including pernicious, the nervous symptoms are more promptly and effectively improved by massive doses of iron than by liver therapy alone. All of his cases received at least 150 grams of Bland's mass each day.

The view that the anemia is not the main factor in the production of the postero-lateral-sclerosis of primary pernicious anemia is based upon the fact that many times the nervous symptoms long precede the anemia. Spiller⁵ has long held this opinion. Castle⁶ states that pernicious anemia is the result of the absence of a specific intrinsic factor of gastric origin. Nervous system symptoms associated with achylia gastrica are not infrequent, notably in pellagra. In tapeworm and hookworm anemias, and in the anemia of sprue nervous system symptoms are encountered, but they may be the result of the toxic factors of the disease and not due to blood impoverishment alone.

In many of the dietary deficiency diseases there is an associated anemia with nervous symptoms, but the magnificent work of Mellanby⁷ tends to prove that here again the anemia cannot be considered the important factor.

* Received for publication September 20, 1935

In all his experimental animals he could demonstrate diminution or depletion of the vitamin A content of the liver, and by the addition of vitamin A or carotin to the diet he was able to prevent degenerative changes in the nervous system. It is of interest that in some cases of postero-lateral-sclerosis of pernicious anemia in humans he found decrease in the amount of vitamin A in the liver. This was not a constant finding, but even the presence of vitamin A in the body does not rule out its faulty utilization.

Weil and Davidson,⁸ in their exhaustive pathological studies on the spinal cord in anemia, concluded that postero-lateral-sclerosis probably never occurs in any secondary anemia. In their series of cases of secondary anemia, changes in the cord were noticed in a few in which the differentiation between primary and secondary anemia was not clear. They do not consider any other changes in the central nervous system than cord changes and include in their group of secondary anemia all cases with 75 per cent hemoglobin or less and 3,500,000 red blood cells or less. In only eight of their cases of secondary anemia, not including the four leukemias, was the red blood cell count under 2,500,000, and in only six cases was the hemoglobin under 50 per cent. In one of these cases involvement of the column of Goll was noted in a patient who died of tuberculous meningitis. The hemoglobin in this case was 28 per cent. In their cases of secondary anemia which showed central nervous system lesions, these lesions were usually the result of metastatic or myelitic lesions. In this paper of Weil and Davidson the number of really severe cases of secondary anemia is too few to warrant their conclusion that cord changes do not occur in secondary anemia. In the 10 cases of primary pernicious anemia used in their paper, in only two was the hemoglobin above 50 per cent or the red blood cell count above two million, so that aside from the toxic factor their pernicious anemia cases represented much more severe red blood cell and hemoglobin deficiency than their secondary anemia cases.

The cases of anemia with nervous symptoms which I present in this paper are very severe cases, in which there was rapid diminution of the hemoglobin and red blood cells by massive hemorrhage from medical or obstetrical causes to almost fatal levels.

CASE REPORTS

Case 1 The first case was from my service at the Episcopal Hospital. Briefly, the patient, a woman, aged 40, suffered from severe postpartum hemorrhage March 1, 1927. She was in a stuporous state for several days following delivery and complained of blindness and a cold, numb feeling of the body, especially in her lower extremities. It was several weeks before her vision returned to what she considered normal. On getting out of bed she experienced considerable difficulty in walking because she "could not tell the position in which she placed her feet and had to watch the ground constantly." The patient states, and her friends confirm the statement, that the hemorrhage was so severe that coal shovels and buckets were used to scoop up the clots after her delivery, so there can be no question that the loss of blood was unusually large although no blood studies were made at the time. At

the time of her observation at the Episcopal Hospital, during November and December 1932, the patient showed a suggestion of nystagmus, incoordination in finger-to-nose test, marked pyramidal tract and posterior column symptoms, diminution of visual acuity with evidence of old optic atrophy, concentric contraction of visual fields, normal gastric analysis and blood picture. Colloidal gold showed a low first zone alteration.

Case 2 A S was reported clinically by Dr W L McConnell^o in January 1907, and is included through the courtesy of Dr William G Spiller from his service at the Philadelphia General Hospital. The patient was admitted Dec 12, 1903. At the time of admission the first blood examination revealed a hemoglobin of 16 per cent and 1,750,000 red blood cells. A few days before admission the patient, while in the county prison, had had a massive gastric or pulmonary hemorrhage. He had been in poor health previously. The following day he noticed dimness of vision. His sight gradually failed until one week after the hemorrhage vision was lost in both eyes. Shortly after the hemorrhage he experienced weakness in both legs and eventually entirely lost his ability to walk. Power in his legs, however, was never entirely lost. Three months after the weakness in his legs he began to experience weakness in both upper extremities. Improvement was very gradual and approximately 10 months later he was able to stand and walk a bit, although extremely ataxic. The following is a summary of notes made by Dr Spiller on Aug 4, 1904: "No facial weakness or nystagmus. The upper limbs are wasted. It is difficult to say whether there is any greater wasting in one part than the other. The biceps tendon reflex is present on each side though not very pronounced. Sensation in the upper extremities is normal. There is ataxia in the finger-to-nose test. Talipes-equino varus on each side. Voluntary power in lower limbs fair at knees, but almost lost at ankles, very feeble in all parts of lower limbs. Lower limbs extremely wasted in all parts. Abnormal position of feet readily overcome passively. Patellar reflex feeble on the left side and detected by a slight contracture of the muscles. The right patella reflex is completely lost. No Achilles, Babinsky distinctly present on each side. The patient is unable to stand. Sensory examination negative."

The following table shows the gradual recovery from the severe anemia on admission.

TABLE I

Date	Hemoglobin	Red Blood Cells	White Blood Cells
	Percentage		
12/23/03	24	2,100,000	4,600
1/4/04	35	2,450,000	5,800
1/13/04	44	2,720,000	1,400
1/27/04	48	2,700,000	4,000
2/27/04	41	2,370,000	4,300
3/5/04	44	3,000,000	5,400
4/12/04	62	3,350,000	5,500
5/18/04	85	4,630,000	5,600
8/30/04	76	5,760,000	8,000

It will be noted it was about six months before his blood reached approximately a normal level. His condition remained grave for some time, but gradually he improved. Loss of vision was permanent. For many years signs of pyramidal tract involvement persisted but eventually he was able to walk without any great difficulty. The last neurological examination of merit was by Dr Fassey on October 14, 1921, and his findings are chiefly negative. Patient was blind, he presented no definite disturbance of gait or station, no sensory disturbance, tendon reflexes were all active and equal, with normal plantar reflexes. Free HCl was diminished and on one examination absent.

In 1924 the patient had a "stroke" and died a few days following it

Pathologically the brain presented multiple areas of softening with advanced arteriosclerosis. The cord was flat and granular. These diagnoses were confirmed microscopically, and in the cord mild bilateral pyramidal tract degeneration was noted. Degeneration of the optic nerves was advanced. General autopsy showed moderate arteriosclerosis and broncho-pneumonia.

It is unfortunate that the cerebral softening complicated this case as the pathological findings are lessened in importance thereby, but there is little doubt of the gravity of the symptoms which date their onset from his severe posthemorrhagic anemia.

Case 3 E. B., female, aged 39, admitted to the service of Dr. Girvin, Presbyterian Hospital, March 14, 1932, discharged June 5, 1932. The patient had been having prolonged menstrual periods with profuse bleeding over a period of two years each period lasting from three to 14 days and always being excessive. Fifteen days prior to her admission she had profuse bleeding with actual gushing at times. She was confined to bed four days prior to admission because of weakness and passed large vaginal clots. At the time of her admission she was extremely weak. The skin and mucous membranes were definitely blanched. Her blood pressure was 100 mm of mercury systolic and 44 mm of mercury diastolic. Vaginal examination revealed a soft cervix, four fingers dilated through which a soft round mass was being expelled. A tentative diagnosis of incomplete abortion was made. Her temperature was 99.2, pulse 132 per minute, pupils equal, moderately dilated and reacted to light. The heart was enlarged slightly to the left, sounds distant, rhythm regular, and a systolic murmur was heard at the apex. Her hemoglobin on admission was 45 per cent, red blood cells 1,880,000, leukocytes 22,000.

The patient began to bleed profusely at midnight of the day of admission. The following morning she was given 300 c.c. of citrated blood and 2,500 c.c. of saline. On March 15 an attempt was made to evacuate the uterus under nitrous oxide anesthesia, but the bleeding was so profuse that the attempt was stopped. In the next few days the patient became extremely drowsy, confused, and was aroused only with some difficulty, and four days after admission became definitely blind and had little more than light perception. She was transfused as follows: March 15, 300 c.c. blood, March 22, 500 c.c., March 25, 375 c.c. On March 19, when I first saw the patient, she was confused, blind and had a definite increase of muscular rigidity resembling a mild Parkinsonism, with some twitching movements, especially in the lower extremities. Her reflexes were all extremely hyperactive, but no Babinski was noted. Mental state was such that sensory examination was impossible. Again, on the twenty-first the patient was able to see objects moving in front of her eyes, but not distinctly. At this examination, with Dr. Cadwalader, there appeared to be evidence of very definite contraction of her visual field. The pupils reacted very slowly to light. There was no paralysis noted. Her reflexes were active and there was a suggestion of ankle clonus on both sides. The twitching movements previously noted were largely confined to the lower extremities and were irregular in nature. Gnostic sensations in the lower extremities were impaired. April 3 a note was made that there was a suggestion of paralysis of the upward associated ocular movements. Her expression was fixed. There was considerable rigidity with a suggestion of catatonia. Her general appearance suggested a developing Parkinsonian state. Her vision improved slowly but steadily, and by April 4, one month after admission, Dr. Langdon stated that central vision tested with a card was about one-third of normal. On May 6 the patient's general condition having improved remarkably, hysterectomy and appendectomy were performed by Dr. Laws and the patient was found to have an adenomyoma of the cervix of the uterus. At the time of her discharge from the hospital the patient's vision was normal in the left eye, with 6/12 vision in the right eye. Nerve heads were very pale and the visual fields were concentrically contracted.

This case is most interesting because of the fact that recovery from severe symptoms was apparently almost complete. Her hemoglobin three days after admission to the hospital had dropped to 27 per cent, with 1,200,000 red blood cells. After that, as a result of transfusions of some 2,000 c c, the patient improved rapidly and these severe symptoms disappeared. The symptoms at the time of admission are remarkably like those of the first two cases. Only the prompt restoration of her blood by transfusion enabled this patient to survive and be restored. At the present time Dr. Langdon reports that her corrected vision is normal, but the visual fields are contracted. No recent neurological examination has been made.

In all three of these cases disturbance of vision was profound early in the course of their illness. Reports of transient and permanent blindness are not uncommon following hemorrhage. Hayes¹¹ in Norris and Oliver's "System of Diseases of the Eye" reports 11 cases following hemorrhage, 10 after gastric hemorrhage and one after hemorrhoidal bleeding. It is interesting to note that in all of these cases the hemorrhage was from a medical cause. Larrey,¹² in his medical memoirs of Napoleonic campaigns, in his discussion of diseases of the eye does not mention a single case of this sort, and the post World War literature does not reveal similar cases although massive hemorrhage was very common. Soldiers are usually in excellent health, and recovery from surgical hemorrhage is usually prompt.

It is interesting to theorize on the basis of the disturbances of the nervous system following a severe hemorrhage. The circulation apparently is kept adequate in the vital structures. The peripheral capillary bed is constricted with the resulting cold, pale skin and the common paresthesias. McGuigan and Atkinson¹³ have shown that hemorrhage remarkably increases the response of the peripheral sympathetics to adrenalin. It appears that as long as this vasomotor constrictor action continues the blood is kept in vital parts, but should there be vasomotor relaxation the blood then enters the less vital parts, and changes may occur in the nervous system.

During anemia the resulting anoxemia, as shown by the work of Landis,¹⁴ favors the development of edema with resulting impairment of function. Should this edema continue over a sufficient period of time permanent damage is sure to result, as in cases 1 and 2. Hemorrhagic anemia develops quickly, and there is little time for adjustment, so that anoxemia rapidly occurs with almost immediate disturbance of function of many portions of the nervous system. In all three cases there was profound disturbance of vision, locomotion and gnostic sensation very shortly after the massive hemorrhage. In cases 1 and 2 some of the symptoms were permanent and severe, while in case 3, where the oxygen carrying power of the blood was quickly restored by transfusion, recovery to almost normal health rather quickly occurred. The suggestive Parkinsonism and visual disturbance improved more slowly than other symptoms, possibly because the cells involved are more susceptible to anoxemia.

In secondary anemias from the slow loss or destruction of blood, symptoms of disturbance of nerve function are seldom a prominent feature, but are fairly constant. Visual disturbances, numbness, tingling and feelings

of coldness, generalized weakness, syncope, and rapid fatigue, resembling myasthenia gravis, are at times noted. In these cases blood is kept in the vital structures because the vasomotor control slowly adjusts itself. Unless the anemia is relieved, a sudden decompensation of the vasomotor system may occur and the vital centers be deprived of blood with resultant death. The brain and spinal cord in these cases show little more than intracellular changes because death occurs before more extensive damage can take place. In cachectic cases a comparatively small hemorrhage may be fatal because the already taxed vasomotor control suddenly decompensates.

CONCLUSIONS

1 Secondary anemia, especially posthemorrhage anemia, may produce organic alteration in the nervous system the optic nerves and pyramidal tracts being most commonly involved. Disturbance of gnostic sensation may occur from anoxemia of nerve endings and not be permanent.

2 Prompt restoration of oxygen carrying power of the blood is necessary to prevent the described symptoms from being permanent.

CASE REPORTS

ADENOMA OF THE PARATHYROID GLAND, WITH HYPERPARATHYROIDISM *

By SAMUEL S RIVEN, M D, F A C P, and MORTON F MASON, P H D,
Nashville, Tennessee

DURING the past ten years great advances have been made in knowledge of the function of the parathyroid glands. Hypoparathyroidism, with the associated disturbance of calcium metabolism, is an important cause of tetany. Oversecretion of the hormone of the parathyroid glands (hyperparathyroidism) causes decalcification of bone, hypercalcemia, hypophosphatemia and increased calcium and phosphorus excretion in the urine. This condition results in the development of generalized *osteitis fibrosa cystica*. In most instances of hyperparathyroidism the changes in the skeletal system are the principal features, but occasionally, as in the case to be reported, renal symptoms predominate, and failure to recognize this fact may lead to error.

CASE REPORT

Mrs E R, a 51 year old white female, was admitted to Vanderbilt University Hospital on April 29, 1935, complaining of pain in the left flank. The pain radiated around the abdomen, down to the genitalia and was associated with burning on urination. Seventeen years ago she had intermittent attacks of bilateral renal colic which lasted for nine months, associated with the passage of several small, dark brown stones. There were no more attacks until January 1935. During the first illness she was advised to discontinue eating meat, and, while on a low protein diet, developed sore tongue, roughness of the skin and swelling of the ankles. Because of these symptoms and pain in the back and lower extremities, she came to one of us on May 3, 1933. Roentgenograms of kidneys, left knee joint and left femur showed only thinning of the bones. The diagnoses of Paget's disease and nutritional edema were made and she was placed on a diet high in protein. On October 6, 1934, she returned because of swelling of the ankles, fatigue, nausea, vomiting, frequency of urination and nocturia. The urine contained some albumin and many pus cells. A serum calcium determination at this time was 13 milligrams per 100 c c †. Because of the hypercalcemia and the roentgen-ray findings of decalcification of the long bones, the patient was placed on a high calcium, high vitamin, high protein diet. Three months later she developed an attack of renal colic, and from January to April 1935 had three such attacks. The patient grew progressively weaker, her appetite became poor, and she lost 15 pounds in weight. In addition, she had cardiac palpitation brought on by nervousness and exertion.

† Normal serum calcium is 9 to 11 milligrams per 100 c c blood

Past History She had had scarlet fever at five years of age, influenza in 1918, and two or three attacks of sore throat. Her tonsils and appendix were removed 17 years ago. Her husband, one brother and one sister all have tuberculosis. She has had no symptoms of tuberculosis and repeated roentgenograms of the chest have been negative.

Physical Examination Physical examination revealed a rather flabby, malnourished, apathetic individual, normally developed. She was very intelligent. The head was peculiarly pointed in shape, the cheeks had a hollow, sunken appearance, and the chin protruded forward. The pupils reacted normally to light and accommodation, the fundus examination showed some variation in the retinal arteries, but there were no hemorrhages or exudate. There was fullness over the thyroid gland but no masses were palpable. The heart and lungs were normal. The blood pressure was 120/74 mm of Hg. Examination of the abdomen revealed distinct tenderness in the left flank. There was definite kyphosis of the dorsal spine and tenderness over the bones of both lower extremities. Pitting edema of the feet and ankles was present extending half-way up the legs.

Laboratory Data Urinalysis: Specific gravity varied from 1.005 to 1.012, no albumin, sediment contained five to six red blood cells and an occasional white blood cell, the benzidine test was positive. Blood: The red blood cell count was 3,760,000, hemoglobin 13 grams, white blood cell count 13,000. The blood smear was normal. Wassermann and Kahn tests were negative. The basal metabolic rate was minus 9 per cent. The phenosulphophthalein renal function test (intravenous) was 55 per cent. The blood non-protein nitrogen varied between 25 and 41 milligrams per 100 c.c. The serum phosphatase was 7 units per 100 c.c.* The serum protein was 6.8 per cent, with 4.3 per cent albumin and 2.5 per cent globulin. The serum calcium was 12.9 to 13.5 milligrams per 100 c.c. The serum inorganic phosphorus was 2.1 to 3 milligrams per 100 c.c. Roentgen-ray examination revealed a large ureteral calculus in the upper segment of the left ureter. "The wing of the left ilium showed marked thickening with striations and also a large area of osteitis in the left sacro-iliac region. There was considerable hypertrophic arthritis of the lumbar spine. There was marked thickening of the bones of the skull. The bones of the hand showed marked thinning of the cortex" (Dr. C. C. McClure). Because of the apparent disturbance in calcium metabolism, it was decided to investigate this more fully. The calcium metabolism was studied as follows. The patient was put on a low calcium diet containing 0.3 grams of calcium per day. After five days on this diet the whole of the urine and feces were collected for a three day period, the former as separate 24 hour specimens, and the calcium content of these was determined. Before commencement of the test period, and at the conclusion of the period, the patient received cachets of carmine, the appearance of the dye in the feces serving as an indicator for the demarcation of the period of observation. The total output of calcium for the three day period was 1,335 milligrams, of which 931 milligrams appeared in the urine and 424 appeared in the feces. In other words, 70 per cent of the total amount of calcium excreted appeared in the urine†. This study was repeated twice with similar results.

Diagnosis The skeletal decalcification, polyuria, nycturia, hypercalcemia, hypophosphatemia and calcium metabolism studies indicated the presence of hyperparathyroidism. An exploratory operation was done on May 29, 1935, with the expectation of finding an adenoma of a parathyroid gland or parathyroid hyperplasia. Dr. Barney Brooks found a parathyroid tumor 2.5 cm. in length and 1 cm. in diameter in the region of the left lower lobe of the thyroid. (Figure 1)

Pathological Report The specimen was a very soft, dark purple, club-shaped, smooth encapsulated tumor. A thin capsule was opened and a layer of blood was

* Normal serum phosphatase is 6 to 12 units per 100 c.c. blood.

† In a normal individual on a similar diet, only 10 to 30 per cent of the total calcium excreted appears in the urine, the remaining 70 to 90 per cent being present in the feces.

released. This revealed a brownish-yellow, dull, smooth tumor mass about one-half the size of the specimen. On cut section it had a smooth, homogeneous appearance and was light caramel in color. Dr. Goodpasture's report on the section was as follows: "The microscopic section consists of a very cellular, irregularly elliptical

FIG 1 Adenoma of the parathyroid gland

piece of tissue measuring 12 by 5 millimeters. Nuclear material as compared with cytoplasm is very abundant so that the tissue stains deeply blue with hematoxylin-eosin. Under low power the tissue seems to be quite uniform in appearance, consisting of epithelial cells arranged in small acini and alveoli compactly situated with very

little stroma and a rich collapsed capillary bed separating them. There are several medium-sized arteries and veins tracing through the substance of the tissue. The composition of the tissue is not entirely uniform because there are several areas situated toward the center of the mass which are less cellular than the surrounding tissue and in which the alveoli are thinned out and often arranged in strands. Here the nests of epithelial cells are widely separated by spaces containing a pink granular precipitate. These spaces appear to be greatly distended lymphatics. In other foci the epithelial cells are compact but contain a relatively abundant pink-staining granular cytoplasm, so that these areas have a paler pinkish appearance in contrast to the denser surrounding areas. Where the alveoli have an acinar arrangement the epithelial cells are low cuboidal in shape and their nuclei are situated toward the basement membrane. Throughout the section the cytoplasm of the cells is faintly pink, containing amorphous granular material and sometimes the cytoplasm appears to be washed out, but in general the epithelial cells throughout the section have irregular basophilic condensations within the cytoplasm. There are a few areas of adipose tissue infiltration within the glandular substance. While for the most part the cells are fairly uniform in size and have regular oval nuclei, there are a great many hypertrophic nuclei scattered irregularly throughout and there are small foci in which the cytoplasm is greatly increased in amount without change in size of the nuclei. In such cells the cytoplasm has a uniform, fine pink granulation and no mitotic figures were seen. There is a distinct but thin capsule surrounding about half of the section and into this there is an irregular growth of glandular acini. There is, however, no evidence of malignancy. The tissue is typically that of the parathyroid gland, and the condition is one of hyperplasia of the glandular cells. Because of the localized character of the parathyroid enlargement, involving only one gland, the nature of the new growth may be regarded as neoplastic, that is, adenomatous in the sense of Castleman and Mallory.¹

Subsequent Course The patient stood the operation well and the first postoperative day was uneventful (May 30, 1935). On the morning of May 31, the second postoperative day, she developed a sensation of oppression in the chest, increased irritability, tingling in the fingers, and positive Chvostek and Trousseau signs. The serum calcium was 9.1 and phosphorus 2.2 milligrams per 100 c.c. For 10 days she had symptoms of tetany, which were easily controlled by the administration of 8 c.c. of 40 per cent calcium chloride four times a day and two doses of calcium gluconate intravenously on the third and fourth postoperative days. At no time was it found necessary to give Collip's parathyroid extract. By June 28, 1935, it seemed probable that she could not pass the stone in the left ureter and on that day it was removed by Dr. E. H. Barksdale.

The partial analysis of the stone was as follows: Weight of stone (oven-dry) 155.6 milligrams, $\text{Ca}_3(\text{PO}_4)_2$ 38.1 per cent, CaC_2O_4 (oxalate) 43.4 per cent, urates, trace, carbonate, trace, cystine, trace, percentage of stone as Ca, 28.3 per cent.

The patient's recovery was uneventful and she was able to leave the hospital on July 13, 1935, her only symptom was occasional mild tingling in the arms.

Re-admission The patient was readmitted to the hospital on September 9, 1935, for calcium metabolism studies. Her only complaints were edema of the ankles and symptoms suggestive of mild tetany. She had gained 23 pounds in weight and felt better than ever before. The physical examination revealed a cheerful, adult female. The skin was warm, dry, and there was a papular pruritic rash with an erythematous base over the ankles and the lower part of each leg. The spine and extremities were not tender. The neurological examination was negative.

At this time the laboratory data were as follows: Urine Specific gravity, 1.007, no albumin, sediment three to four white blood cells, no red blood cells. Blood Red blood cell count 4,000,000, white blood count 8,000, hemoglobin 12.2 gm. Venous

pressure in the arms was 85 millimeters of saline. Blood non-protein nitrogen 38 milligrams per 100 c.c. Serum protein 6.4 per cent, albumin 4.4 per cent and globulin 2.0 per cent. Serum calcium 9.8 milligrams per 100 c.c. Roentgen-rays showed little change in the cranial bones, but the wing of the left ilium showed bone structure much nearer normal than on any previous occasion.

The metabolic studies were repeated and are shown together with the preoperative studies in table 1. Compared with the preoperative period when the total calcium excretion for three days was 1,335 milligrams, of which 931 milligrams appeared in the urine and 424 milligrams in the feces, the total excretion now for three days was only 558 milligrams, of which 169 milligrams appeared in the urine, and 389 milligrams in the feces.

TABLE I

Calcium Excretion on Low Calcium Diet before and after Removal of Parathyroid Adenoma (three-day metabolism period, diet containing approximately 0.3 gm calcium per day)

5/15/35-5/17/35 (Before) Gm Calcium		9/15/35-9/17/35 (After) Gm Calcium	
Urine	Feces	Urine	Feces
0.931	0.425	0.169	0.389
Per cent excreted in urine 69%		30%	

The values of the preoperative and postoperative serum calcium and phosphorus determinations are represented in figure 2. Before operation, the serum calcium was high, ranging from 12.5 to 13.5 milligrams per 100 c.c. and the serum inorganic phosphorus was low, varying from 1.7 to 3 milligrams per 100 c.c. After recovery from the operation the serum calcium varied from 9.8 to 10.1 and the serum inorganic phosphorus from 3.0 to 4.7 milligrams. These findings indicate clearly that the hormone from the adenoma was directly concerned in the hypercalcemia which was present before the operation.

DISCUSSION

Von Recklinghausen² in 1891 first called attention to the condition known as *osteitis fibrosa cystica*. He emphasized the generalized nature of the disease, pointing out that it affected all the bones, thus differing from the solitary cysts of bone or benign giant cell tumors. In 1904, Askanazy³ first described a case of *osteitis fibrosa cystica* associated with a parathyroid adenoma. Erdheim⁴ in 1907 described three cases of osteomalacia associated with parathyroid tumors. In 1923 Dawson and Struthers⁵ pointed out the frequent association of renal calculi with the presence of areas of metastatic calcification in the lungs, kidneys, and myocardium in cases of *osteitis fibrosa cystica*. It was not until 1926, however, that Mandl⁶ performed the first operation for the removal of a parathyroid tumor in a case of *osteitis fibrosa cystica*. The patient completely recovered.

Collip⁷ in 1925 discovered parathormone and studied the effect of experimental hyperparathyroidism. He found that the essential characteristic was the development of hypercalcemia sometimes exceeding 20 milligrams per 100 c.c. of serum.

In 1930 Hannon Shorr, McClellan and DuBois⁸ studied the biochemical aspects of *osteitis fibrosa cystica* and through their investigations definitely established the presence of hypercalcemia and hypophosphatemia. In the same year Bauer, Albright and Aub⁹ described the increased urinary output of cal-

FIG 2 Calcium and phosphorus studies made before and after operation. The numbers on the longitudinal ("normal") line indicate days before or after operation. The day of operation is indicated by the vertical line.

cium and phosphorus in a case of *osteitis fibrosa cystica*. They found it to be six to seven times greater than in the normal individual. They also found that these changes in metabolism were equivalent to those of a normal individual receiving 100 units of parathyroid hormone daily. Excellent reviews of the subject of hyperparathyroidism have been published, notably by Hunter and Turnbull,¹⁰ Barr and Bulger,¹¹ and Jaffe.¹² Recently Castleman and Mallory¹ have studied the histology of the parathyroid glands in cases of hyperparathyroidism.

In 1934 Albright, Aub, and Bauer¹⁰ reported 17 proved cases of hyperparathyroidism. They gave a detailed description of the condition and described the following clinical types: (1) classic hyperparathyroidism (Von Recklinghausen's disease). Skeletal manifestations predominate and consist of decalcification, cysts, tumors, and eventually fractures. (2) Osteoporotic form of hyperparathyroidism. Presenting symptoms are due to general decalcification and there are no cysts or tumors. (3) Hyperparathyroidism with

nephrolithiasis Presenting symptoms are associated with renal stones and with no gross skeletal changes (4) Hyperparathyroidism with renal insufficiency (nephrocalcinosis) The symptoms are those of Bright's disease (5) Acute parathyroid poisoning This is a condition simulating acute parathyroid poisoning in dogs with sudden death and characteristic pathologic changes (6) Hyperparathyroidism simulating (or complicated by) Paget's disease In this classification our patient belongs to types 2 and 3, presenting renal symptoms extending over a period of 17 years, and finally, manifestations of generalized decalcification without cysts or tumors

COMMENTS

In view of the increase in the number of reported cases in recent years a resume of the important clinical features of hyperparathyroidism is given This disease may occur at any age period The youngest patient reported by Bauer, Albright and Aub was 13 years of age and the oldest 62 years of age, although most cases fall in the middle age group The sexes are equally affected

Although a positive diagnosis cannot be made without chemical data, the symptoms of hyperparathyroidism are usually quite characteristic The onset is insidious and may consist only of mild pains in the bones In the instances where the skeletal changes predominate, a spontaneous fracture may be the first event that calls attention to the disease In more advanced hyperparathyroidism muscular weakness, lassitude and hypotonia are constant symptoms and may finally lead to difficulty in coordination There is diminished irritability of muscle to electrical stimulation These symptoms are attributed to the hypercalcemia Many patients with the disease are classified and treated as neuroasthenics prior to the recognition of the true nature of their symptoms

Hyperparathyroidism with renal manifestations may present symptoms exclusively renal and these may have persisted for many years These are symptoms of renal calculus, pyelitis, pyelonephritis with or without gravel Increased thirst, which is attributed to the increased excretion of calcium and phosphorus, is commonly present Polyuria, however, is not always present and it is interesting to note that when it occurs the incidence of stones is less Bone symptoms may be vague or entirely absent Albright, Baird, Cope and Bloomberg¹⁴ in a study of the renal complications of hyperparathyroidism emphasize that all of the symptoms and signs of nephritis may be present They stress the importance of the recognition of the accompanying bone changes in the diagnosis of the underlying hyperparathyroid state in such cases They further point out that with profound kidney damage there is interference with calcium and phosphorus excretion in the urine Albright, Aub and Bauer¹³ report eight instances of hyperparathyroidism discovered as a result of performing routine blood calcium and phosphorus determinations in all patients with urinary calculi

Clinically, hyperparathyroidism may resemble other conditions as osteomalacia, solitary cysts, Paget's disease, senile osteoporosis, solitary benign giant cell tumor, osteogenesis imperfecta, multiple myeloma, metastatic malignancy, renal rickets and basophilic adenoma of the pituitary (Cushing's disease) An excellent discussion of the differential diagnosis is given by Albright, Aub and Bauer,¹³ by Jaffe,¹² and by Gutman Swenson and Parsons¹⁷

Hyperparathyroidism cannot be accurately diagnosed without the demonstration of the presence of biochemical disturbances which occur in the body as a result of the over-secretion of the parathyroid hormone. Of significance are high serum calcium and low serum phosphorus values in the blood. These values may vary from 12.5 milligrams to over 20 milligrams of calcium per 100 c.c. of serum, and from 1.0 to 3.0 milligrams per 100 c.c. of inorganic phosphorus. These metabolic changes are not in themselves diagnostic, for high calcium values may occasionally be observed in multiple myeloma, metastatic carcinoma of bone, and in certain diseases accompanied by hyperproteinemia. Moreover in not a few instances of hyperparathyroidism the inorganic phosphorus may be normal. The most convincing chemical evidence of hyperparathyroidism is the demonstration of alterations in the calcium balance controlled over a period of time on a fixed low calcium diet. A negative balance indicating an excretion of calcium in excess of that ingested strongly supports the diagnosis. Although calcium excretion in the feces varies with the intake, the urinary calcium nearly always maintains an abnormally high level in hyperparathyroidism. In certain instances, however, as in severe nephritis associated with renal insufficiency, the urinary excretion of calcium may be diminished and confuse the picture. In these cases the roentgen-ray evidence of generalized decalcification of bone will constitute a significant diagnostic finding.

Roentgen-ray findings, when they do exist, consist chiefly of deformities, cysts, tumors, fractures and evidence of generalized thinning of bone. This is best seen in the flat bones and in the skull. Occasionally irregular thickening may be observed in the temporal, parietal and frontal bones of the skull, but more commonly there is definite evidence of decalcification. In instances of renal involvement without bony changes, metastatic calcified areas in the kidneys may be present. The most important roentgen-ray finding, however, is a progressive thinning of all bones.

Treatment The medical treatment of hyperparathyroidism is of no value. Diets high in calcium and phosphorus may prevent the decalcification of bone, but increase the incidence of renal calculi. It is generally agreed that vitamin D is of little value. The treatment is surgical and the surgeon may expect a good-sized tumor in cases with marked hyperparathyroidism. But he must be a good surgeon and courageous for one does not always find the tumor at the common site for the parathyroid glands. A search for the tumor may lead him into the anterior mediastinum. It must be borne in mind that removal of a normal parathyroid gland is dangerous and may lead to marked postoperative tetany which may be fatal. The surgeon must also exercise careful judgment in deciding upon how much to remove. For here, as in the thyroid, the decision between a sub-total removal and complete extirpation may affect the future of the patient's life. It must also be borne in mind that parathyroid tumors may be multiple and if the removal of one does not cure the patient a second operation may have to be performed at a later date.

The complication that arises after operation is postoperative tetany. Increased irritability of the muscles, carpo-pedal spasm, positive Chvostek and Trousseau signs may appear within the first 24 hours after the operation. They are accompanied by marked diminution of calcium in the urine and return of the serum calcium to normal or subnormal values. The low values may persist

for weeks and even months after the operation. The control of postoperative tetany is obtained by the administration of calcium by mouth, calcium gluconate intravenously and Collip's parathyroid extract. Calcium in some form must be administered frequently, as it is very rapidly excreted. Eventually a readjustment of the activity of the remaining parathyroid tissue occurs and these symptoms disappear.

The improvement following operation is dramatic. The patient's general appearance changes, lassitude is replaced by a feeling of energy and the bone pains immediately disappear. Changes in bone structure may be observed by repeated roentgenographic examinations. Although these changes do not parallel the marked symptomatic improvement the bones eventually present a normal appearance.

SUMMARY

A case record of adenoma of the parathyroid gland with hyperparathyroidism and renal calculus (calcium stone) is presented. The preoperative diagnosis was based on a history of renal colic for many years, the roentgenographic evidence of decalcification of bone, and the presence of a negative calcium balance with hypercalcemia, hypercalciuria and hypophosphatemia. An adenoma of the parathyroid gland was removed at operation. Prompt recovery from the hyperparathyroid state ensued.

Calcium metabolism studies made before and after operation are recorded.

SUBACUTE BACTERIAL ENDOCARDITIS OF THE MITRAL VALVE PREVIOUSLY RENDERED INCOMPETENT BY INFARCTION OF THE PAPILLARY MUSCLE AND SHORTENING OF THE CHORDAE TENDINAE*

By I I LEMANN, M D, F A C P, *New Orleans, Louisiana*

THE present communication is made as a contribution to the study of two problems first, the production of murmurs in coronary infarction, and second, the pathogenesis of subacute bacterial endocarditis. The occurrence of murmurs and of subacute bacterial endocarditis in relation to coronary infarction have both been repeatedly reported. The significance which I wish to attribute to them in the light of the case to be reported is new.

CASE REPORT

Male, aged 53 (at the time of the attack), suffered a coronary infarction on January 2, 1931. The evidence was convincing. He had pain in his chest and numbness of his arms. The pain in his chest was over the sternum and precordium. The patient did not remain quiet, but was constantly moving about. The pain came on during the night and lasted several hours when he summoned me about 6 a m, January 2. At that time the blood pressure was 180/120 mm of Hg, the heart rate was 80, without any abnormalities of rhythm or sound, A₂ was accentuated. On January 3, the temperature rose to 101°, the pulse to 100, and the respiration to 30. The blood pressure was 175 systolic and 100 diastolic. On January 4, the temperature rose to 101°, the pulse was 100, respiration 20, and the blood pressure was 160/115 mm of Hg. On January 5, the temperature was 100.5°, the pulse 80, and the blood pressure was 135/100. On January 6, the blood pressure was 125/90, and there was a soft systolic murmur at the apex. On January 7, sternal pain recurred during the night, temperature 100.5°, blood pressure 120/90. By January 9, the murmur had changed from the soft character previously described to the "zing" of the Jew's-harp character. The temperature continued to rise to 99 to 99.4°. On January 10, the blood pressure was 90/65 mm of Hg, on January 11 it was 106/75, on January 12, 116/85, and on January 14, 130/95. There was then a systolic murmur at the second left interspace, but it was not musical there as it was at the apex. On January 16, the blood pressure was 116/90 and the heart rate 76, and on January 20, the blood pressure was 130/100. The electrocardiogram made on January 20 showed Auricular rate 80, ventricular rate 80, sinus rhythm. P-R interval, 0.16 sec, Q R S,

0.09 sec Left axis deviation I_{r} inverted In the second lead the T take-off was high and the S-T interval above the iso-electric line Slurring of Q R S in all three leads

In April 1931, he had a slight elevation of temperature again to 101.5° , and with this some bloody sputum There were, however, no abnormalities found in the lungs on physical examination A roentgen-ray report on May 16, 1931 was as follows "Examination of Chest The right diaphragm is well within normal limits The left diaphragm is resting at a level somewhat higher than the right, which reverses the

FIG 1 Infarct of the intraventricular septum involving the papillary muscles of the posterior flap of the mitral valve Subacute bacterial endocarditis attacking the mitral valve

usual position However, the left diaphragm appears to be elevated by a large amount of gas contained in the stomach and colon beneath the diaphragm, probably elevating this The heart shadow measures 5 cm to the right, $11\frac{1}{2}$ cm to the left, or a total of $16\frac{1}{2}$ cm, while half the inside diameter of the chest measures $15\frac{1}{2}$ cm The heart is therefore considered to be 1 cm larger than the standard for comparison The aorta is within normal limits The pulmonary fields show no visible evidence of pathologic change"

In November 1931, he again had some bloody sputum, but throughout 1931, until

the summer of 1932, he felt remarkably well and was quite active, even playing golf without fatigue. In August 1932, he had another febrile attack, with temperature rising to nearly 103° . He was sick nearly two weeks, during which time he again spat blood. The blood pressure had continued to range from 135 to 155 systolic, and from 100 to 110 diastolic. He had been made to lose considerable weight, 25 to 30 pounds, by restriction of intake of food, so that by June 1933 he weighed 143 to 145 stripped, less than he had weighed for 20 years. He had continued to play nine holes of golf without dyspnea or fatigue. This had been permitted in spite of great concern on my part. In December 1933, the blood pressure was 165/125. The electrocardiogram on January 9, 1933 was as follows: Atrial rate 103, ventricular rate 103, P-R interval, 0.17 sec., QRS, 0.10 sec., left axis deviation, slight shift down of S-T₁, slight slurring of R₁ and downward direction of R₂, low T₁₋₂, deep Q₁, P₁ diphasic. On June 9, 1934, the following note was made: "He has continued to play nine holes of golf three times a week. He is never out of breath, walks slowly and ascends stairs slowly. Has no longer any chest pains, only once in five months has he had these pains, and then at night. They passed off after he had eaten a few candies. He considers his heart better, it gives him much less concern. His nerves are in bad shape, in fact throughout the years he had been under very great nervous strain, and has had occasion for worrying a great deal. He has always slept restlessly and suffered much from insomnia, for which it was necessary for him to take amylal frequently."

Beginning on June 19, 1934, he was in bed for 18 days because of fever rising to 102° for which no cause could be found. After he was free of fever for 10 days he was allowed up again, but he never regained his strength, and during July he continued to complain of lassitude. On August 2, it was noted that he had temperature of 99.2° , and he was sent home again to bed. The temperature began to range then from normal in the morning to a maximum of 101° in the evening. No definite cause for the temperature was found until a blood culture, taken on August 11, showed *Streptococcus viridans*. The number of colonies increased rapidly, and on September 23, there were 250 colonies of *Streptococcus viridans* per cubic centimeter of blood. Repeated transfusions of whole blood, 250 c.c. each time, were given at intervals of a week from August 17 to October 18. Although the number of colonies diminished, so that on October 16 there were only two colonies per cubic centimeter of blood, the condition throughout September and October remained about the same except for a progressive loss of weight. There were never any petechiae. The second week in November he had great tenderness of the palms of both hands over the pads at the base of the phalanges, and also on the soles of the feet at the base of the phalanges. This tenderness lasted for a few days. Throughout September, October and November there was great soreness and stiffness of the neck muscles. The spleen was never felt, and there never was any indication of embolism in the spleen or elsewhere. The temperature range throughout September, October and November was low, usually to a maximum of 100.5° occasionally to 101° . On November 12, the temperature rose to 103° , and the next 10 days to his death on November 21 were quite stormy. On November 12, he had a coughing spell, becoming very hysterical. The next night there was a sudden edema of the lungs, and the patient was practically pulseless. The surface of the body was cold and clammy. He was apparently moribund on November 14, 15 and 16, but on November 17, he was better and even oriented at times. The temperature ranged up to 103° . On November 18, 19 and 20, he was in delirium and stupor, practically pulseless. On November 20 and 21, there was dullness throughout râles at the base of the left lung. He died on November 21. Respirations had gone to 60, the temperature to as high as 105° .

I am indebted to Drs. John A. Lanford, Samuel Colvin and Kurt Neugarten for the following notes on the autopsy.

Autopsy Report The body is that of a white male, apparently 50 years of age, approximately 5 feet 11 inches in length, and weighing about 150 pounds. The body shows some evidence of loss of weight, although the fat is still normally distributed. No petechiae are noted. The thorax is well developed and of the sthenic habitus. The abdomen is slightly distended. There are no scars. The left side of the scrotum reveals a left hydrocele measuring about 6 cm in diameter, and containing approximately 50 cc of light straw colored fluid. The extremities show no changes. The cervical and axillary lymph nodes are not enlarged but the inguinal nodes show slight adenopathy.

Peritoneal Cavity The peritoneum is smooth and glistening. There are about 500 cc of straw colored fluid present. The appendix is normal. The urinary bladder is not distended. The spleen is enlarged in size and in its usual location, as is the liver. The other abdominal viscera are in their normal positions. The diaphragm extends to the fifth rib on the right side and the fifth intercostal space on the left. The mesenteric lymph nodes are not enlarged. The stomach and intestines are greatly dilated.

Thoracic Cavity The parietal pleurae are smooth and glistening. There is no free fluid present and only a few recent fibrinous adhesions on the outer side of the lower lobe of the right lung. The right lung shows a large solid area involving almost entirely the lower middle and part of the upper lobes. The left lung shows only patches of pneumonia here and there. The heart is in its usual location but is greatly enlarged.

Heart and Pericardium The parietal pericardium is covered over nearly its whole extent with a light cheesy appearing material. About 20 cc of cloudy fluid containing many small flecks of fibrin are present. The fibrinous exudate is particularly abundant over the right auricle and the great vessels, less so over the left auricle and left ventricle. The heart is considerably larger than normal. It has lost the normal conical shape. There is a moderate amount of fat beneath the epicardium through which the muscle appears as brownish-red in color. Over the right ventricle and to a considerable extent over the posterior aspect of the left ventricle, this brownish-red muscle exhibits irregular areas varying in size shining through the epicardium as islands with a large grayish-yellow center and a pinkish-red periphery (areas of apparent necrosis). At the posterior sulcus longitudinalis there is a large dull ivory white area (3 by 5 cm). This involves chiefly the left ventricle but extends also for a small distance to the right ventricle. Palpation reveals this area to be thinner and less resistant than the rest of the ventricular wall, yet one has the impression that it is more solid—a thin fibrous scar.

The right auricle, somewhat increased in size, is partly occupied by an *ante mortem* thrombus (fibrinous mass) which completely fills up the auricular appendage and extends into the upper half of the auricle. Beneath this exudate the endocardium is partly ulcerated. The tricuspid and pulmonary valves are normal. The tricuspid orifice admits four finger tips. The foramen ovale is closed. The chamber of the right ventricle is also increased in size. Sections through its wall show irregularly scattered areas of necrosis similar to those already described as seen on the external surface of the heart.

The chamber of the left auricle is markedly dilated. The mitral orifice admits two finger tips. Here the endocardium is thick, grayish-white, and the muscle is not to be seen through it. There is an ulceration (3 by 2.5 cm) on the anterior left lateral wall of the chamber. This extends down on to the auricular surface of the mitral valve. On the endocardium above the line of attachment of the posterior mitral flap, there are flat, granular, grayish-pink vegetations with two tongue-like continuations upon the floating part of the valve. These "tongues" reach the free edges of the valve and present a picture resembling a horseshoe. Besides these vegetations on the

auricular aspect of the posterior flap, there are other similar ones toward the aortic flap of the mitral valve, chiefly where the two flaps are joined anteriorly. These vegetations vary from miliary to lentil size and consist of smooth grayish-white fibrinous verrucae upon which pinkish granular punctiform spots are seen here and there. These vegetations continue upon the ventricular aspect of the valve and also for almost 1 cm upon the chordae tendinae of the posterior flap of the valve.

The left ventricular chamber is somewhat ballooned out, this being particularly noted in the posterior part of the interventricular septum corresponding to the region of the fibrous scar previously described. The internal aspect of this area is grayish-red and differs distinctly from the surrounding brownish-red of the rest of the ventricular wall. The endocardium, however, is smooth. The upper corner of the oval shaped area of the scar forms a deep depression in the muscular wall. There, the trabeculae carneae have completely disappeared leaving only small flattened bridges at the base of the scar. Further, one notes a difference in the structure of the anterior and posterior ventricular wall (internal aspect) as well as of the papillary muscles. The anterior papillary muscle and the trabeculae carneae of the anterior wall have their normal shape. The posterior papillary muscle, the base of which is included in the scar, is shortened and appears as a flat strip merging into the ventricular wall. The tips of the papillary muscle can no longer be seen. The thin smooth chordae tendinae are stretched. They hold the posterior flap of the mitral valve down against the posterior wall of the ventricle so that during life only slight movement of this posterior flap could have been possible.

The attached portion of the aorta shows some slight thickening in the sinuses of Valsalva around the orifices of the coronary vessels. The right coronary when opened is found completely thrombosed. The left coronary is thickened and its lumen generally narrowed being represented by a mere pin-point opening. It is free from thrombus formation except in its smaller subdivisions. The aortic cusps are normally thin and smooth. The wall of the left ventricle measures 13 to 15 mm in thickness and on section has a mottled appearance. There are dirty yellow areas surrounded by a brownish-red ring.

Lungs The right lung measures 22 cm in length, 12 cm in width by 6 cm in thickness. The external surface shows a massive area of bluish-black discoloration extending over the entire surface with the exception of a small area along the periphery of the lower lobe and the upper half of the upper lobe. Along these latter areas are small patches of emphysematous tissue. The remainder of the lung is solid and of the consistency of liver, and on section is deep red in color and upon pressure only bloody material escapes, there being no air in this portion. A bloody frothy fluid escapes from the periphery. Weight 750 grams.

The left lung measures 22 cm in length, 11 cm in width by 5 cm in thickness. The external surface is pinkish-red in color and is streaked with areas of bluish-black scattered throughout both lobes. The cut surface is pinkish-red in color for the most part and upon pressure exudes a frothy blood-tinged fluid. There are some small consolidated areas throughout the parenchyma, several of which are somewhat triangular in shape. Weight 425 grams.

Liver The liver measures 20 cm in length, 26 cm in width by 7 cm in thickness. Its external surface is smooth and glistening, and brownish-red in color, mottled with many small areas of yellowish discoloration. Upon section, the organ is typically nutmeg in appearance and generally congested. Innumerable small yellowish-white specks stand out prominently. The organ is very much enlarged. Weight 1615 grams.

Gall-Bladder The gall-bladder is almost collapsed and contains only a small amount of bile. No stones are palpated. The external surface is adherent to the omentum and is torn away with much difficulty. It is pinkish-yellow in color, smooth and glistening except in the adherent areas.

Adrenals The adrenals are pyramidal in shape, measuring 4 to 3 cm. The external surface is slightly lobulated and pinkish-yellow in color. Upon section, the cortex is dirty yellow in color and not well differentiated from the medullary portion.

Kidneys The left kidney measures 12 cm. in length, 7 cm. in width by 5 cm. in thickness. There are several large retention cysts seen externally, extending into the kidney tissue for $1\frac{1}{2}$ cm. in depth. The external surface is lobulated and granular in appearance. The capsule strips with some difficulty revealing a granular pinkish-red congested surface. The cut surface reveals a cortex which is well differentiated and measures from 5 to 7 mm. in thickness. The organ is congested in appearance. There is a large amount of fat in the pelvis. Weight 190 grams.

The right kidney measures 12 cm. in length, 6 cm. in width by 5 cm. in thickness. It varies in no way from the left kidney with the exception that the retention cysts found here are much smaller than in the left kidney. Weight 175 grams.

Pancreas The pancreas measures 20 cm. in length, 4 cm. in width by $1\frac{1}{2}$ cm. in thickness. Its external surface is pinkish-yellow in color and lobulated in appearance. The cut surface is yellow in color and lobulated. The organ shows no gross changes with the exception that it is more flabby than usual. Weight 110 grams.

Spleen The spleen measures 15 cm. in length, 10 cm. in width by 5 cm. in thickness. Its external surface is grayish-red in color and smooth and glistening with the exception of two large raised infarcts which are present at the upper and lower poles respectively. These infarcts are pale pinkish-orange in color and are sharply demarcated from the surrounding tissue. Upon section they are $1\frac{1}{2}$ cm. and 1 cm. in diameter respectively, both exuding a purulent yellow discharge from their bases. The infarcts themselves are necrotic and friable. The remainder of the cut surface of the spleen is deep red and congested in appearance with innumerable small yellowish areas of focal necrosis seen scattered throughout the surface. Weight 300 grams.

Gastrointestinal Tract The stomach is greatly distended with air as are the entire small and large intestines, especially the cecum.

Blood culture, taken at autopsy under sterile precautions, shows the presence of *Streptococcus viridans*.

Anatomical Diagnoses Coronary thrombosis with infarction (old and recent), *Streptococcus viridans* septicemia, subacute bacterial endocarditis, mitral, acute and chronic myocarditis, ante-mortem thrombus of right auricle, pericarditis, fibrinous, lobal and lobular pneumonia, chronic nephritis, multiple infected infarcts of spleen, passive congestion of liver and spleen, hydrocele.

THE SIGNIFICANCE OF MURMURS OCCURRING IN CORONARY THROMBOSIS AND CARDIAC INFARCTION

Murmurs in cases of coronary thrombosis are mentioned by most writers. Paul White,¹ for example, writes "Murmurs may or may not occur, the commonest is that of functional mitral regurgitation due to dilatation—an apical systolic murmur—although at times a sclerotic change involving the base of the mitral valve may result in organic mitral regurgitation. Basal murmurs are less common in coronary disease, an aortic systolic murmur may be found, due to aortic dilatation, in turn usually resulting from an associated hypertension, but sometimes such a murmur is due to aortic stenosis caused by sclerotic involvement of the aortic valve, if this latter process is marked a systolic thrill will be felt over the aortic area and will be transmitted into the neck. An aortic diastolic murmur is much less common but may result from either of the lesions just noted which produce the aortic systolic murmur." Samuel Levine² writes "In almost half of the cases a slight or moderately loud systolic murmur can be heard,

and very rarely an aortic diastolic murmur. This latter finding was present in only one case of this entire series, and he had aortic stenosis and insufficiency. There was not a single instance of mitral stenosis in this group. In about one-half of the cases no murmur whatever could be heard." Castex^{3,4} has described in cases of cardiac infarction murmurs heard during part of systole (telesystolic in contradistinction to holosystolic, heard throughout systole). Castex claims priority in having related merosystolic souffles to infarct of the myocardium. In his first article he attempts to explain the pathogenesis of the souffle as follows: "According to these findings it is logical to admit that the merosystolic souffle originates by vibration of the blood column upon contraction of the infundibular region of the left ventricle, due to the fact that the blood column finds itself in zones of different dimensions as a result of the infarct which placed a zone of that region in such a manner as to make contractions impossible. This theory explains the merosystolic souffle in the two patients and in turn is firmly based on it." In his second communication Castex refers to the experiments of Bondi who "arrived at the conclusion that most if not all of the cardiac souffles were the result of the vortex action of the blood column."

"According to the conception of Bondi there exists not merely one source for the souffles but there are many locations where the souffles may be produced. They may be distributed over the greater part of the internal ventricular wall. These locations are particularly numerous in the apex region of the ventricular cone." DiCio and Battio⁵ report a case of painless coronary occlusion in which the diagnosis was based chiefly on the finding of a merosystolic (meso- and telesystolic) souffle. The diagnosis was confirmed at autopsy. Hyman and Parsonnet⁶ write "About one half of the patients suffering from acute coronary thrombosis exhibit cardiac murmurs. These murmurs are usually systolic in time but occasionally a diastolic blow may be heard at the base of the heart. The mechanism responsible for the establishment of these murmurs apparently is concerned with the dilatation phenomena of the heart muscle encompassing the valvular orifices. For this reason the murmurs will vary not only in their intensities but also in their duration and time factors. Indeed, it is not uncommon to observe many alterations in these three characteristics throughout but a single day." "We have not been able to draw any definite conclusions in regard to prognostic information to be derived from a close study of the murmurs developing for the first time during a coronary attack. At the same time, when such murmurs are discovered and when these show characteristic alterations at each succeeding examination, certain information may be secured in regard to the state of the heart muscle. Of all the various phenomena developed by the coronary thrombosis syndrome murmurs are unquestionably of the least importance." It will be noted that after the murmur in my case changed from a soft blowing character to one with the "zwing" of the jew's-harp there was no further change.

Dr. Fred Smith⁷ says "The damage to the papillary muscles and the mitral valve structures is an important feature in the sclerosis of the coronary arteries. The papillary muscles are likely to be involved by the occlusion of either of the main branches of the left coronary artery. The changes in these structures contribute to the alteration in the first heart sound at the apex and to the production of the systolic murmur frequently heard in this location." It occurred to

me, in considering the sequence of events in my case, that a reasonable explanation would be the location of an infarction at that point in the ventricular wall which would involve the papillary muscle, and I pictured to myself that an infarction at this point with resultant necrosis and connective tissue replacement must necessarily result in shortening of the chordae tendinae and limiting the closure of the mitral valve. We would thus have a mitral regurgitation due to organic disease though not of the mitral valve itself. This mental picture and *intra vitam* diagnosis of infarction involving the papillary muscles of the mitral valve was proved at autopsy to be correct.

SUBACUTE BACTERIAL ENDOCARDITIS COMPLICATING CORONARY INFARCTION

White¹ lists subacute bacterial endocarditis among the complications of coronary disease. "In addition to such complications as coronary thrombosis, cardiac aneurysm, cardiac rupture, congestive failure, heart-block, and other arrhythmias, and embolism from intracardiac thrombosis, coronary disease is frequently accompanied by hyperpiesia and general arteriosclerosis, sometimes by chronic rheumatic valvular disease, diabetes, nephritis, and cerebral hemorrhage or thrombosis, and less often by luetic aortitis, thyroid disease (either thyrotoxicosis or hyperthyroidism), bacterial endocarditis, and congenital defects." The sequence in which the relationship of the two conditions is usually thought of is embolism of the coronary artery due to subacute bacterial endocarditis. It is believed that the present report is the first of an implantation of subacute bacterial endocarditis upon a heart previously damaged by infarction. It is chiefly held that subacute bacterial endocarditis occurs only in hearts in which the valves are already abnormal by reason either of a congenital anomaly or of previous inflammatory disease. In the present case the mitral valve attacked by subacute bacterial endocarditis was neither anomalous, nor had it been the site of a previous inflammatory process. Apparently, therefore, a perfectly smooth and normal valve, when handicapped by congenital anomaly or by abnormal attachment (as for example shortening of the chordae tendinae due to infarction), falls easy victim to subacute bacterial endocarditis.

I wish to point out, too, the difference between my case and those reported by C Magarinos Torres² who divides his cases of parietal endocarditis into two large groups. In one of these groups parietal endocarditis is associated with valvular disease. This is what he calls valvulo-parietal endocarditis. In the other group the parietal endocarditis occurs with intact valves. This he terms genuine parietal endocarditis. In the case reported here subacute bacterial endocarditis attacked the smooth but handicapped mitral valve.

SUMMARY

- 1 A case of coronary thrombosis is reported in which on the basis of a systolic murmur a diagnosis of infarction involving the papillary muscle was made. This diagnosis was substantiated at autopsy.

- 2 It is suggested that the occurrence of murmurs may be used as an additional means of locating the exact point of infarction on the ventricular wall.

- 3 The handicapped mitral valve, though free of any previous inflammatory disease and of congenital anomaly, later became the site of subacute bacterial endocarditis.

DIABETES REFRACTORY TO INSULIN, WITH REPORT OF A CASE

By SAMUEL S ALTSHULER M D F A C P and S E GOULD M D,
Eloise, Michigan

IN reviewing the literature on this subject one is struck by the fact that many cases are spoken of as "insulin refractory" which might better be termed "insulin resistant," that is, cases in which an unusually large amount of insulin must be administered in order to control the glycosuria. The case which we are reporting is truly insulin refractory, no relationship is demonstrable between the amounts of insulin given and the subsequent glycosuria.

In most instances the physiological responses to insulin are predictable, but the mechanism of its action is still problematical. The proper understanding of this mechanism is reserved for some time in the future when the etiology of diabetes mellitus shall be clear.

The theory that diabetes is the result of a functional disorder of the pancreas is based on the work of two groups. In 1889 Von Mering and Minkowski¹ showed that extirpation of the pancreas produces diabetes. In 1922 Banting and Best² in McLeod's laboratory demonstrated that diabetes may be controlled by the injection of insulin which is derived from the extracts of pancreatic islands.

Pathologically, typical and constant lesions characteristic of diabetes have never been found. The changes noticeable in the diabetic pancreas may also be present in the non-diabetic pancreas. Even in fatal cases of diabetes, where no pancreatic lesions are found, extraction of the gland shows the presence of insulin sufficient to continue life for several weeks. This fact and others have been advanced as evidence that one or more of the other organs in the body must have a part in the production of diabetes. The glycosuria may be due to secondary functional changes in the pancreas, or the action of the pancreas-produced insulin may be nullified by some other substance produced elsewhere in the body.

Although the hyperfunction of the thyroid has been said to impair the func-

From the Departments of Medicine and Pathology of the William J Seymour Hospital, Eloise, Michigan, and the Department of Pathology of Wayne University, College of Medicine, Detroit

tional ability of the islands of Langerhans, clinically we have seen hypothyroidism co-exist with diabetes. The hypersecretion of the adrenal medulla has also been mentioned as a possible cause of diabetes, but Houssay and Lewis³ showed that diabetes in animals follows its usual course in the absence of the adrenal medulla.

There is far more evidence to involve the pituitary than either of the mentioned organs. Colwell⁴ has written a splendid review of the literature upon the relation of the hypophysis to carbohydrate metabolism, and Collip⁵ more recently has pointed out the experimental, chemical, and clinical evidence for the presence of a diabetogenic factor originating in the pituitary gland. The mutually antagonistic actions of pituitary extract and insulin have been well demonstrated.

In the treatment of diabetes, when the insulin requirement exceeds the anticipated amount, we must consider the presence of a complicating condition. Pollack⁶ has given a very good summary of the possibilities. Cases completely refractory to insulin, however, are not common and there are only three reported in the literature with autopsy findings. Two of these cases had pituitary tumors, the third, other diagnosable complications. Acromegaly in which there is an acidophilic adenoma of the pituitary is frequently associated with glycosuria.

Of the three cases mentioned, Mahler and Pasterny⁷ report one showing inactivity of insulin in an acromegalic with glycosuria. A tumor of the hypophysis was found at autopsy.

Ulrich⁸ reports a patient with a pituitary adenoma who had two attacks of pronounced glycosuria with hyperglycemia. The first period extended over a month and disappeared spontaneously. The second occurred two years later and continued until the death of the patient. Insulin had little effect on the level of the blood sugar during both of these periods.

The third case reported by Chailton,⁹ was complicated by pulmonary tuberculosis and luetic infection. The diabetes was relieved by anti-luetic treatment and the patient died of the tuberculosis.

The following case is reported because we feel that it helps to establish the relationship of the pituitary to carbohydrate metabolism.

CASE REPORT

Mrs. M. S., colored female, aged 35, was admitted to the William J. Seymour Hospital on August 9, 1933, complaining of blindness, headaches, and "diabetes."

The patient's "diabetes" was discovered incidentally at the Henry Ford Hospital in August 1928, when she was admitted for a laceration of the dorsum of the left hand and division of the tendons of the extensor digitorum communis and extensor pollicis. The laceration was repaired, the patient was placed under a diabetic regime, and insulin was prescribed, evidently she did not follow the diabetic treatment as she did not return after the laceration was healed.

She was next seen in the Out-Patient Clinic at the Detroit Receiving Hospital on August 25, 1931 complaining of headache and blurring of vision. Examination showed a markedly decreased acuity of vision in the right eye with light perception only in the left eye. Examination of the fundi was negative. She was seen about once a month, and after one year the vision in the right eye was also reduced to light perception only.

The etiology of the amblyopia was not determined. The patient's blood Wassermann and Kahn were negative, and roentgen-rays of the skull in 1931 and again in 1932 showed no signs of an intracranial lesion. Examinations of the fundi remained

negative. She was treated with diet and insulin but her diabetes was never controlled.

The patient said that during this time she had symptoms of polydipsia, polyuria and itching around the genitalia.

At the time of her admission to the Seymour Hospital, the patient had only light perception and was complaining of frequent distressing headaches.

In her catamenia, menses began at 13 years and were of the regular 28-4 day type. Her last menstrual period occurred two years before. Her husband and two children, 11 and 9, were all living and well.

The examination revealed a well-developed, well-nourished young colored female with constant grimacing of the face and rolling of the eyes. Both pupils were widely dilated and showed no reaction to light or accommodation, there was no evidence of cataracts. The fundus examination showed both discs to be well defined and pale although they did not appear atrophic. The arteries were small, with very little evidence of arteriosclerosis. There were no exudates or hemorrhages. The thyroid was not enlarged. The lungs were clear. The heart was normal and the blood pressure 110 mm of mercury systolic and 70 diastolic. The abdominal examination was negative. There was no edema of the extremities. The tendon reflexes were not obtained. The neurological examination was otherwise negative.

The laboratory examinations showed. Urine, slightly cloudy and acid with a specific gravity of 1.008 to 1.025, albumin, trace, sugar, + + + +, sediment (not catheterized), many white blood cells.

Blood count (August 10, 1933) hemoglobin, 12.9 grams, red blood cells, 4,500,000, white blood cells, 4,150, polynuclear neutrophils, 37 per cent, lymphocytes, 62 per cent, monocytes, 1 per cent. Blood calcium, 9.5 mg per cent. Blood Kahn, negative.

Spinal fluid (Dec 20, 1933) Kahn + + + +. Anti-luetic treatment in the form of iodides and bismuth was given and the spinal fluid test repeated on April 4, 1934, showing 6 cells, globulin, trace, sugar, 65 mg per 100 cc, colloidal gold curve 1111221000, Kahn negative.

The glucose tolerance test on January 3, 1934 showed fasting blood, 286 mg per cent, first hour 435, second hour 370, and third hour 350 with sugar in the urine in every specimen.

Roentgen-ray of the skull on December 9, 1933 revealed "Sella within normal limits. No evidence of erosion. No evidence of increased intracranial pressure."

The patient was placed on a diabetic diet containing carbohydrate 100 gm, protein 70 gm, fat 150 gm. An attempt was made to adjust the insulin as shown in figure 1, gradually increasing it to 85 units daily divided into four doses. This, however, did not desugarize the patient, and her blood sugar ranged between 250 mg and 322 mg per 100 cc. After 13 weeks with no success whatever in controlling the diabetes, the insulin was discontinued for two weeks, during which period the urine showed a constant glycosuria and became positive for acetone and diacetic acid and the blood sugar ranged between 272 mg and 344 mg per 100 cc. The total absence of insulin made no difference in the diabetic state except for the development of a ketosis.

Insulin was started again and given every four hours throughout the 24, totaling 120 units daily for one week. There was still a glycosuria and the blood sugar ranged from 192 mg to 286 mg per 100 cc. Because the patient objected to such frequent insulin injections, we administered 110 units daily in four doses for six weeks. The urine showed a glycosuria and the blood sugar ranged from 235 mg to 286 mg per 100 cc. The insulin was discontinued again for two weeks during which time the urine again showed positive acetone and diacetic acid with the glycosuria. The blood sugar ranged from 323 mg to 333 mg per 100 cc. Insulin was resumed in three daily doses totaling 96 units. This was continued for four weeks during which time the acetone and diacetic acid disappeared and glycosuria persisted with the blood sugar ranging from 216 mg to 392 mg per 100 cc.

During this entire period the patient complained of frequent severe headaches. Because of the lack of choking of the discs or evidence of increased intracranial pressure, it was deemed advisable to investigate the head somewhat further. An encephalogram was therefore done on April 21, 1934 by Dr. F. Schreiber. The roentgen-ray showed "No evidence of disturbance of the symmetry of the air-filled ventricular system."

FIG 1

Following the performance of the encephalogram the patient vomited frequently and complained of severe headaches. Two days later she became unconscious and died on April 23, 1934. There were no clinical evidences of diabetic coma. The urine showed a one plus acetone. Blood sugar before death was 450 mg per 100 c.c.

PATHOLOGICAL REPORT

External Appearance The body is that of a well developed and nourished, obese, middle-aged, colored female, 165 cm in length. The hair is black and thick. The eyes and teeth are negative. The breasts are well developed and firm. The chest is

well developed. The abdomen is moderately distended with gas. The extremities and external genitalia are negative.

Cranial Cavity The meningeal vessels are congested. On lifting up the frontal lobes of the brain a circumscribed oval tumor, measuring 5 cm in length, 3 cm in width and 3 cm in depth is seen resting upon and adherent to the pituitary gland,

FIG 2 Sagittal view. Note cystic structure with fibrous wall, old blood content. Hypophysis attached below.

apparently attached to the stalk and posterior lobe. The tumor lies in relation to the following structures, all of which are compressed by it: the optic chiasm superior-anteriorly, the corpus callosum superiorly, and the cerebral peduncles and pons posteriorly. The arteries of the Circle of Willis are in close apposition to the tumor. Careful examination does not reveal origin of the tumor from any of the regional vessels. Upon sagittal section the tumor is seen to be free above and adherent to the pituitary below. It is cystic in nature, being distended by a dark, brownish-red, sanguineous fluid which is under moderate pressure. The walls of the cyst vary from 0.5 to 3.0 mm in thickness, are tough and fibrous, and in some places contain bits of lime. After escape of the fluid content a soft friable, almost crumbly dark brownish-red substance is seen. This arises from the inner lining of the cyst, over an area 1.5 cm in diameter. The remainder of the inner lining is quite smooth, and contains a number of scattered pinpoint sized spots of a shining colorless material, which upon examination under the microscope are seen to contain cholesterol crystals. The pituitary gland is compressed and flattened. The sella turcica is definitely deepened and ballooned beyond normal limits. The brain weighs 1150 gm.

Thoracic Cavity Both lungs are free from adhesions. The left lung weighs 400 gm and shows a smooth pleural surface. There is superficial congestion and edema. The cut surface is deep red in color and on pressing exudes a foamy sanguineous fluid. The bronchi are injected and the pulmonary vessels congested. The right lung weighs 400 gm and shows similar changes. The heart is soft and small, weighing 250 gm. The myocardium is congested and flabby. The left ventricle wall

measures 10 to 12 mm in thickness, the right ventricle wall 3 to 4 mm. The valves are negative. The coronary vessels and aortic arch are negative. The trachea and larger bronchi are injected. The thoracic and abdominal portions of the aorta are negative.

FIG. 3. Suprasellar hematoma with fibrous cyst wall compressing hypophysis.

Abdominal Cavity. The panniculus measures 5 to 6 mm. The entire bowel is distended with gas. The spleen weighs 125 grams. The capsule is grayish-blue in color and smooth. The parenchyma is soft and congested. The adrenals are of normal appearance. The kidneys each weigh 125 gm. The capsule of the left kidney strips easily exposing a smooth external surface. The cut surfaces are congested, the parenchyma very soft. The right kidney shows similar changes. The bladder, uterus, oviducts and ovaries are negative. The liver weighs 1200 gm. Externally it is smooth. The cut surface is pale brown and shows dilated central veins and irregular areas of fatty infiltration. The gall-bladder is distended with bile. The biliary tract and ampulla of Vater are negative. The esophagus, stomach, duodenum and small and large intestines are congested. The pancreas is normal in appearance.

Gross Diagnosis Suprasellar cyst (Craniopharyngioma?) Parenchymatous degeneration of heart liver and kidneys Generalized passive congestion Moderate intestinal distention

FIG 4 Wall of hematoma showing cholesterin clefts and compressed hypophysis

Cause of death sudden increase of intracranial pressure resulting in compression of circulatory and respiratory centers by the tumor mass

MICROSCOPIC EXAMINATION

The soft, friable, dark brownish-red substance within the cyst is made up of old blood and fibrin with a few scattered degenerating cells and contains a number of large cholesterin clefts. At the base of attachment to the cyst wall, this blood takes a brighter red stain. The cyst wall is made up of fibrous tissue which shows areas of fibroblastic proliferation on the inner surface, and a few areas of calcification. There are a number of regions on the inner surface showing foreign body reaction and focal accumulations of chronic inflammatory cells, consisting mainly of lymphocytes. One-fourth to one-half of the thickness of the cyst wall is made up of a

layer of epithelial cells of the anterior lobe of the hypophysis. This layer of cells lies toward the peripheral surface of the cyst wall, and consists mainly of chromophobic cells and acidophilic cells, among which the latter are prominent. Numerous chromophobic cells are seen to be undergoing degeneration, the cytoplasm having a ground glass appearance, and the nucleus being pale staining or absent. Many of the cells are disintegrating, while the outlines of others may still be recognized. In some areas groups of degenerating chromophobic cells have a foamy appearance. Due to degeneration of these cellular elements, the stroma is rendered prominent. Within the stroma, as within the fibrous tissue of the remainder of the cyst wall, there are a number of deposits of blood pigment.

The inner surface of the cyst shows no epithelial lining, and no suggestions of enamel or keratin materials.

These sections were reviewed by Dr. Carl V. Weller, Professor of Pathology, University of Michigan, whose interpretation follows: "In my opinion this is not a neoplasm. Neither is it a developmental cyst. The cystic structure here is essentially an old hematoma with a marked deposition of cholesterol and a foreign body giant-cell reaction about the cholesterol crystals. The nests of cells in the surrounding connective tissue are compressed cells from the anterior lobe and pars intermedia of the pituitary. This might well have been an aneurysm of the internal carotid artery or of the cavernous sinus or some other vascular structure, or an old hemorrhage."

SUMMARY AND COMMENT

This patient presents an example of diabetes entirely refractory to insulin. During the 34 weeks she was under observation the hyperglycemia and glycosuria had no relation to the amount of insulin administered. The total omission of insulin, however, resulted in a ketosis. This failure of insulin action suggests that the diabetes was not due to a dearth of insulin but that there was some factor present which had an inhibitory or antagonistic effect on both the endogenous and the exogenous insulin. At autopsy a large suprasellar cystic hematoma was found compressing the hypothalamic structure, including the anterior and posterior lobes of the hypophysis. This pathological finding points to the pituitary as the source of the antagonistic substance.

Whether this antagonistic effect is a direct one acting through the blood or on the tissue cells or on the liver is a matter for speculation and investigation. In this case no abnormal adrenal or thyroid factors were present either clinically or pathologically to suggest that the pituitary effect had come indirectly through these glands.

We are led to agree with Ulrich that the failure of insulin to produce its expected result in cases of glycosuria warrants consideration of the presence of a hypophyseal disturbance. The refractoriness to insulin may thus be considered as a diagnostic sign of the presence of a lesion in this region.

EDITORIAL

SURGEON GENERAL CUMMING RETIRES FROM ACTIVE DUTY

THE retirement, on February 1, of Dr Hugh S Cumming, the fifth Surgeon General of the U S Public Health Service, marks the active conclusion of the distinguished career of an eminent sanitarian and public health leader Following his graduation from the University of Virginia in 1893, Dr Cumming entered the career corps of the Public Health Service (then called Marine Hospital Service) in 1894

His early work consisted of a variety of assignments, including epidemic duty during yellow fever outbreaks and outbreaks of smallpox He served at important maritime quarantine stations during the height of several yellow fever epidemics, and later served a tour of duty in the Orient Subsequently he was placed in charge of studies of Stream Pollution Investigations with which he was occupied for a period of several years

When Dr Cumming was appointed Surgeon General of the Public Health Service in 1920, he entered that important office with a background of experience that was most valuable in meeting the many perplexing problems that confronted him During the sixteen years that he served as Surgeon General of the Public Health Service he gave to that organization, as well as to the public health profession of the United States, an able leadership

Several important and outstanding achievements mark the four terms that Dr Cumming served as Surgeon General Among these may be mentioned the following

(1) The reorganization of the hospital work and expansion of the hospital facilities of the Public Health Service to meet the emergency of temporarily caring for ex-service men and women who were beneficiaries of the Veterans Administration

(2) The completion of the National maritime quarantine system by securing transfer to Federal control of the last State-owned quarantine stations in operation, which were located at the port of New York and at several ports in the State of Texas

(3) The establishment of a National Leprosarium for the care of lepers in the United States

(4) The successful control of outbreaks of bubonic plague at several ports

(5) The development and expansion of important research in field investigative activities of the Public Health Service

(6) The improvement and development of international relations and cooperation in public health affairs

Dr Cumming had the unusual distinction of serving as Surgeon General under five presidents

The Public Health Service is one of the oldest medical establishments in the Federal Government. Its origin dates from an Act of Congress approved by President John Adams on July 16, 1798. Until 1870 the principal functions of the Service were hospital care for American merchant seamen, and this work was conducted by the Treasury Department through local physicians. The first Surgeon General, Dr. John M. Woodworth, took office in 1871, and served for a period of eight years. He was succeeded by Dr. John B. Hamilton, who served for a period of twelve years. The third Surgeon General was Dr. Walter Wyman, who administered the work of the Service for a period of twenty years. Dr. Rupert Blue next served as Surgeon General for a period of eight years. Dr. Cumming, the fifth Surgeon General of the Public Health Service, served for sixteen years as administrative head of his organization.

Dr. Cumming became a Fellow of the American College of Physicians in 1923. His official duties interfered with his active participation in the annual meetings but he showed at all times a deep interest in the College. On the occasion of the Clinical Sessions in Baltimore he was instrumental in arranging as a special feature a day in Washington which included a most interesting program by members of the United States Public Health Service. Dr. Cumming was a member of the Board of Governors of the College for many years and was responsible for the proposal of a number of the officers of the Public Health Service for membership.

The medical profession and all persons interested in public health work view with extreme satisfaction the work accomplished by Dr. Cumming while serving as the head of the Public Health Service and the leader of the public health profession in this country. His ability and achievements were recognized not only throughout the United States but abroad, as he served as a member of the Health Section of the League of Nations, a member of the Permanent Committee of the International Office of Public Health, Paris, and as Director of the Pan American Sanitary Bureau. In his retirement from active service, the congratulations and best wishes of the medical profession attend him.

REVIEWS

Clinical Laboratory Methods By PAULINE S. DIMMITT, Ph G 156 pages, 15 × 22 cm F. A. Davis Company, Philadelphia 1934 Price, \$2.00

This small book presents very concisely the most used methods of clinical pathology, bacteriology, and blood chemistry. It is composed of 148 pages, and the author has divided it into 18 chapters. The methods described are those in common use, most of them having been subjected to long and critical tests. The tests are described in simplified terms, and it has the added advantages of illustrations. The book should be of the greatest value to those who wish to perform some of the most frequently used laboratory methods which are described by the author.

J. H.

Gynecology By BROOKE M. ANSPACH, M.D. Fifth Edition 832 pages, 19 × 26.5 cm J. B. Lippincott Company, Philadelphia 1934 Price, \$9.00

The fifth edition of Anspach's textbook of Gynecology is an excellent single volume work, meeting the needs of the teacher, student and practitioner. This edition is radically changed, for in order to include many of the newer ideas in regard to endometriosis, uterine bleeding, endocrine disturbances, etc., the text had to be altered and many sections re-written.

The plan of presentation follows, in a general way, that laid down in the earlier editions. The opening chapters deal with embryology, anatomy and physiology of the generative organs, and are followed by a section devoted to examinations of the genito-urinary organs and the lower intestinal tract. The following twelve chapters are devoted to a discussion of the injuries of the pelvic floor, mal-positions of the uterus and the diseases of the external and internal generative organs, all being presented in a thorough and comprehensive manner. The chapters on ectopic pregnancy and ovarian tumor are of special interest. In addition to the affections of the generative organs, disorders of the urinary and intestinal tract are next taken up, their presentation being brief but adequate. The remaining sections are devoted to a discussion of various subjects, including backache, sterility, endocrine and menstrual disorders, irradiation therapy, pre- and post-operative preparation of the patient.

This treatise on gynecology is a practical work, clearly and concisely presented, based on the mature personal experiences of the author and on the knowledge obtained from the outstanding literary contributions of the world. The numerous illustrations, some being in color, are well selected and executed, adding greatly to the elucidation of the text. A sufficiently complete bibliography is found at the end of each chapter, which will be of aid to those desirous of more detailed information on the subject.

This work should prove of marked value to the student and practitioner, and is highly recommended.

J. M. H., JR.

Benjamin Rush, Physician and Citizen By NATHAN G. GOODMAN 421 pages, 16 × 23.5 cm University of Pennsylvania Press, Philadelphia 1934 Price, \$4.00

A solid, well documented account of the life and times of the first great physician of this country. The author deserves the gratitude of all who have been interested in the many-sided life of this medical man who was not only a medical educator, a professor of chemistry, a founder of temperance and antislavery societies, the first American psychiatrist, but also a great patriot and a courageous moulder of public

opinion in the Revolutionary period. A man of strong opinions, not unmixed with obstinacy, he made many enemies and had a historic falling out with Washington himself.

The author devotes separate chapters to various aspects of Rush's career. The account of the yellow fever epidemics is of particular interest. As a biographer the author does not yield to the modern temptation to dramatize the subject and the scene. But, if at times his narrative seems a little plodding, it is never dull and the reader feels that he is reading history and not journalism.

M C P

Diseases of the Heart. By JOHN COWAN, B A, M D, D Sc, FR F P S, and W I RITCHIE, O B E, M D, F R C P E, F R S E, with a chapter on The Occular Manifestations of Arterial Disease by ARTHUR J BALLANTYNE, M D, FR F P S. Third edition. vi + 631 pages, 15 × 23 cm, 335 illustrations. William Wood and Co., Baltimore. 1935. Price, \$9 00.

This volume is not written in a particularly clear or concise fashion, and at times it seems rather disconnected. Too many briefly reported clinical cases are used to illustrate the text, often they do not particularly illuminate the point in question, and occasionally, in the reviewer's opinion, unwarranted deductions are made from such cases. There are many references to the extensive literature concerning the heart, and controversial matters are introduced without discussion adequate for a textbook. On the other hand some important viewpoints are not represented at all. High blood pressure and arteriosclerosis are not clearly separated, and there is no chapter on the former condition. In the therapeutic procedures considered will be found some which in this country are largely only of historic interest.

W S L, JR

What You Should Know about Heart Disease. By HAROLD E B PARDEE, M D. Second edition. 127 pages, 13.5 × 19.5 cm. Lea and Febiger, Philadelphia. 1935. Price, \$1 50.

This small volume is intended to help a heart patient understand his disease. It includes an explanation of the physiology and anatomy of the heart, discussions of various types of heart disease, including the arrhythmias. Symptoms are explained and there is discussion of the outlook for a patient with heart disease. Treatment is described, including drugs. The book is recommended to the attention of physicians who feel it desirable for certain heart cases to be more fully informed concerning heart disease.

W S L, JR

Krebs—im Lichte biologischer und zugleich anatomischer Forschung I Band. By JOSEPH LARTSCHNEIDER, M D. Franz Deuticke, Leipzig and Wien. 1934.

This little volume of 192 pages and 48 illustrations is the first of a series of small books on cancer, written by Dr J Lartschneider, giving his experiences and studies over a period of forty years. The approach, as the title indicates, is from biological and comparative anatomical research.

The author gives an historical review of cellular pathology and compares it with the older theory of humoral pathology. He emphasizes that the cancer problem is still unsolved by cellular pathology and compares the attempt to explain cancer by this means to an architect who attempts to build a building with laborers only and without material. Humoral pathology which dominated the medical world for so many centuries, he likens unto an architect who attempts to build a building with material only.

and without labor. It is fortunate that humoral pathology came in contact with cellular pathology and thus collapsed. He warns, however, that cellular pathology dominates scientific medicine to the exclusion of other influences.

With these thoughts in mind the author discusses in the first volume various aspects of the problem of epidermal cancers (Ectodermkrebs). There are 13 chapters in all, the first being on the natural history of animal skin, giving also detailed consideration of human skin. The other chapters deal with such subjects as Strict Limitation of the Concepts of Epithelium, Waldeyer's Theory of Cancer, Physiological Epithelial Fusion and Physiological Bone Fusion, Rickets, Tooth Enamel and the Work Mode of Enamel Cells during Attacks of Rickets.

All of these subjects are presented in an interesting and new light, but the work is somewhat difficult to read on account of its intense detail. It is, no doubt, a definite contribution to the cancer problem.

A second volume in two sections has been received which will be given notice in a subsequent review.

G E W

COLLEGE NEWS NOTES

NLW LIFE MEMBERS

Dr Herman O Mosenthal (Fellow), New York City and Dr Carl H Gelenthien (Fellow) Valmoia N M, have recently become Life Members of the American College of Physicians

GIFTS TO THE COLLEGE LIBRARY

Dr J C Geiger (Fellow), Director of Public Health of the City and County of San Francisco—a copy of the manual entitled "Handbook of Accepted Remedies, Symptoms and Treatment of Poisoning Diagnostic Procedures, and Miscellaneous Information" This manual was prepared by Dr Geiger to serve as a guide in his department as well as for the use of the general profession

Acknowledgment is also made of the following gifts

Dr Linn J Boyd (Fellow), New York, N Y—a translation of Prof August Bier's "Contributions to the Physiology and Pathology of Circulation"

Dr Joseph Hajek (Fellow), New York, N Y—two reprints

Dr Carl R Howson (Fellow), Los Angeles, Calif—one reprint

Dr Frederick R Taylor (Fellow), High Point N C—one reprint

Dr Hyman I Goldstein (Associate), Camden, N J—one reprint

STATE MEETING OF BALTIMORE MEMBERS

Under the Governorship of Dr Henry M Thomas, Jr, Maryland members of the American College of Physicians conducted a state meeting at Baltimore on April 8, 1936 The program opened with a reception in the Board Room of the University Hospital, followed by a group of clinics in the Gordon Wilson Hall of the University Hospital and a dinner at the Hamilton Street Club The clinical program consisted of the following papers

"Pneumothorax Treatment of Pneumonia," Dr Harry M Stem, "A Case of Hair Dye Poisoning," Dr Raymond Peters, "Conditions Simulating Coronary Thrombosis in the Electrocardiographic Findings," Dr William S Love, Jr, "Hypertension Associated with Renal Tumor," Dr J Edmund Bradley, and "Multiple Apical Cavitations," Dr M C Pincoffs

At the dinner informal talks were given by Dr Sydney R Miller, past President of the College, by Dr M C Pincoffs Editor of the ANNALS OF INTERNAL MEDICINE, and by four or five other Fellows of the College The meeting was voted a great success and plans are being made to hold the next meeting in October 1936, at the Maryland State Tuberculosis Sanatorium at the invitation of Dr Victor Cullen (Fellow)

Under the Presidency of Dr Chesley Bush (Fellow), Livermore, and the Chairmanship of Dr Harold G Trimble (Fellow), Oakland, the California Tuberculosis Association held its annual meeting in Sacramento April 2 to 4, inclusive Dr J A Myers (Fellow), associate professor of preventive medicine in the Medical and Graduate Schools of the University of Minnesota, presented a paper entitled "The Contributions of Organization" Dr Sidney J Shipman (Fellow), San Francisco, delivered a paper, "Tuberculous Stenosis of the Bronchus," and Dr Edward Hayes

(Fellow), Monrovia, delivered a paper, "Relief Problems and Tuberculosis Control from the Viewpoint of a Physician" Other members of the College who officially appeared on the program as discussants of papers included Dr Benjamin W Black (Fellow), Oakland, Dr F M Pottenger (Fellow), Monrovia, Dr Samuel Hurwitz (Fellow), San Francisco, Dr Charles L Ianne (Associate), San Jose, Dr Mumford Smith (Fellow), Los Angeles, and Dr W C Voorsanger (Fellow), San Francisco

The Illinois Tuberculosis Association held its twenty-seventh annual meeting at Decatur, April 6 to 7 Dr D O N Lindberg (Fellow), superintendent and medical director of the Macon County Tuberculosis Sanatorium, delivered a paper on "The Role of the Chest Roentgenogram in Tuberculosis", Dr Robinson Bosworth (Fellow), superintendent and medical director of the Rockford Municipal Sanatorium, "Essential Considerations Affecting the Selection of Patients Who May Profit Most from Sanatorium Treatment, and Primary Reasons for Eliminating Certain Groups from the Sanatorium" Dr Gerald B Webb (Fellow), chief of medical staff, Sunnyside Sanatorium, Colorado Springs, Colo., delivered the banquet address, "An Outline of the History of Tuberculosis" Dr Cecil M Jack (Fellow), chairman of the Macon County Tuberculosis Sanatorium Board, presided at a luncheon and Dr F M Meraner (Fellow), President of the Peoria County Tuberculosis Association, presided at the medical session

Dr Austen Fox Riggs (Fellow), Stockbridge, Mass., has been appointed to the staff of the Williams College health department at Williamstown

Dr Sigmund S Greenbaum (Fellow) has been advanced from associate professor to professor of dermatology and syphilology, University of Pennsylvania Graduate School of Medicine

The following Fellows appeared on the program of general assemblies of the eighth annual spring conference of the Dallas Southern Clinical Society, March 16 to 19

Dr Francis G Blake, New Haven, Conn., "Treatment of Lobar Pneumonia", Dr Alan G Brown, Toronto, Ont., "Meeting the Nutritional Requirements of Infancy and Childhood", Dr Byrl R Kirklin, Rochester, Minn., "Diagnosis of Early Pulmonary Tuberculosis", and Dr John A Kolmer, Philadelphia, Pa., "Susceptibility, Immunity and Vaccination in Infantile Paralysis"

During February, at the regular clinical pathologic conference in the Peter Bent Brigham Hospital, Boston, Dr Henry A Christian (Fellow), Hersey professor of the theory and practice of physic at Harvard Medical School and physician-in-chief of the Peter Bent Brigham Hospital, was presented with a volume of medical papers dedicated to him by his former students, colleagues and house officers, as a token of affection on his sixtieth birthday Dr Francis G Blake (Fellow), Sterling professor of medicine at Yale University School of Medicine, New Haven, made the presentation

Dr Paul P McCam (Fellow), Sanatorium, N C., addressed the thirty-second annual meeting of the National Tuberculosis Association at New Orleans, April 22 to 25

Dr Lee D Cady (Fellow), St Louis, is President of the St Louis Medical Society

Dr Marcus W Newcomb (Fellow), Browns Mills, N J, is President of the Medical Society of New Jersey

Dr F M Pottenger (Fellow), Monrovia, Calif, is President of the Association for the Study of Internal Secretions

Dr Edward Weiss (Fellow) Philadelphia, has been advanced from clinical professor to professor of clinical medicine at Temple University School of Medicine

Dr Edgar Erskine Hume (Fellow) librarian of the Army Medical Library Washington, D C, addressed the New York Academy of Medicine on 'The Medical Work of the Knights of St John of Jerusalem' The program was arranged in co-operation with the section of historical and cultural medicine

Dr Joseph T Beardwood, Jr (Fellow), Dr Edward S Dillon (Fellow) and Dr Edward L Bortz (Fellow), all of Philadelphia, addressed the New York Diabetes Association, March 20 on the clinical aspects, complications and treatment of "Diabetic Acidosis," respectively The program of the clinical section was presented by the Philadelphia Metabolic Association

Dr Leonard G Rowntree (Fellow) delivered one of the lectures, "Organotherapy from the Internist's Viewpoint," in the thirty-sixth group of Mary Scott Newbold Lectures before the College of Physicians of Philadelphia on March 4

Dr John B Youmans (Fellow), associate professor of medicine, Vanderbilt University School of Medicine, Nashville, Tenn, has been appointed director of graduate courses, having special charge of courses given for practicing physicians with the cooperation of the Commonwealth Fund

Dr Karl D Figley (Fellow), Toledo, Ohio, recently addressed the Chicago Society of Allergy on "Iodized Oil in Intractable Asthma"

Dr John J Dumphy (Fellow), Worcester, Mass, addressed the New England Heart Association February 24 on 'Coronary Symptoms in Pernicious Anemia'

Announcement has been made that Dr Raymond B Allen, associate dean of graduate studies, Columbia University College of Physicians and Surgeons, New York, N Y, has been appointed dean of Wayne University College of Medicine, Detroit He will succeed Dr Walter H MacCracken (Fellow), who resigned a year ago In the meantime Dr William J Stapleton, Jr (Fellow), has been acting as dean Dr Stapleton will become associate dean

Dr Charles Walter Clarke (Fellow), New York City, has under his direction a special bureau in the Health Department for the control of venereal disease, functioning in connection with a campaign by the Department for the control of these diseases An appropriation of \$100,000 has been approved by the Works Progress Administration for this project

Dr David Riesman (Fellow), Philadelphia, delivered a lecture, "Diagnosis and Treatment of Early Circulatory Failure," in connection with the fourth annual clinical lectures of the Mercy Hospital

Georgetown University School of Medicine has added a course in medical social economics to its curriculum of the senior year. Among lecturers on the various phases of the subject appear the following Fellows

Dr Arthur C Christie
 Dr Oscar B Hunter
 Dr Henry C Macatee
 Dr J Russell Verbycke, Jr
 Dr Wallace M Yater

Dr James H Hutton (Fellow), Chicago addressed the Chicago Society of Industrial Medicine and Surgery recently on "Endocrinology in Industrial Medicine"

Dr Ira A Darling (Fellow), formerly superintendent of the Warren State Hospital, Warren, Pa, has been appointed superintendent of the Springfield State Hospital at Sykesville, Md

Dr W McKim Marriott (Fellow), dean and professor of pediatrics at Washington University School of Medicine, St Louis, recently directed a two weeks' graduate course in medicine given at Washington University the latter part of April for physicians in Calhoun, Barry, Branch, Eaton, Allegan, Hillsdale and Van Buren counties and Battle Creek, Mich, provided by the W K Kellogg Foundation, in connection with its community health project

Dr Anthony Bassler (Fellow), Dr Max Einhorn (Fellow) and Dr Samuel Weiss (Fellow), all of New York City, have been elected honorary members of the Belgian Gastro-Enterologic Society

Under the sponsorship of the Woman's Auxiliary of the Philadelphia County Medical Society, its sixth annual health institute was conducted on April 14. Among the speakers were the following Fellows, all of Philadelphia

Dr E J G Beardsley, "What Life Teaches the Doctor"
 Dr Martin E Rehfuess, "Diet After Forty"
 Dr Joseph C Doane, "Hearts and the Family Budget"
 Dr Louis H Clerf, "Household Aids to Health"
 Dr George E Pfahler, "Cancer—Increasing Hope for the Patient"
 Dr Samuel B Scholz, Jr, "Periodic Health Examinations"

Dr George W Covey (Fellow), Lincoln, Nebr, was inducted as President of the Nebraska State Medical Association at its annual meeting April 7

Dr Herbert L Bryans (Fellow), Pensacola, Fla, is one of a number of physicians selected to participate in the weekly radio program of lectures on medical economics, sponsored by the Florida Medical Association

Under the Presidency of Dr James E Paullin (Fellow), the Medical Association of Georgia held its annual session at Savannah, April 21-24. Dr William B Castle (Fellow), associate professor of medicine, Harvard Medical School, Boston, delivered the Abner Wellborn Calhoun Lecture on "Fundamental Aspects of the Diagnosis and Treatment of Anemia". Among other guest speakers were Dr James S McLester (Fellow), Birmingham President of the American Medical Association, "Influence of the Present Day Depression Upon the Nutritive State of the American

People" and Dr Jonathan C Meakins (Fellow), Montreal, former President of this College, "Management of the Chronic Heart"

Dr Carl H Gellenthien (Fellow), Valmora, N M, addressed the Des Moines Academy of Medicine and the Polk County Medical Society recently on "Practical Methods of Sanatorium Treatment of Pulmonary Tuberculosis"

The second annual graduate clinical meeting of the Alumni Association of the University of Buffalo School of Medicine took place April 18, and was addressed, among others, by Dr Walter C Alvarez (Fellow), Rochester, Minn, "Helpful Hints in the Diagnosis of Puzzling Types of Indigestion" and Dr Ernest E Irons (Fellow), Chicago, "Chronic Arthritis, a General Disease Requiring Individualized Treatment" Dr Reginald Fitz (Fellow), Boston, delivered the banquet address on "The Biography of the Famous Dr Watson of the Sherlock Holmes Stories"

Dr William Devitt (Fellow), director of Devitt's Camp for Tuberculosis near Allenwood, Pa, has been elected President of the Pennsylvania Tuberculosis Society

Dr Wallace M Yater (Fellow), Washington, D C, Dr William J Kerr (Fellow), San Francisco, Calif, and Dr Howard B Sprague (Fellow), Boston, Mass, were among the guest speakers on the program of the twelfth annual meeting of the American Heart Association in Kansas City, May 12

Under the Presidency of Dr George W Grier (Fellow), Pittsburgh, Pa, the American Radium Society held its annual meeting in Kansas City May 11 to 12 Dr George E Pfahler (Fellow), Philadelphia, as a former lecturer, received the Janeway Medal

Dr Joseph L Miller (Fellow), Chicago, Dr Ralph A Kinsella (Fellow), St Louis, Dr Philip S Hench (Fellow), Rochester, Minn, and Dr William J Kerr (Fellow), San Francisco, were among the speakers on the educational program on the differential diagnosis of diseases of joints at the meeting of the American Association for the Study and Control of Rheumatic Diseases at Kansas City, May 11

Dr Charles S Holbrook (Fellow), New Orleans, has been elected Vice President of the Southern Pediatric Association

Under the Presidency of Dr Morris Murray Peshkin (Fellow), New York City, the Association for the Study of Allergy held its annual meeting in Kansas City, May 11 to 12

Dr John G FitzGerald (Fellow), director of Connaught Laboratories and of the School of Hygiene, University of Toronto, has been appointed a member of the Permanent Commission of Biological Standardization of the Health Organization of the League of Nations

In recognition of his achievements in science, Dr James B Collip (Fellow), professor of biologic chemistry, McGill University Faculty of Medicine, was presented with a gold medal by the Royal Society of Canada at a meeting in Ottawa, during February

Dr Ralph Pemberton (Fellow), Philadelphia, appears on the program of the fifth International Congress on Rheumatism, to be held in Lund, Sweden, September 3 to 5, and in Stockholm, September 7 to 8

HARLOW BROOKS, M D

PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS, 1923 TO 1925

IN MEMORIAM

DR HARLOW BROOKS

Dr Harlow Brooks was born at Medo, Minnesota, on March 31, 1871. He received his preliminary education in the High School of Medo, and later graduated from the University of Oregon. In 1895 he received the degree M D from the University of Michigan School of Medicine, and from the same School received the honorary degree of M Sc in 1930. He took a postgraduate course of study at the University of Freiberg, and at the Polyclinic in Munich. He was Assistant Demonstrator of Anatomy at the University of Michigan School of Medicine in 1895, Instructor of Histology and Embryology, Bellevue Hospital Medical College, 1895-1898, Research in Bacteriology, New York State Hospitals, Pathological Institute, 1897-1920, Professor of Clinical Medicine, New York University Medical College, 1922-1929. At the time of his death he was Emeritus Professor of Clinical Medicine, New York University Medical College, Visiting Physician, Bellevue Hospital, Consulting Physician, New York City, French, New York Polyclinic, Union, Fifth Avenue, Hackensack, New Jersey, Beth Israel, Greenwich, Mount Vernon, Saint John's, Southside (Bay Shore), Flushing, Jamaica and Montefiore Hospitals, Hospital for Joint Diseases and Norwegian Lutheran, Deaconess's Home and Hospital. His World War record—Major, Lieut Colonel, and Colonel, M C, U S A, Chief of Medical Service base hospital, Camp Upton, Chief Consultant in Medicine First Army Corps, A E F, Senior Consultant in Medicine, Second Army Corps, A E F, awarded Distinguished Service Medal and a General Citation. He was a member of the American Legion and of the Association of Military Surgeons.

He was a member of Phi Alpha Sigma fraternity, member of the Harvey Society, Society of Experimental Biology and Medicine, Association of American Physicians, American Medical Association, American Gastroenterological Association, Medical Society of the State of New York, New York County Medical Society, and the American College of Physicians. He was elected Fellow of the American College of Physicians at its first regular meeting held in New York in December 1916. He was elected President in 1923 in which capacity he served for two years. In 1925 he was elected to the Board of Regents where he served for three years, in 1929 he was elected to the Board of Governors on which he served for two years. He also served on various committees and gave generously of his time and energies to the work of the College.

Dr Brooks was a prolific writer and published many monographs and special articles on medical and biological subjects. He was the Editor of Lippincott's Everyday Practice Series.

He was keenly interested in animal life, exploration, mountaineering and was an honorary Fellow in the New York Zoological Society and a

member of the Explorer's Club, Adventurer's Club, and the Camp Fire of America

He was one of the outstanding diagnosticians of his time and was called in consultation more frequently probably than any other doctor in the United States. He was looked upon as an authority in diseases of the circulatory system. He was often referred to as the doctor's doctor, being constantly sought by his brother practitioners in cases involving their immediate families, among whom he was known as the "Beloved Physician."

Few physicians of his time gave so generously of their services to the poor.

As a young pathologist, Dr. Brooks collaborated with Dr. William Welch at Bellevue Hospital in advanced research work that resulted in the discovery of the bacillus named after Dr. Welch which is responsible for the disease commonly called gas bacillus infection, and which, by a curious coincidence, was the cause of his death.

One of the contributing factors which enabled Dr. Brooks to maintain his enthusiasm for his profession and for life in general was his devotion to his hobbies which were varied. He was a skilled musician and a collector of outstanding works of art, as well as an anthropologist of note. His collection of Indian relics surpassed any similar private collection in the world, containing a few specimens not to be found in any other collection.

Probably his great physical stamina was due, in part at least, to his love for fishing and hunting, in each of which he was an outstanding expert. Often Dr. Brooks would remark that he gladly devoted ten months each year to the pursuit of his profession but retained two months to seek recuperation and happiness in the great open spaces.

One of the outstanding characteristics of this great physician was his genius for friendship. His friendship was a living vital force upon which rested profound gratification and innermost happiness. When Dr. Brooks bestowed his friendship it was for the duration of life. He was truly catholic in these friendships which were confined to no one profession or social stratum. Caring little for individual accomplishments, Dr. Brooks demanded honesty, frankness, and I was about to add, loyalty in his friends. However, since loyalty is the quintessence of true friendship it may be omitted.

I have somewhat stressed this phase of Dr. Brooks' character because to him it was the dominating influence of his life, and also because in these times of emotional upheaval and cross purposes the gift of true friendship is a God-given talent which is all too rare.

And so from out of our midst has been taken this great physician, this talented gentleman, this indefatigable worker, this scientist of renown, this man of many enthusiasms, of loyal friendships, of kindly heart and broad sympathies—gifted in so many ways and with so many talents that the world is richer for his having lived in it. Those who had the privilege of close

association with Dr Brooks will carry ever in their hearts the memory of his cheering and inspiring presence and the light of his Christian spirit

WILLIAM GERRY MORGAN

OBITUARIES

DR CHRISTOPHER M REYHER

Dr Christopher M Reyher (Fellow), of Gary, Indiana, met a tragic death in the path of a speeding train on February 12, 1936

Dr Reyher was born at Garriett, Ind , in 1881 He received his medical degree from Northwestern University Medical School in 1906 For many years he was engaged in general practice, but later specialized in pediatrics He was a member of the staffs of the Mercy and Methodist Hospitals, Gary, Ind , a member of the Lake County Medical Society, Indiana State Medical Association and the American Medical Association He became a Fellow of the American College of Physicians in 1925 He served as Secretary and later as President of the Board of Health of Gary and during his ten years in office made many important contributions to the public welfare

Dr Reyher was one of the best loved and most respected members of the medical profession in Gary His death brought forth expressions of regret and of tribute from all his colleagues as well as from a great host of patients to whom he had ministered during his twenty-six years of practice in that community

DR EDWARD QUINTARD

Dr Edward Quintard (Fellow), New York, N Y , physician and man of letters, died suddenly at the age of sixty-nine years on February 12, 1936 in Chattanooga, Tenn , where he had gone to attend a meeting of the Board of Regents of the University of the South Dr Quintard was a graduate of Columbia University College of Physicians and Surgeons, 1887 He was emeritus professor of medicine and consulting physician to the New York Postgraduate School and Hospital His influence and vision helped to guide this institution in its infancy After a broadly cultural education both here and in Europe, Dr Quintard first became attached to the New York Postgraduate School as clinical assistant He was rapidly promoted through the various grades and became professor of medicine in 1904 He had also served as director of the department of medicine for many years Also, in 1904, he was elected a member of the Board of Directors and served as Vice President until his retirement in 1918 He was a member of his local and national societies and had been a Fellow of the American College of Physicians almost from its inception, dating back to 1917 He made many important contributions to medical literature

His death brought personal sorrow to a large number in every walk of life Always a lover of good fellowship, Dr Quintard by his enthusiasm

and his mellow personality endeared himself to all who worked with him. In the latter years of his life, he gave great beauty to the world in his writing and painting, and was able to devote much time to literary and philosophical pursuits.

Selected, in part, from a resolution of the Board of Directors of the New York Postgraduate Hospital and furnished through the courtesy of Walter W. Palmer, M.D., F.A.C.P., Governor for eastern New York.

DR. ALBERT HARRISON BRUNDAGE

Dr. Albert H. Brundage (Fellow) of Woodhaven, Queens County, N. Y., died March 12, 1936, after many years of impaired health, aged seventy-three.

Dr. Brundage was born at Candor, Tioga County, New York, March 3, 1862. He graduated from the New York University Medical College in 1885. He held the additional degrees of A.M., Ph.D., Ph.D. and M.S. He was particularly interested in toxicology, being the author of "A Manual of Toxicology." For the last several years he had been consulting toxicologist in the Bushwick Hospital, medical inspector and lecturer in the Department of Health of the City of New York and a member of the auxiliary staffs of the Lutheran and Jamaica Hospitals. He became a Fellow of the American College of Physicians in 1929.

DISTURBANCES OF THE ENDOCRINE BALANCE AND THEIR RELATION TO DISEASES OF METABOLISM *

By C N H LONG, M D , D Sc , *Philadelphia, Pennsylvania*

LAST year it was my privilege to address the College upon the subject of carbohydrate metabolism and the implications that recent work in this field had upon our knowledge of diabetes mellitus

Since this address appeared to meet with a certain measure of approval from you, I have ventured this evening to speak again upon certain pieces of work that to my mind are significant to those of us whose interest is concerned with the so-called diseases of metabolism

It appears to me that it is becoming more and more apparent that the clinical condition that follows hypo- or hyperfunction of an endocrine organ is not merely due to the loss or plethora of that particular internal secretion, but is a result of the disturbance of the normal hormonal equilibrium of the body

The work of the last few years has shown that the anatomical, and probably to a large extent the functional integrity of the majority of the endocrine organs, is dependent upon the anterior pituitary

The secretions of this gland either stimulate the production of hormones in the other endocrines or else enable these endocrines to maintain their secreting elements in such a condition that the production of their characteristic hormones becomes possible. There is then, in the truest sense of the word, an interrelationship between the anterior pituitary and the other organs of internal secretion. So widespread is the influence of the anterior pituitary over the whole endocrine system that at the present time it is difficult to consider any glandular interrelationship in which the possible participation of the anterior pituitary must not be allowed for

Thus it is becoming equally apparent that not only is the destruction of the anterior pituitary followed by a generalized endocrine atrophy, but also that removal of the gonads, thyroid or adrenals is followed by anatomical alterations in the anterior pituitary. These alterations are of such a striking

* Presented at the Detroit meeting of the American College of Physicians, March 2, 1936

From the George S. Cox Medical Research Institute, University of Pennsylvania, Philadelphia

ing character that it is difficult to conceive that they are not attended by equally significant changes in function. If this is so, then myxedema and Addison's disease should be considered not only as conditions dependent upon diminished thyroid or adrenal cortical activity, but also from the point of view that an altered level of anterior pituitary function may be contributing to the clinical condition. In consequence, it becomes of some interest to discuss briefly the effects upon the anterior pituitary of the destruction or removal of the adrenals, thyroid and pancreas.

A The Adrenal Cortex Comparatively few observations are recorded upon the effect of adrenalectomy upon the anterior pituitary in animals, and these, probably on account of the stains employed, have yielded but little information. Recently, Crooke,¹ using a modification of the Mallory stain, has carefully studied this organ in 12 authenticated cases of Addison's disease. Not only was the general cytology examined, but in five cases a differential cell count was made. This author finds that the basophiles are greatly reduced in number along with a variable degree of reduction of the acidophiles. These changes were found in one individual even after treatment with cortical extract for 19 months. Crooke has suggested that this loss of basophiles may be associated with the hypoglycemia that is such a constant feature of this disease. This is supported by his later observation that hyperactivity of the basophiles such as is observed in pituitary basophilism is associated with an elevated blood sugar.

In view of the striking alterations induced in the anterior pituitary as a result of destruction of the adrenal cortex it would be surprising if this organ retained its normal degree of function. Grollman's² experiments upon adrenalectomized rats maintained with minimal doses of cortical extract indicate that the failure of growth and reproductive function in chronic adrenal insufficiency is due to hypofunction of the anterior pituitary. Such animals will grow again only if given pituitary extracts rich in the growth promoting principles. The injection of potent adrenal cortical extracts is at this time incapable of restoring normal growth. Histological examination of the anterior pituitary of such animals reveals a diminution of both the basophilic and acidophilic cells, the former undergoing the greatest change.

B The Thyroid Numerous studies have been carried out upon the changes in the anterior pituitary following thyroidectomy in animals and in cases of human hypothyroidism. Practically all authors are agreed that the acidophiles are greatly reduced, while certain authors have observed alterations in the basophiles. Zeckwei and her co-workers³ have recently published an excellent paper upon the alterations in the anterior pituitary of young thyroidectomized rats. They find that in all cases where the rats have become stunted in growth the acidophiles had practically disappeared while the basophiles had undergone remarkable changes, becoming enlarged, vacuolated, and containing hyaline material. Zeckwei has made the interesting and probably correct suggestion that the cessation of growth in these young thyroidectomized rats is a consequence of the reduction of the

acidophilic elements of the pituitary. It would be of great interest to know if the administration of anterior pituitary extracts would cause these cretin rats to resume growth.

The above results clearly show that destruction or removal of the adrenals or thyroid causes marked structural alterations in the anterior pituitary. In addition to these anatomical changes evidence is also accumulating that certain aspects of the deficiency, usually attributed to the loss of the thyroid or adrenal secretion, are in reality to be attributed to the concomitant pituitary dysfunction.

Diabetes mellitus is a disease of metabolism that is at present held to be due to hypofunction of the islands of Langerhans. In view of the alterations induced in the anterior pituitary by hypofunction of the adrenals and thyroid it is surprising that so few histological studies of this organ in diabetes have been made. However, Fry⁴ and Kraus⁵ have reported that following pancreatectomy in animals, or in human diabetics, there is present a proliferation of eosinophiles and an accumulation of colloid material. On the other hand, Warren was unable to confirm such changes in the pituitaries of the diabetics he studied.

There is no doubt, however, of the striking effects of hypophysectomy upon an experimental diabetes, and in view of the bearing of these findings upon the problem of glandular interrelationships and disturbances of the metabolic processes it is necessary to consider in some detail the factors known at present to influence the diabetes of a totally depancreatized animal.

FACTORS MODIFYING AN EXPERIMENTAL DIABETES

As I pointed out last year, the demonstration by Houssay and Biasotti⁶ that hypophysectomy greatly alters the response to total pancreatectomy in animals necessitates a revision of our previous ideas, not only upon the mechanism by which experimental diabetes is produced but also upon the factors normally operating to control the protein, fat and carbohydrate metabolism of the body.

There are three major factors which, when in equilibrium, result in what we speak of as a normal metabolism. These are (a) the secretions of the various endocrine organs, (b) the liver, and (c) the tissues. Disturbance of any of the former such as follows the extirpation of an endocrine organ is followed by a condition in which not only is the metabolic equilibrium disturbed by the loss of this particular secretion, but also by the uncompensated activity of the remaining glands.

The interest excited by the effects of the anterior pituitary hormones upon metabolism should not lead us to neglect the fact that the liver is in all probability the organ upon which their influence is mainly exerted. It is this organ that is the site of glucose formation and probably of the major processes of fat metabolism. Thus, as Mann and Magath,⁷ and Yater, Markowitz and Cahoon⁸ have shown, removal of the liver even from a

totally depancreatized dog results in a rapid fall of the blood sugar, and Campos⁹ has demonstrated that in hepatectomized toads potent anterior pituitary extracts do not exert their usual effect of increasing the blood sugar.

Finally the metabolism of the tissues themselves can be greatly modified by various hormones. Insulin increases their utilization of carbohydrate while epinephrine diminishes it. The effect of the anterior pituitary hormones upon the metabolism of the tissues is a subject which so far has not been investigated. It may well be that one of the factors reducing carbohydrate utilization after pancreatectomy is not entirely the absence of insulin, but is in large part due to the inhibition of glucose oxidation by the pituitary hormones themselves.

Thus it is not surprising that as investigation proceeds a number of conditions are being found by which the usual effects of pancreatectomy can be modified. These can be roughly divided into

(a) *Alterations of the endocrine balance*

- (1) Hypophysectomy (Houssay⁶)
- (2) Adrenalectomy (Long and Lukens¹⁰)

(b) *Disturbances of liver function*

- (1) Complete or partial hepatectomy (Mann and Magath⁷)
- (2) Marked fatty infiltration such as follows the giving of low choline diet to a depancreatized animal maintained on insulin (Best et al¹¹)

(c) *Tissues*

Reduction of body weight by fasting (Allen¹²)

(d) *Lesions of the hypothalamus*

It has been reported by Davis, Cleveland and Ingram¹³ that cats depancreatized after placing suitable lesions on the hypothalamic area exhibit a modified diabetes. Whether such lesions exert their effect by interference with the function of the anterior pituitary or whether they interrupt nervous pathways concerned with metabolic processes remains to be decided.

THE RELATION OF THE ABOVE FINDINGS TO HUMAN DIABETES

In the experimental work cited above the pancreas has been removed before or after the establishment of one of the conditions outlined above. Thus the diabetes studied has been of primary pancreatic origin. It is obvious, however, that the chief interest from a clinical point of view would be in the establishment of the fact that alterations in the functional activity of certain endocrine organs, the liver or central nervous system, could give rise to diabetes mellitus. Now it will be recalled that for many years the view has been held that all cases of diabetes mellitus in man were the result of hypofunction of the islands of Langerhans, and it should also be emphasized that the majority of autopsies upon diabetics disclose pathological

changes in these structures. Nevertheless this unitarian view of the etiology of diabetes in man has not been universally accepted.

Since it has been demonstrated that the removal of the hypophysis or adrenals will modify an existing pancreatic diabetes it is profitable to examine the effects upon carbohydrate metabolism of conditions in which there exists hyperactivity of the anterior pituitary or adrenal cortex.

One of these conditions is acromegaly in which there is present a functioning tumor of the anterior pituitary. In these individuals, as has been repeatedly shown, glycosuria and often frank diabetes are of common occurrence.

Of recent years the extraordinary condition commonly known as "Cushing's syndrome" or pituitary basophilism has received an increasing amount of attention. Although the first cases described by Cushing were associated with a small basophilic adenoma of the anterior pituitary, it is now recognized that in adults the same condition is produced by the presence of an adrenal cortical carcinoma or adenoma. Recently this paradox has been further complicated by the report of three individuals with tumors of the thymus gland who also exhibited this interesting clinical picture.

Lukens and I have examined the records of 20 cases of this syndrome associated with proved basophile adenomas of the pituitary. Of these, 14 exhibited glycosuria. A similar study of 55 cases of proved adrenal cortical tumor or hyperplasia showed that half of them had a demonstrable impairment of carbohydrate tolerance. Finally, all three cases of Cushing's syndrome associated with thymic tumors exhibited glycosuria.

It is obvious from a study of these cases that there exists a generalized glandular derangement, and it is important for an understanding of the glycosuria that is found to investigate what endocrine disturbance is common to these three types of cases. (a) In basophilic adenomas of the pituitary hypertrophy of the adrenal cortex, often reaching a marked degree, is common. (b) In the cases associated with adrenal cortical tumor or hyperplasia it has heretofore been assumed that the hyperactivity of this organ was responsible for the condition observed. (c) In all three reported cases of thymic tumor the adrenal cortex has been enlarged.

These findings, together with the fact that total adrenalectomy is effective in reducing the glycosuria of a depancreatized animal, suggest that the glycosuria observed in the above groups is associated with hyperactivity of the adrenal cortex. Here, however, we cannot rest, since last year Crooke,¹⁴ in an excellent cytological study of the anterior pituitary of six cases of basophilic adenoma, three of adrenal cortical carcinoma and three of thymic tumor, has demonstrated that in all instances the basophile cells were the site of a curious hyaline change. Since this hyaline change is presumably demonstrable in all cases of Cushing's syndrome and since hyperplasia of the adrenal cortex, although very common, is not invariably present, we are forced to conclude that a direct association between hyperactivity of the adrenal cortex and glycosuria has not yet been established.

It may well prove to be that several causes, among them adrienal cortical or thymic hyperactivity, may precipitate this activation of the anterior pituitary. Once this is established a generalized glandular derangement follows, one result of which is glycosuria, and not infrequently clinical diabetes mellitus.

Nevertheless these facts do not answer our original enquiry as to whether individuals without acromegaly or Cushing's syndrome ever develop diabetes mellitus as a consequence of pituitary dysfunction. All the evidence gathered from the effects of various procedures upon experimental diabetes together with that obtained from a study of cases with undisputed pituitary or adrienal dysfunction, although highly suggestive of such an etiology in at least some diabetics, is by no means conclusive. It would, however, appear to offer an advantageous method of approach to the study of the etiological basis of the disease in man.

FACTORS DETERMINING GLUCOSE TOLLRANCE

Himsworth,¹⁵ in a well documented and ingeniously argued series of papers, has advanced the view (a) That the response of the blood sugar of normal individuals to the ingestion of glucose is determined solely by the carbohydrate content of the diet previous to the test. With a low carbohydrate diet the curves indicate a decreased tolerance to ingested glucose, but as the proportion of dietary carbohydrate is increased, curves indicative of an improving glucose tolerance are obtained. (b) The sensitivity of the individual to a given amount of insulin increases with the amount of carbohydrate in the diet. (c) It is commonly assumed that when glucose is ingested the supply of insulin is temporarily increased to meet this circumstance. Himsworth points out that this supposition is unnecessary since his work indicates that increasing the amount of carbohydrate in the diet increases the efficiency of the usual supply of insulin to such an extent that the additional carbohydrate is easily disposed of. In consequence it is unnecessary to postulate variations in insulin secretion in response to carbohydrate ingestion. As will be seen shortly, Soskin et al.,¹⁶ from an entirely different type of experiment, have arrived at similar conclusions. These views are of course at variance with those of other workers, particularly Zuntz and LaBarre,¹⁷ and it would appear that the stage is set for a controversy similar to that waged over the continuous or intermittent secretion of epinephrine. (d) Of even greater interest are Himsworth's views as to the reason for the greater efficiency of insulin when a large amount of carbohydrate is being ingested. He has advanced the hypothesis that insulin as secreted by the pancreas is physiologically inactive and requires the presence of an activator, probably supplied by the liver, in order to bring out its well known effects upon carbohydrate utilization. He implies that a large carbohydrate intake favors the production of the "activator" while low carbohydrate diets inhibit its production. Now it will be apparent that if

this view is correct, diabetes could occur in an individual with a normal insulin supply as a result of a deficient quantity of insulin activator

On the basis of this hypothesis, Himsworth has attempted to classify human diabetes into two groups (*a*) insulin sensitive, and (*b*) insulin insensitive. The former are those in whom a deficiency of insulin production by the pancreas is the essential defect. These individuals are those in whom injected insulin is highly effective, and furthermore are the group of diabetics who are most likely to tolerate a high carbohydrate-low fat diet without any increase in insulin requirements.

The insulin insensitive group, on the other hand, are those individuals who will not tolerate an increase in carbohydrate intake unless the insulin supply is correspondingly increased. Himsworth believes that the insulin insensitive group of diabetics are those in whom insulin deficiency is not the primary cause of the disease, but are diabetic because of a deficiency of some substance which in normal individuals is essential for the proper action of insulin.

Soskin and his co-workers,¹⁶ although in agreement with Himsworth that the pancreas does not secrete an increased amount of insulin after glucose ingestion, disagree with him upon the question as to whether insulin requires to be activated before it becomes physiologically effective in the body.

These workers hold that when the blood sugar level falls below a certain value the formation of glucose in the liver from non-carbohydrate sources (gluconeogenesis) is stimulated, and conversely, when the blood sugar level rises above a certain point, the amount of gluconeogenesis is decreased. Furthermore, it is held that this capacity of the liver to regulate the formation of glucose in accordance with the needs of the body is normally under the control of the opposing influences of the hormones of the pancreas and hypophysis. Their experimental work has led them to the conclusion that the variable factor in this endocrine balance is not the supply of pancreatic insulin but the amount of liver gluconeogenesis and consequently the amount of hypophyseal activity. Therefore, when glucose is ingested the ensuing changes in the blood sugar curve are not the result of an increased secretion of insulin, but are determined by alterations in the amount of glucose formation by the liver.

When this hypophyseal-pancreas-liver relationship is disturbed by pancreatectomy, then excessive gluconeogenesis continues during glucose ingestion and a diabetic tolerance curve results, conversely, when the hypophysis is removed, the marked decrease in the gluconeogenetic processes renders the organism insulin sensitive and increases the tolerance to glucose. When both pancreas and hypophysis are excised an intermediary level is established at which point "normal" tolerance curves may be found.

In view of this work, along with that of Houssay and others, it appears that other reasons than lack of an insulin activator might be ascribed to cases of insulin-insensitive diabetes. Thus it has been established (*a*) that hypo-

physcctomized animals are insulin sensitive, (*b*) such animals have an increased carbohydrate tolerance, (*c*) normal animals may be rendered insulin insensitive by the injection of anterior pituitary extracts even though the composition of the diet remains unchanged, and (*d*) such injections decrease their carbohydrate tolerance. Therefore, instead of invoking a hypothetical insulin activator, is it not more reasonable to say that the anterior pituitary hormones play a conspicuous rôle in determining the response of the organism not only to ingested carbohydrate, but also to exogenous and endogenous insulin?

It may thus be postulated that Himswoth's insulin sensitive group of diabetics are those (as he himself has pointed out) in whom the defect is an inadequate supply of insulin, while the insulin insensitive group are those diabetics in whom a relative preponderance of hypophyseal activity is the exciting cause of the disease even though their supply of pancreatic insulin remains within normal limits.

I wish, however, to emphasize that no experimental work supporting a classification of diabetes along these lines has yet appeared, nor has any evidence yet been adduced that in certain diabetics the hypophyseal or adrenal function is deranged.

The interest of these experiments, apart from the fact that they ascribe an extra-pancreatic origin to certain cases of diabetes, lies in the concept that the response of the organism to such a physiological process as the ingestion of carbohydrate is determined not by the liver, pancreas or tissues acting alone, but by a response that necessitates the readjustment of an equilibrium that is normally maintained by the activity of the endocrine organs. This, of course, is merely a restatement of the principle of homeostasis that the work of Cannon¹⁸ has done so much to disclose.

Long continued disturbances of this equilibrium such as are induced by chronic hyper- or hypofunction of one or more endocrine organs, result in conditions which are clinically spoken of under such names as Graves' disease or Addison's disease. While it is obvious that acute deprivation of any particular hormone may result in death before any secondary consequences can be established, this is not the condition that is usually encountered in man.

It is my belief that a better understanding of the diseases of metabolism that are associated with a disturbed endocrine function can be reached by ceasing to regard them merely as an expression of the effects of alterations in function limited to one endocrine organ, but rather in the light of our newer knowledge of the close interrelationship between all the organs of internal secretion.

These remarks should not be interpreted as endorsing ill-timed surgical assaults upon the pituitary and adrenals either in the case of hyperthyroidism or diabetes mellitus, since as I have previously pointed out, no evidence is yet available that these organs are primarily involved in the appearance of these diseases in man.

A COMPARISON OF THE EFFECTIVENESS OF GLUTAMIC ACID HYDROCHLORIDE AND DILUTE HYDROCHLORIC ACID AS THE REPLACEMENT THERAPY IN ANACIDITY MEASURED BY FRACTIONAL GASTRIC ACID TITRATION AND HYDROGEN-ION CONCENTRATION CURVES

By HARRY SHAY, M D , and J GERSHON-COHEN, M D , M Sc (Med),
Philadelphia, Pennsylvania

For the most part, anacidity has been regarded an interesting but scarcely serious medical curiosity. In the absence of gastric carcinoma, or of blood changes suggestive of Addisonian anemia, little consideration has been generally given the anacidity. In fact, since the work of Castle,¹ it has progressively diminished in importance as a factor in anemia. Clinically, spectacular therapeutic results have been obtained from the administration of hydrochloric acid for the relief of vague, but distressing, digestive symptoms, or in the more obvious gastrogenous diarrhea. Experimentally, time and effort have been lavished upon the study of the response of the achlorhydric to histamine and to the ability of the anacid stomach to secrete parenterally injected neutral red, but small thought indeed has been given to the possibility of a far-reaching and insidious effect of anacidity upon the body's physiology.

Numerous papers have pointed out the relatively higher incidence of anacidity in cholecystitis, diabetes, arthritis, and their like, but the likelihood of anacidity being cause rather than effect has gone almost completely unsuspected. We believe this relationship will become evident when the physiology of the upper small intestine is completely understood.

Scattered evidence is now available, and more is certain to be added, to show that the duodenum is rivalled only by the pituitary as the source for a multiplicity of hormones with many, and extended, physiological effects. Further, the trigger that sets this off is the arrival of the gastric hydrochloric acid into the duodenum. We attribute this action to the hydrochloric acid as the intrinsic agent. It is not, however, the sole agent capable of inaugurating the reaction, for any substance that can alter the osmotic conditions in the duodenum away from isotonicity will activate the duodenal mucosa to a greater, or a lesser, degree.

Forgetting for a moment the action of the gastric hydrochloric acid in initial protein digestion, or as a bactericide, let us examine the part it might play upon its entrance into the duodenum. We need only recall its rôle in

* Received for publication January 3, 1936.

To Mr Samuel S. Fels the authors are deeply grateful for his active cooperation in these investigations. Mr Fels not only made the grant under which the studies were originated and carried through, but at weekly conferences contributed much of real value to the studies.

the crucial experiment of Bayliss and Starling,² using the denervated isolated jejunal loop to demonstrate the hormonal mechanism for the external secretion of the pancreas. Gastric hydrochloric acid as the intrinsic agent supplying the stimulus in the duodenum and upper jejunum in the production of a substance capable of diminishing the blood-sugar concentration, has been suggested since the work of Freud and Saadi-Nazim³ in dogs in 1926. Whether this is due to another hormone which stimulates the pancreatic islets, or whether hydrochloric acid itself is able to modify a raised blood-sugar level, or whether both mechanisms are operative is, so far, not entirely clear. We are about to publish data which demonstrate this mechanism for man and which indicate the separate action rather than the islet stimulation. In his discovery of cholecystokinin, Ivy⁴ has shown the relationship of the gastric acid to gall-bladder emptying. Recently, we⁵ demonstrated the importance of the same acid as the intrinsic agent in the duodenum which acts as the control of the local mechanism concerned with gastric evacuation. It is also likely from our studies of the motor function of the resected stomach⁶ that the gastric motor inhibitory hormone conceived in the work of Farrell and Ivy,⁷ Lim,⁸ Quigley,⁹ and their co-workers is dependent for its intrinsic motivation upon the hydrochloric acid of the stomach. The importance of this acid in the absorption of calcium from the intestine was recently graphically demonstrated by Ivy¹⁰ in the bone changes produced in young and adult dogs after gastrectomy.

Thus, because of the manifold and extended effects of which it is possibly the source, anacidity demands more interest than a cursory one in its etiology and in its replacement therapy—which is for the present quite simply, the attempt to simulate as accurately as possible a normal gastric acid curve.

METHOD

Fourteen patients with anacidity were studied. Nine remained anacid after histamine. Fractional gastric analysis was used throughout. The patients reported after an overnight fast. The fasting gastric contents were removed through a Rehfuess tube, and then the test meal, which consisted of 20 grams of zweiback and 300 c c of distilled water, was ingested. The gastric response to this meal was first determined, specimens being removed at quarter-hour intervals for two hours, or until the stomach was empty. Each specimen was titrated for free acid to dimethylamidoazobenzol and for total acid to phenolphthalein, and recorded in the usual manner in c c of tenth normal acid per 100 c c of gastric contents. Hydrogen-ion concentration was determined with the quinhydrone electrode.

The same patients were then studied after addition of varying amounts of dilute hydrochloric acid to the water before ingestion of the meal. A dropper was used for measuring the acid in order more closely to simulate the clinical method of administration. This dropper yielded 16 drops to the c c. Glutamic acid and glutamic acid hydrochloride were administered

in capsules (0.31 gram each) in two portions, one-half when half the test was taken, and the other half at the end of the meal. Extractions and determinations were carried out as with the "webback-and-water" meal. One hundred and four fractional analyses were made on the 14 patients.

DISCUSSION

Replacement therapy in anacidity has pretty generally taken the form of hydrochloric acid. Some years ago, Arthur F. Hurst¹¹ recognized the inadequacy of the official pharmacopoeial dosage and advocated quantities of 4 to 6 c.c. which was, and still is, considered by many to be a radical recommendation. Later, Crohn,¹² and Kern, Rose, and Austin¹³ demonstrated the failure of the usual therapeutic doses of dilute hydrochloric acid to modify intragastric acidity in achlorhydria. Superficially the usual doses are found to be therapeutically efficient, but when measured by actual titration and hydrogen-ion determinations in fractional gastric studies, it is surprising to see how ineffective massive doses are to establish even an approach

to what would be considered a normal gastric acid response. (See charts.) An amount of hydrochloric acid as large as 120 to 160 drops (7.5 to 10.0 c.c.) added to the Ewald meal (charts 5 and 7) produced a low free acid curve during the fractional analysis, while 80 drop portions (5 c.c.) were usually inadequate to show any free acid to Topfer's reagent at any time (charts 1, 5, and 7). The results obtained in the hydrogen-ion concentration curves confirmed the titration values insofar as the addition of smaller quantities of the acid to the meal failed to produce a pH reading below 3.5, at which point free acid will be demonstrated by Topfer's reagent. (Charts 3, 4, and 7.) (In several thousand pH determinations on gastric samples with the quinhydrone electrode, we have always obtained a free acid reaction to Topfer's when the pH reading was below 3.5.) It would appear, therefore, that the therapeutic effects derived from the administration of the usual dosage of hydrochloric acid are definitely not dependent upon the

presence in the stomach of any free acidity at the time of digestion. From our experiences with the rôle of the hydrochloric acid in the duodenum, we venture the opinion that the beneficial clinical results are caused by the altered osmotic conditions produced in the upper intestine by the administered acid.

GLUTAMIC ACID HYDROCHLORIDE

Glutamic acid (α -amino-glutamic acid) was isolated by Ritthausen¹⁴ in 1869 from vegetable proteins by acid hydrolysis. It is very probably one of the essential amino acids, and in 1913 Abderhalden¹⁵ determined that it was a constituent of normal blood. Ikeda¹⁶ isolated the acid from a Japanese seaweed to which it gives its peculiar flavor. Moreover, in Japan it has for some time been used as a seasoning for foods, and in that country the use of the sodium salt—the most useful of the non-poisonous metallic radicals—has become widespread. Newbough and Marsh¹⁷ studying the toxic effects of amino acids established that doses of glutamic acid as large as two grams per kilogram body weight, when injected into rabbits and puppies, gave no evidence of renal injury. Tagawa¹⁸ considers glutamic acid a physiological protein decomposition product which, like meat extracts, has the ability strongly to stimulate hydrochloric acid secretion, while secre-

tion by the stomach is still possible. In the metabolism of glutamic acid, cognizance must be taken of the fact that three of its carbon atoms enter into the formation of glucose¹⁹. This, according to Ringer, Frankel and Jonas,²⁰ takes place by way of succinic acid.

Combined with hydrochloric acid to form a white powder, glutamic acid lends itself to easy administration in capsule form. Recently, von Bergmann²¹ recommended its use in anacidity, and Mahlei²² studied its effect, in the form of muipsin (glutamic acid hydrochloride and pepsin), on both the gastric chemistry and on the appearance of the gastric mucosa through the gastroscope. Mahlei found that even in large dosage, it produced no hyperemia. We have done comparative studies with glutamic acid hydrochloride,* and with varying quantities of the official dilute hydrochloric acid. In contact with water, the combination is readily broken up, and the hydrochloric acid liberated. Considering that glutamic acid hydrochloride was one of the first amino acid salts to be isolated in pure form (Hlasiwetz and Habermann²³ in 1873), it is indeed surprising that it did not find its way much earlier into the replacement therapy of anacidity.

If we take the titration and hydrogen-ion concentration figures as seen in the charts 1 to 8 as a measure of the effectiveness of the replacement therapy in anacidity, the superiority of glutamic acid hydrochloride over the official dilute hydrochloric acid is obvious. With relatively small amounts of this combination, a close parallelism of the gastric acid curve in the achlorhydric with that which would be the response in the normal acid stomach to the usual Ewald test meal can be seen—a simulation not achieved even with enormous doses of the official hydrochloric acid solution.

At times we obtained titration figures, especially after the larger doses of the glutamic acid, which are normally never seen in the gastric juice. These were probably caused by a portion of the ingested drug which had not been mixed with the gastric contents. Charts 6, 7, and 8 also demonstrate the marked difference between free and total acid titration, following the use of glutamic acid hydrochloride. This is probably due to the glutamic acid content.

We have attempted to determine the approximate equivalent of the glutamic acid hydrochloride in terms of dilute hydrochloric acid both in vitro and in vivo. Table 1 represents the titration and pH figures of varying amounts of dilute hydrochloric acid, glutamic acid, and glutamic acid hydrochloride, each dissolved in 100 c c of distilled water. Titration was done to pH 7.4 using a comparator block and phenol red as indicator. Hydrogen-ion concentration was determined with the quinhydrone electrode. It will be noted that solutions of glutamic acid alone were included only up to three capsules (0.93 gr.), since that represented the degree of solubility of that acid in 100 c c of water.

In vitro experiments showed the titration figure of the contents of one

* Glutamic acid hydrochloride was kindly supplied by the Calco Chemical Company, Inc., for these investigations.

TABLE I

Dissolved in 100 c c distilled H ₂ O	Titration to pH 7.4 (c c N/10 per 100 c c)	pH
10 drops dil HCl (U S P)	16.3	1.85
1 cap glutamic acid	17.0	3.23
1 cap glutamic HCl	34.3	2.14
20 drops dil HCl	31.9	1.57
2 cap glutamic acid	34.1	3.20
2 cap glutamic HCl	68.7	1.92
30 drops dil HCl	46.1	1.41
3 cap glutamic acid	45.5	3.19
3 cap glutamic HCl	101.0	1.85
40 drops dil HCl	64.3	1.27
4 cap glutamic acid	Not completely soluble	
4 cap glutamic HCl	133.5	1.76
60 drops dil HCl	98.6	1.11
6 cap glutamic HCl	202.0	1.67
80 drops dil HCl	132.5	1.00
8 cap glutamic HCl	270.7	1.58

capsule of glutamic acid hydrochloride to be equivalent to about 20 drops of dilute hydrochloric acid, or equivalent to one capsule of glutamic acid (0.31 gm) plus 10 drops of dilute hydrochloric acid. The titration of larger amounts of the glutamic acid hydrochloride bear out this relationship. Yet *in vivo* the effectiveness of the glutamic acid hydrochloride in altering the intragastric reaction is far greater than its equivalent *in vitro* titration would indicate (charts 7 and 8).

If then the intragastric effects are to be considered a measure of the therapeutic efficiency, one capsule (0.31 g) of the glutamic acid hydrochloride appears to be as effective as a massive dose of the dilute hydrochloric acid. If to this greater ability to alter the gastric chemistry is added the ease of administration and the elimination of the unpleasant mouth effects of the official acid, we have in glutamic acid hydrochloride a highly desirable addition to the replacement therapy of anacidity. In one patient we noticed that considerable bladder irritation and frequency produced when adequate dosage of the official acid was administered to control a gastrogenous diarrhea were entirely relieved when glutamic acid hydrochloride was substituted. Clinically we have obtained satisfactory results from the administration of one capsule (0.31 g) of the glutamic acid hydrochloride shortly after the beginning of the meal, and another capsule at the completion of the meal.

SUMMARY AND CONCLUSIONS

The problem of anacidity has been subjected to rather one-sided investigation, and achlorhydria and its relation to duodenal function carries many implications which have thus far been overlooked. Gastric hydrochloric acid is the intrinsic agent which upon its arrival into the duodenum

originates the production or liberation of a group of hormones that have far-reaching physiological effects, and this gives to replacement therapy a greater significance than the mere relief of vague digestive symptoms or of a gastrogenous diarrhea. The inadequacy of the official dilute hydrochloric acid, even in massive doses, to alter gastric chemistry is illustrated by fractional gastric analyses, both by acid titration and hydrogen-ion determinations. The marked superiority of glutamic acid hydrochloride in relatively small dosage over the dilute hydrochloric acid is similarly demonstrated, as well as its advantages in administration.

In all, 104 gastric studies were made on 14 cases of achlorhydria, nine of whom had shown no response to histamine injection. The charts used for illustrations were selected from this group.

THE MEDICAL AND ECONOMIC ADVANTAGES OF ROENTGENOGRAPHIC CHEST SURVEY OF ALL HOSPITAL ADMISSIONS¹

By FRED JENNER HODGES, M D , *Ann Arbor, Michigan*

FEW radiographic procedures lend themselves more readily to routine mass application than simple postero-anterior filming of the chest. Other than removal of clothing above the waist-line no advance preparation of the patient is necessary. Great speed without sacrifice of quality can be attained in handling patients because positioning is simple and exposure time is measured in split seconds. Photographic processing in volume offers no serious problem.

Roentgenographic examination of the chest provides a wealth of detailed information concerning the thorax and its contents unrivaled by any other method of approach. The finished film serves furthermore as a valuable objective record which may be preserved for future reference. Even those roentgenograms presenting no recognizable abnormality become valuable as controls against which later chest changes may be contrasted. The predominance of requests for roentgen-ray consultations in which chest examination is required among all of the numerous procedures employed by the roentgenologist bespeaks the soundness of this contention.

It is by no means an uncommon experience to find roentgen-ray evidence of extensive pulmonary or mediastinal disease in the face of negative or inconclusive physical findings. Such findings, furthermore, may be associated with no suggestive symptoms. Purely upon the basis of such reasoning there seems to be no valid reason for withholding the benefits to be derived from this simple procedure from any patient seeking medical advice.

There is one possible reason, however, the validity of which need scarcely be urged, namely, prohibitive cost, cost not only to the person who must pay the material roentgen-ray expense as well as the professional fee for interpretation but, in addition, the initial investment cost to the hospital, clinic, or private practitioner of roentgenology. In order to test the actual value of routine roentgen-ray chest survey and to determine whether or not the cost need necessarily prove prohibitive, all patients registering in the University Clinic, both the hospital and out-patient groups, during the period from June 27 to July 13, 1935 inclusive, were so examined. It was recognized in advance that there could be no prospect of a permanent institution of the plan unless it could be shown that it could justify itself amply in the matter of medical value and at the same time prove itself to be self-supporting without imposing financial hardship upon registering patients. Before

* Read before the Fifth General Session of the American College of Physicians, Detroit, March 4, 1936.

From the Department of Roentgenology, University of Michigan, Ann Arbor, Michigan

the test was begun it was decided that unless the following benefits could be demonstrated the plan could not hope to become permanent

- 1 Increased diagnostic accuracy
- 2 Increased diagnostic speed
- 3 Economy for the patient (lowered aggregate roentgen-ray cost to group)
- 4 Economy for the institution (increased speed in clearing patients, no loss of revenue in Department of Roentgenology)
- 5 Increased availability of roentgenological service to entire patient group by spread of cost

PHYSICAL FACILITIES AND METHOD OF PROCEDURE

In order that patients might be examined with greatest possible dispatch and the minimum inconvenience, apparatus was set up in a small room 12' by 12', immediately adjoining the room in the registration department where blood samples are routinely taken for serological examination. Seven temporary dressing rooms were erected in the corridor as well as a small, light-proof film loading room. To insure roentgenograms comparable to those made with the regular chest apparatus in the roentgen-ray department, a machine was installed capable of producing satisfactory exposures at six foot distance in 1/50 second. High speed of exposure furthermore eliminated the necessity for rigid fixation of the patient. A technician was provided throughout registration hours as well as a ward helper to attend patients. Stock celluloid films of 14 by 17 size were used rather than less costly paper, again in order to maintain uniformity of roentgenographic quality as well as to permit photographic processing with existing facilities. All films were developed during the night by a second technician employed for that purpose to avoid crowding in the roentgen-ray dark room. All films were identified photographically with date and a serial number which last was entered upon a card bearing a duplicate imprint of the patient's admission data. When processed, all films were stored for three months, unread, in order that the immediate results of the test might not alter the regular handling of the patient and to permit ultimate disposal of the cases without bias. At the end of the three month period all films were read in unbroken sequence by the assembled staff of the Roentgenology Department. Diagnostic statements were recorded in accordance with a prearranged code designed to permit direct transfer to punch cards for mechanical sorting (table 1). In addition to diagnostic material, such information as age, sex, race, service to which admitted, registration number, and home county were also recorded on the cards. Similar punch cards in the main record room, accessible by registration number, were already available carrying complete information regarding clinical diagnosis, type of treatment, and disposition of the case. Roentgen-Ray Department records were available in similar form permitting correlation between survey film diagnosis and any subse-

TABLE I

Classification of diagnoses made from survey films

- A Frank negative admission roentgenogram
- B Positive admission roentgenogram which may or may not be clinically significant
 - 1 Anomalies of ribs
 - 2 Other bony change, ribs or spine
 - 3 Abnormal aorta
 - 4 Pleural changes apex, axilla, diaphragm, costophrenic angle
 - 5 Calcification pleura, lymph nodes, parenchyma
- C Positive admission roentgenogram, clinically significant
 - 1 Abnormality, thyroid or mediastinum
 - 2 Abnormal cardiac size or shape
 - 3 Non-tuberculous pulmonary disease
 - 4 Pleural effusion
 - 5 Intrathoracic glandular tuberculosis
 - 6 Parenchymal tuberculosis

quent roentgenologic opinions which had been rendered. The total expense of the test was borne by the Department of Roentgenology as an investigative project. Patients were submitted to subsequent roentgen examination only at the express desire of the clinic staff and for reasons they deemed sound. Neither the economic limitations nor the medical indications of roentgen-ray examination were disturbed.

RESULTS

During the 11 full working days and three half days of the test period a total of 1,116 newly admitted patients were subjected to chest survey examination. Every person passing through the blood-sampling room was so examined. Persons admitted directly to the hospital as emergency patients were not included. The films in 15 instances were for one reason or another unsatisfactory, leaving a total of 1,101 chest films representing a like number of individuals.

The various situations listed in the diagnostic code employed (table 1) are shown in table 2 grouped under the three main subdivisions A, normal, B, changes of questionable importance, and C, clinically significant situations.

TABLE II

Service	No Pts	Class A	Class B	Class C
Unidentified	1		1	
Obstetrics	14	8	6	
Oral Surgery	28	21	5	2
Urology	33	19	18	6
Neurology	60	41	15	4
Ophthalmology	70	48	18	4
Otology	73	43	22	8
Gynecology	75	54	19	2
Dermatology	83	55	24	4
Bone and Joint	89	63	23	3
Surgery	113	73	24	16
Pediatrics	184	164	15	5
Medicine	278	162	80	36
Total	1101	751 (68.3%)	260 (23.6%)	90 (8.1%)

As was to be expected, the majority of the patients examined showed no roentgen evidence of chest abnormality. Group B, those in which non-significant deviations from the normal were observed, is interesting, but one can scarcely justify wholesale roentgen-ray examination on the basis of such returns. It is with the 81 per cent, which showed unequivocal changes usually indicative of significant disease, that our chief interest lies.

These 90 individuals had been filtered out of the entire series as persons harboring thoracic situations of prime medical importance. The yield may at first glance appear small, yet when it is remembered that these 90 patients came to the clinic for all manner of situations, it will be recognized that in many instances the discovery of the chest lesion was often times scarcely to be expected on the basis of symptomatology. As a matter of fact, 50 of these 90 patients were cleared through the clinic without being referred to roentgenology, and in but 15 of that 50 was the chest situation, demonstrated by the survey film, diagnosed on the basis of physical findings. This leaves 35 patients in whom chest changes, presumably clinically significant, were observed in survey roentgenograms upon admission whose later study without roentgen examination failed to reveal intrathoracic disease. Careful review of all available data in this selected group of cases showed that in 10 instances the originally observed abnormalities were perhaps open to some question, that in seven instances the abnormality consisted of cardiac enlargement only, while in four instances the probable clinical significance of the observed changes might well be questioned. This process of elimination left a very significant group of 14 patients, representing 15.5 per cent of the entire "C" group, or 1.5 per cent of the entire test series, which must be considered as diagnostic failures in so far as chest status is concerned. These 14 cases deserve individual consideration. Four of these cases showed evidence of pneumonitis of unspecified character.

Case 1 E P, f, aged 40. Admitted 7-5-35 to Otolaryngology
Survey film. Pneumonic infiltration, right median base
Clinical diagnosis. Previous thyroidectomy and tracheotomy. Vocal cord palsy
Discharged 7-17-35
No re-admission

Case 2 E M, m, aged 59. Admitted 6-27-35 to Neurology
Survey film. Pneumonitis, right base
Clinical diagnosis. 1. Left hemiplegia
2. Latent lues
3. Borderline heart size
4. Arteriosclerosis
Discharged 6-27-35
No re-admission

Case 3 I M, f, aged 55. Admitted 7-12-35 to Dermatology
Survey film. Pneumonitis
Clinical diagnosis. Rodent ulcer, recurrence
Discharged 7-12-35
No re-admission

Case 4 S B , f , aged 7 Admitted 7-2-35 to Pediatrics
Survey film Pneumonitis, right base
Clinical diagnosis 1 Strabismus
2 Tetra saginata
Discharged 7-2-35
No re-admission

The roentgen-ray findings in all of these represent disease which may yet manifest itself by serious clinical symptoms and may well prove to be of serious importance

Five of the group presented roentgen signs of tuberculosis

FIG 1 Minimal pulmonary tuberculosis, left apex

Case 5 M T , f , aged 17 Admitted 7-12-35 to Orthopedic Surgery
Survey film Minimal pulmonary tuberculosis, left apex (figure 1)
Clinical diagnosis Healed chronic osteomyelitis, right femur
Discharged 7-12-35 (same day)
No re-admission

Case 6 J K , m , aged 42 Admitted 7-10-35 to Internal Medicine
Survey film Minimal pulmonary tuberculosis
Clinical diagnosis Questionable chronic ulcerative colitis
Discharged 7-16-35
No re-admission

FIG 2 Minimal pulmonary tuberculosis, right apex

Case 7 C M , m , aged 26 Admitted 7-10-35 to Oral Surgery
Survey film Minimal pulmonary tuberculosis right apex (figure 2)
Clinical diagnosis Abscessed tooth (tooth extraction)
Discharged 7-10-35 (same day)

No re-admission Record at University Student Health Service 2-28-36 reveals tuberculosis recognized July 1933 No such information on University Hospital record

Case 8 G B , m aged 52 Admitted 7-8-35 to Internal Medicine
Survey film Minimal pulmonary tuberculosis
Clinical diagnosis Gastritis
Discharged 7-10-35
No re-admission

FIG 3 Tuberculous pneumonia, right upper lobe

Case 9 A M , f , aged 12 Admitted 7-2-35 to Pediatrics
 Survey film Tuberculous pneumonia, right upper lobe (figure 3)
 Clinical diagnosis Septic tonsils and adenoids
 Tonsillectomy
 Adenoidectomy
 Biopsy Negative for tuberculosis of tonsils
 Discharged 7-9-35
 No re-admission

FIG 4 Substernal thyroid enlargement and metastatic pulmonary lesion, right apex

In all of these cases, tuberculosis if recognized would surely have been subject to careful clinical evaluation and treatment

Case 10 O D , m , aged 19 Admitted 7-1-35 to Orthopedic Surgery
 Survey film Apparent dextro-cardia
 Clinical diagnosis Idiopathic scoliosis
 Discharged 8-5-35
 Re-admission

Without further study the exact cardiac status can scarcely be determined from the single exposure

Four cases showed evidence of neoplastic metastasis to the lung

Case 11 F D , m , aged 68 Admitted 7-1-35 to Neurology

Survey film 1 Enlarged thyroid

2 Metastatic pulmonary lesion, right apex (figure 4)

Clinical diagnosis 1 Cerebral arteriosclerosis—paranoia

2 Arteriosclerotic heart disease

Discharged 7-3-35

No re-admission

FIG 5 Metastatic pulmonary lesions

Case 12 R H , m , aged 35 Admitted 7-2-35 to Otolaryngology

Survey film Metastatic pulmonary lesions (figure 5)

Clinical diagnosis Tubo-tympanitis

Discharged 7-2-35

No re-admission

Case 13 M G, f, aged 65 Admitted 6-27-35 to Gynecology
Survey film Multiple neoplastic metastases to lungs (figure 6)
Clinical diagnosis Undifferentiated medullary carcinoma, uterus
Roentgen therapy 7-5-35 to 7-9-35, 650 r 200 KV, to each of four pelvic ports
Clinical note 8-2-35—"Patient failing"—no further treatment advised
Death 8-11-35 No autopsy

FIG 6 Multiple neoplastic metastases to lungs

Case 14 R W , m , aged 67 Admitted 7-1-35 to Urology
 Survey film Discrete pulmonary lesion Neoplastic metastasis or primary tuberculous lesion
 Clinical diagnosis Chronic prostatitis and epididymitis
 Discharged 7-1-35
 No re-admission
 (Unquestionably the handling of these patients would have been altered in the light of positive knowledge of metastasis)

These 14 instances of overlooked intra-thoracic lesion taken from the total admissions of 14 successive days indicate that we may expect one such oversight as a daily occurrence in spite of the care with which patients are examined The correction of this situation is of importance not alone to the individual patient in terms of future well-being, but also to the institution and its staff in protecting its reputation for diagnostic accuracy If insurance against daily errors in diagnosis can be purchased without excessive cost neither physician nor patient can afford to be without its protection

Considering the 40 cases of the "C" group in which accurate diagnosis was later achieved through roentgen information derived from examinations conducted at the request of the clinical staff, one finds that in several instances costly time was lost which would have been saved had the reports of the survey films been made immediately available This delay amounted to only two days in 29 instances, while in 11 cases 4 to 90 days elapsed before diagnosis was made from roentgen evidence The average time loss per patient for this group of 40 people was 6.75 days, representing a very real though unnecessary financial load

Four cases in particular from this group deserve specific mention

1 R H , f Admitted 7-2-35 to Gynecology
 Survey film Minimal pulmonary tuberculosis
 Clinical diagnosis Chronic pelvic inflammation No response to conservative treatment

Roentgen-ray consultation 8-15-35 Minimal pulmonary tuberculosis
 (Still under treatment 3-1-36)

It is true that the course of treatment was not altered in this case

2 A T , f , aged 65 Admitted 7-10-35 to Dermatology
 Survey film Disseminated pulmonary tuberculosis (figure 7)
 Clinical diagnosis Pyogenic ulcer of scalp
 Roentgen examination of skull Luetic osteitis suggested
 Roentgen-ray consultation, chest, 8-1-35 Disseminated pulmonary tuberculosis
 Death 9-1-35
 Autopsy 9-2-35 Miliary tuberculosis lungs, spleen, liver, peritoneum, and left kidney Tuberculosis of scalp and skull

The generalized nature of the disease was unsuspected for 22 days

3 M S , f , aged 60 Admitted 7-8-35 to Medicine
 Survey film Neoplastic metastases right base (figure 8)
 Clinical diagnosis Carcinoma of colon
 Transferred to Surgery Cecostomy, 7-10-35

a

b

FIG 7 Disseminated pulmonary tuberculosis

FIG 9 (a) Large metastatic lesion, left upper lobe (Admission survey film) (b) Same case examined on direct refer 11 days later

FIG 10 (a) Reduction in size of metastatic lesion following roentgen therapy (b) Continued growth of metastatic lesion despite further irradiation

Roentgen-ray consultation (7-16-35 and 7-18-35) bedside chest examination
Postoperative pneumonia (respiratory movement resulted in blurring of sharply defined border of lesion)

Biopsy via sigmoidoscope 7-27-35 Adenocarcinoma

Discharged 8-9-35

Nineteen days earlier the nature and prognosis of this case could have been determined

4 M N, m, aged 29 Admitted 7-5-35 to Genito-urinary Surgery

Survey film Large metastatic lesion left upper lobe (figure 9 a)

Clinical diagnosis Teratoma of testis

Roentgen-ray consultation 7-16-35 Neoplastic metastasis, left lung (figure 9 b)

Roentgen therapy, 7-16-35 to 7-26-35, 1500 r, 200 KV, to scrotum, 600 r, 200 KV, to each of 10 chest and pelvic ports

Surgery 8-6-35 Removal of testicle

Biopsy 8-6-35 Chorioepithelioma

Roentgen-ray consultation, 8-6-35 Marked reduction in size of chest lesion (figure 10 a)

Roentgen therapy 8-28-35 to 9-10-35 400 r, 200 KV, to each of 10 ports

Roentgen-ray consultation, 1-3-36 Chest lesion enlarging

Roentgen therapy 1-7-36 to 1-8-36 600 r, 200 KV, to each of 2 chest ports

Roentgen-ray consultation, 2-19-36 Further increase in size of chest lesion

A delay of 11 days awaiting result of Aschheim-Zondek test before metastasis was recognized and radiation therapy instituted

COST OF SURVEY

Looking into the all important matter of costs of the venture several very interesting facts have come to light The actual material cost of producing single exposure chest roentgenograms on transparent film by the routine survey plan already outlined is surprisingly low even when one takes into account all items fairly chargeable against the project

TABLE III

Material or Non-Professional Cost of Survey

Capital cost	\$50 00*
40 gallons of developer @ 45¢	18 00
40 gallons of fixing solution @ 20¢	8 00
Technician 14 days @ 35¢ per hour	39 20
Ward-helper 14 days @ 33¢ per hour	36 96
Dark room labor 4 hours daily, 14 days @ 50¢ per hour	28 00
Stenographic service 32 5 hours @ 50¢ per hour	16 25
1116 14 by 17 films	558 89
	<hr/>
	\$755 30

* Note This figure represents a total capital investment for chest radiographic apparatus \$5000 00 plus \$1000 00 for necessary building alterations with interest at 6 per cent amortized over a five year period which is customary in this institution

It is our intention, if and when the chest survey plan becomes a permanent feature in this institution, to use transparent celluloid film cut to the special size of 13 by 14 inches This will mean narrowing the film by one inch and shortening the film by three inches which in the majority of cases will permit

inclusion of the entire thorax. For unusually large patients, 14 by 17 films can still be used, and conversely for small children 11 by 14 or even smaller films can be used. Since film costs vary directly with film area this will permit a still further reduction in the material cost of this type of examination. In fact, had the 13 by 14 size been used in this particular test the saving would have amounted to \$168.29. This additional saving will more than cover the customary 25 per cent charged against all budget expenditures in this institution for general administration overhead.

At this point it should be emphasized that over and above the preparation of satisfactory roentgenograms at material costs such as those already enumerated, the examination of such films by physicians trained in their interpretation is all-important if a survey of this sort is to have any medical value whatever. It goes without saying that this medical service entails further expense which can by no means be overlooked. By well established precedent throughout all branches of medicine the right to establish a suitable fee for his own personal services has long been reserved to the physician himself. It is not the intention of this communication to suggest what a proper fee for this medical service should be, but rather to point out that established roentgen laboratories, whether privately owned or operated by hospitals or clinics, can render an exceedingly valuable service to referring physicians at a cost which need not be prohibitive. It will be remembered that the plan calls for a simple survey of the chest of *all* new admissions in order to quickly uncover unsuspected manifestations of disease within the thorax, to provide a record of that patient's chest for future reference and to direct both the roentgenologist and the referring physician in the matter of requesting and carrying out further, more detailed studies in those cases where further study seems advisable. It must not be inferred that present fees for individual stereoscopic examination of the chest or other special procedures are necessarily exorbitant. The reporting of survey films by mere indication as to whether the chest appears to be barren of pathological changes, shows evidence of changes which though interesting may not be significant, or shows definite evidence of abnormality requiring further study, is not time consuming and, if done in quantity, is not costly from the material viewpoint nor need it be costly from the professional viewpoint.

SUMMARY

To test the theory that it would be profitable to subject all persons presenting themselves for physical examination and treatment to a preliminary roentgenographic survey of the chest, this sort of examination was conducted on all patients registering at the University Hospital for a period of 14 successive clinic days. At the outset it was postulated that five conditions must be met if the plan were to be considered practicable. The first of these conditions, "increased diagnostic accuracy," was adequately met by the final results for a conservative estimate shows that in the group of

patients so studied 14 were found to present significant, if not alarming, chest situations which were not discovered by other means

The demand that the survey plan must demonstrate the ability to "increase diagnostic speed" was well shown by the fact that patients with significant chest changes, ultimately satisfactorily diagnosed, could have had these diagnoses pronounced on the average of 6.75 days sooner

It was postulated that the plan should constitute "no added financial burden to patients," that the aggregate roentgen-ray cost to the group of patients so examined did not exceed the amount paid by those few who by one method of selection or another might be sent for roentgenological examination of the chest in the ordinary course of events. Actually, of the total group surveyed numbering 1116 individuals, 164 patients were referred in for chest examination, the results of the admission survey having been withheld. These individuals actually paid in the aggregate \$99.00 more than the material cost of surveying the entire group. It is further true that the total survey cost did not include professional fee for interpretation. If one is willing to offset this additional cost to the patient group by the indeterminate saving, certainly to be affected by the reduction in time of complete examination set forth in the preceding paragraph, it may be assumed that no additional cost would have been imposed upon the patient group.

It is impossible to determine accurately the extent of any possible loss in revenue in the Roentgen-Ray Department which the fourth postulate insisted must not occur. It seems logical to assume that the 50 patients shown to have definite pathological changes in the chest, who were not subsequently subjected to roentgen examination at the request of the examining physician, would have been studied more thoroughly had the survey findings been known. Though the Department of Roentgenology would undoubtedly lose certain chest examinations done more or less on suspicion by the referring physician, it would at the same time gain more interesting and more extensive work as the result of the discovery of unsuspected chest lesions in the survey process.

The fifth and last condition to be met, namely, that roentgenological service presumably valuable might be extended to all patients by spreading costs has undoubtedly been satisfactorily shown to be true. Many of the benefits to be derived from a survey of this sort are not at first glance recognizable. Months, even years after the patient's original admission subsequently developing chest lesions may be compared in so far as their roentgen appearance is concerned with that same chest as it appeared on the date of first admission.

CONCLUSIONS

- 1 The methodical practice of submitting all patients presenting themselves to a hospital or clinic for physical examination to routine roentgenographic examination of the chest can be accomplished expeditiously and without great inconvenience to the patient.

2 Roentgenographic chest survey of all hospital and clinic admissions assists the examining physician in quickly determining which patients may profitably be subjected to more searching examination by the roentgen method

3 Routine chest survey may be expected to disclose alarming chest changes in approximately 8 per cent of patients presenting themselves to a general hospital or clinic

4 Significant chest disease unrecognizable by other methods and often totally unexpected on the basis of chief complaint and history may be expected in something over 1 per cent of large, diversified patient groups

5 Roentgenographic chest survey offers a means of increasing the speed with which obscure chest situations may be accurately diagnosed

6 The cost of offering this one type of roentgenographic service to all patients need not constitute an unwarranted financial burden upon patients

CHRONIC ARTHRITIS, A GENERAL DISEASE REQUIRING INDIVIDUALIZED TREATMENT ^{*}

By ERNEST E. IRONS, F A C P, *Chicago, Illinois*

HUNDREDS of discussions and scores of books have been written about arthritis—and still they come, largely because this condition occasions more disability than any other disease in temperate climates, and its care presents a greater multitude of difficulties. In presuming to bring to you so age-worn a subject, I plead as excuse the request of your President, and the fact, expressed in my title, that in recent years there has come a great change in the general conception of the relation of disease of the joints to disease of the rest of the body. This altered viewpoint makes easier the understanding of the variable course and symptomatology of arthritis, and facilitates the formulation of a program of treatment suited to each patient. I can offer little that is new, but perhaps may present old observations in a relationship which will be serviceable in planning treatment.

Before passing to the problems of chronic arthritis it is of interest to recall that much acute arthritis is clearly related to infections, and occurs as a part of the general infectious process. Frequently the causative organism such as gonococcus, streptococcus or pneumococcus is demonstrable in cultures from the infected joints. The number of joints involved, however, is remarkably small when considered in relation to the number of times that bacteria must reach joint structures in the course of the demonstrated bacteremias of infectious diseases. Furthermore, the infected joints usually heal under appropriate treatment and rest, without residual impairment of function. We may conclude that the cartilage and other joint tissues of normal persons are fairly resistant to infectious insults.

This suggests that when joints fail to heal, and the arthritis passes into more chronic forms, factors other than the initial infection, such as inferior cartilage, impaired blood supply and nutrition, may be concerned in the disease.

Causes other than infection such as serum disease, hemorrhagic diseases, as well as trauma, may also initiate acute arthritis. The parallelism noted between the acute arthritic phenomena of serum disease and the exacerbations of arthritis in rheumatic fever can be readily extended to some of the acute exacerbations of chronic arthritis which follow acute respiratory infections.

The concept of chronic arthritis as a general disease, rather than one of the joints alone, is steadily gaining ground. It is generally conceded that there are many initiating and contributing causes of chronic arthritis. These include infection, trauma, the wear and tear of use, heredity, dis-

^{*} Presented at the Detroit meeting of the American College of Physicians, March 2, 1936.

turbances of vascular supply or of general and local nutrition, metabolic and glandular dysfunction and the degenerative changes of advancing age. Various combinations of these causes and conditions in individual patients result in varying clinical pictures, whose common factor is involvement of joints and structures attached to the bony skeleton. No one single cause or condition is common to all cases of arthritis.

Many classifications of chronic arthritis have been suggested, but as so often happens the simplest seems the best, and the division of chronic arthritis into atrophic (rheumatoid) and hypertrophic (osteo-) arthritis, suggested by Garrod in 1890, and by others later, has been adopted by the American Committee. The British Committee suggests a classification, similar but somewhat more elaborate.

Atrophic (proliferative, rheumatoid) arthritis occurs in the younger age groups, often in women, and is characterized by multiple joint involvement with fusiform appearance of joints of fingers, often ulnar deflection, and later ankylosis. The onset is either insidious or acute, and evidence of initial and often of continuing infection is frequent. In many patients constitutional effects with slight fever, anemia, and poor nutrition are marked.

Hypertrophic arthritis begins on the average somewhat later, or beyond middle life, in persons often well-nourished, and causes disability from slight to severe crippling. It is usually polyarticular but may be monoarticular. Lipping of joints, and hyperostoses are frequent, ankylosis is rare. Fibrous thickenings, Heberden's nodes with later bony hyperplasia at the terminal joints of the fingers are common. The effects of the trauma of work are often noted in the hands and spine of the laborer. Evidences of infection are much less frequent than in the atrophic form and when discovered, their removal influences but little the course of the arthritis. Arthrosis, which has been suggested to replace the term arthritis of this type, has at least the virtue of being less committed to the inflammatory concept.

Certain difficulties are met with, however, in accepting the dictum that the two types are etiologically and clinically distinct diseases in the same sense that lobar pneumonia and typhoid fever are from the beginning, by reason of their etiology, different diseases.

Now and then joints in the same patient show in one the pathologic anatomy commonly found in atrophic arthritis and in another the pathologic changes of hypertrophic arthritis. While evidences of infection predominate in atrophic arthritis and are usually minimal in hypertrophic arthritis, there are exceptions in which acute inflammatory processes occur in the hypertrophic form. The Heberden nodes, frequently found in chronic hypertrophic arthritis, may at times become acutely tender, red, and swollen following acute (such as respiratory) infections. Trauma of work, a large factor in hypertrophic arthritis, also appears in evidence in atrophic arthritis in which the right hand in a right handed person shows more extensive change than the left.

The location of the affected joint and the degree of its exposure to the trauma of weight bearing have been shown to influence the type of arthritis which develops. The effect of heredity seems as clear in atrophic arthritis occurring in grandmother, mother and daughter as in the family incidence of early hypertension. Racial, familial and individual peculiarities in connective tissue response to injury, as illustrated by the variable formation of keloid in surgical scars, and the varying rapidity and extent of callus formation after fractures indicate the wide range of individual tissue response to trauma. The same factors undoubtedly influence the healing of tissues of joints.

Is it not possible that the disease process in chronic arthritis assumes this or that course with the production of one or another type of arthritis by reason of the kind, age and resistance of tissues of the patient whose joints have suffered an initial insult? It may even be argued that the same insult which initiates in one person an atrophic arthritis, might, if received by a person whose tissues were less vulnerable, have caused no more than a temporary disability. In this connection, consider the variety of types of arthritis which may follow gonococcal infection, from an acute temporary and quickly healing arthritis, to the chronic forms, indistinguishable from "atrophic arthritis" or again from spondylitis ankylopoietica of the British classification.

The predominance of infection in atrophic arthritis as compared to hypertrophic arthritis is evident, but the cause for this predominance may well lie in the poor resistance to infection of the patients' tissues in general, including those of the joints, which also in these cases are less well able to withstand injury and heal than are those of persons with a better heredity.

In this sense we may regard the person whose general resistance to infection is below the normal, and whose cartilage and joint tissues are by reason of heredity less able to withstand insults and to heal than are those of normal persons, as potentially a candidate for atrophic arthritis. In such a person, further lowering of resistance to infection, malnutrition, overwork, extreme nervous strain, as well as severe infections, especially those of the respiratory tract, become etiologic factors in the atrophic arthritis which follows. The arthritis which gives the clinical name to the condition is thus only one expression of the more fundamental general disease.

It is generally agreed that the division of chronic arthritis into two great groups, the atrophic (rheumatoid) and hypertrophic (osteo-) arthritis is extremely serviceable. One of the chief values of this classification rests on the fact that it takes into consideration the previous reactions of the tissues of the patient and so prophetically indicates the kind of changes he is likely to suffer in the future, and, therefore, the measures which should be taken to meet and modify the disability which threatens him.

Borderline cases, and those in which both types are found in the same patient, are accounted for by unusual combinations of causes including vary-

ing exposure to trauma, and the peculiar tissue reactions of the individual patient

With this multiplicity of continuing causes of chronic arthritis in mind, the original initiating cause, not infrequently undeterminable, becomes less important, and the care of the present problems of the patient moves to the fore

Again, we may ask, does the presence or absence of infection determine the course and type of the arthritis, or is infection present (either active, or apparently not participating in the progress of the disease) by reason of decreased general body resistance to infection, and not because of the presence of arthritis? If the latter, we may then conceive of atrophic arthritis as occurring in persons whose cartilage and joint structures heal less readily when injured than in the usual normal person, and whose resistance to infection is also below the normal. When such a person suffers from an infection his joints are less likely to escape, and once involved, healing is incomplete and the process becomes a progressive one. He is likely to suffer from recurrent infections especially streptococcal, with exacerbations of joint disease, and studies of his blood will show the evidences of infection

The process in the joints, which gives the name of arthritis to the illness, is subordinate to the more fundamental basic constitution of the patient, in respect to his general resistance to infection and to the ability of his joint tissues to heal or to resist varying degrees of trauma. Again the emphasis falls on the general features of disease in the body rather than on that in the joints alone. In the established case of hypertrophic arthritis, infection seems to play but a minor part, nutrition suffers little, there are degenerative changes in cartilage and much of the disability results from marginal ossification, and mechanical interference with joint motion

TREATMENT

Clinical experience and methods of treatment of chronic arthritis have progressed through the study of the effects of treatment of groups of patients by one or another method, such as the search for and removal of infections, the giving of this or that drug, attempts at immunization by vaccines, the use of special diets or the employment of physical therapy. These surveys have required enormous expenditure of effort, and an industry that commands admiration. Some of these studies have been well controlled and have taken into consideration the natural history of arthritis and its well recognized tendency to spontaneous remissions. Others have consisted of uncritical observation of many patients for short periods, and are of little or no value

Some patients have been benefited by each of the remedies exhibited but, as might be anticipated, no one remedy has proved to be curative in a large proportion of groups of patients so selected

No two patients present the same combination of symptoms nor are

their problems to be met in exactly the same manner. Different combinations of causes may result in arthritis of essentially the same type, although certain causes undoubtedly tend to be associated with one or the other type. The type of arthritis which will develop depends on the age, nutrition and kind of tissues of the patient.

For purposes of a general survey and classification of arthritis, the study of patients in large groups is necessary, but for purposes of treatment and cure the unit of study is the individual patient. In chronic arthritis, as in the solution of current economic problems in medicine, methods of mass production are bound to fail.

There are certain general and special measures from which can be selected those applicable to each patient. Rest for the patient as well as for his joints heads the list. In many cases this means rest in bed. Removal of causes of worry and apprehension in so far as this can be accomplished in these times of unrest is as essential as physical repose. Elimination of infection is of first importance in many, and will contribute to the improvement of still other patients.

A well-balanced diet, including milk, eggs, meat, fruit and vegetables, affording full caloric requirement, with ample protein and fat, is important especially in atrophic arthritis. In the obese, reduction of weight will give relative relief from trauma to weight bearing joints. Reduction of carbohydrates may at times decrease local swelling and distress of joints. A diet excessively high in sugar and starches, frequently adopted by patients invalided with arthritis, is undesirable also because it is likely to be deficient in proteins, fat, and vitamins and contains insufficient residue to provide for efficient elimination. An abundant fluid intake will promote elimination by the kidneys and bowel.

Most of the drugs specially devised for the treatment of arthritis have not justified the claims made for them. In general the trend is away from excessive drug therapy in arthritis. Preparations of the salicylic group are useful for their analgesic action. Iron and other antianemic drugs in combination with diet are of great value in combating anemia. Thyroid deficiency, frequently present in chronic arthritis, is met with appropriate doses of thyroid extract. Vaccines as a routine treatment are as ineffective as are certain of the widely heralded drugs. There are, no doubt, many instances in which vaccines have been helpful, but more often they have been used as a sort of occupational therapy by patient and physician, sometimes to the exclusion of more effective agencies.

In addition to measures taken to remedy general anemia and malnutrition of the patient, local treatment to improve nutrition and circulation in the joints is required. Heat, dry and with moist packs, combined with gentle massage increases local blood supply. The degree of active and passive motion to be employed is to be determined in each case, with the necessity of gentleness always in mind. For these purposes, simple appliances and those improvised in the home are desirable. In the past year we have been

treating the cold clammy extremities of atrophic arthritis with negative pressure by means of the Pavaex machine. The skin temperature is increased, and in the small group of selected patients so treated the joints have improved.

Chronic arthritis, especially in its advanced stages, requires skilled orthopedic care. Much may be accomplished in correction of deformities and improvement of posture of the arthritic. More important still is treatment earlier in the disease, to prevent deformities and contractures. If ankylosis is unavoidable, positions of joints most serviceable to the patient should be secured.

In spite of the present popularity of vitamins, it would seem that much of the reputed necessity for vitamins may be obviated by moderate attention to the maintenance of a balanced diet including the conventional articles of milk, fresh fruits and vegetables, eggs and meat. In so far as there is probability of an unavoidably incomplete diet or lack of sunlight, the vitamin deficiency may be supplied in form and amount necessary for the general welfare of the body. There is still some doubt as to the wisdom of supplying this or that vitamin in large doses for the cure of disease of the joints. Neither is an immediate favorable effect on the joints clearly proved, nor have the more remote, and possible unfavorable effects of massive doses of vitamin-containing substances on human tissues been determined.

Gout is not so rare as some have thought, and may occur alone or in combination with either of the two great types of chronic arthritis. Preparations of colchicum, and appropriate modification of diet are as effective as ever in gout.

Osteochondritis or epiphysitis of the spine originating in rapidly growing children with characteristic lesions involving the vertebral bodies may cause early pain, disability and bone deformity, and in later life contribute to osteoarthritis. The recognition of these lesions by means of the history and by the roentgen-ray will obviate a fruitless search for local infections and suggest necessary rest and support for the painful backs of these youngsters.

Much can be done for the patient with chronic arthritis. Recognition and treatment of his general defects in nutrition and in resistance to infection, and his individual tissue response to injury, are as important as treatment of his joints. The resultant of causes and tissue responses is recorded in the changes already evident in the joints.

Classification of chronic arthritis into atrophic and hypertrophic types is advantageous and practical. While it may express to a varying extent etiologic factors, it is more important as an indication of the aggregate result of both general and local causes which have been active in each patient, and of the probable subsequent course of the disease.

The patient with arthritis is best treated not as one of a crowd, but individually, with reference to his own special problem of general as well as local disease.

TREATMENT OF PNEUMONIA WITH SERUM CONTAINING TYPE-SPECIFIC, HETEROPHILE, AND NEUTRALIZING ANTIBODIES ¹

By VLERNER B CALLOMON, M D , and JOHN UNGAR, JR , M D ,
Pittsburgh, Pennsylvania

THE value of the conventional antipneumococcus sera, both unconcentrated and concentrated, has been shown to lie for the greater part in their content of type-specific protective antibodies. Unfortunately, their field of usefulness has been restricted chiefly to Type I infections, although there is some evidence of activity in Type II and in Types VII and VIII infections ¹. In Type III and most Group IV infections evidence of any curative value is lacking. For some years immunologic observations have been accumulating which have led to the preparation of an antipneumococcus serum containing additional immune factors.

In 1911 Forssman ² observed that the injection of guinea pig tissues into the rabbit results in the production of antibodies which not only react with their homologous antigen, but also hemolyze sheep's red blood cells. Because these antibodies react with antigens other than those which produce them, the term heterophile has been applied to both antibody and antigen. It later developed that this type of antigen is present in a variety of animal and bacterial species, while absent in others. Injection of heterophile antigen into animals in whose tissues it is lacking results in the formation of heterophile antibodies. This does not occur when animals whose tissues contain heterophile antigen are so injected. Among the animal species containing heterophile antigen are the guinea pig, cat, dog, mouse, chicken, and horse. Among those containing none are the ox, rat, rabbit, and man.

In 1931 Bailey and Shorb ³ published the results of experiments from which they concluded that heterophile antigen is present in pneumococci, and in common with heterophile antigen from other sources is capable of inducing the production of heterophile antibodies when injected into the rabbit. These antibodies react with heterologous as well as homologous types of pneumococci. They also reported that serum from human convalescent pneumonia patients shows a definite increase in heterophile antibody titer.

This latter observation has failed of confirmation by Finland, Rueggesser, and Felton, who recently reported their inability to demonstrate significant increases in heterophile antibody content of serum from human pneumonia cases or from cases immunized against pneumococcal antigen ⁴.

Further experiments by Bailey and Shorb ⁵ were reported in 1933.

* Received for publication December 13, 1935.

From the Section on Respiratory Diseases, Division of Medicine, Allegheny General Hospital.

These bore out their earlier conclusion that pneumococcus heterophile antibodies are not type-specific, and in addition disclosed that the heterophile antibodies in antipneumococcus rabbit serum are partially neutralized by normal horse serum, and to a greater degree by antipneumococcus horse serum. This, of course, demonstrates the presence of natural heterophile antigen in normal horse serum and the increase of heterophile antigen in antipneumococcus horse serum. Furthermore, they found that the addition of various proportions of antipneumococcus rabbit serum to antipneumococcus horse serum enhanced its opsonic power for pneumococci. This opsonic activity seemed to be intimately associated with the heterophile antibody fraction.

In 1930 Jamieson and Powell⁶ found that some pneumococcus filtrates contain toxic substances which can be demonstrated and measured by intradermal tests in human beings and certain breeds of rabbits. They were able by subcutaneous injection of horses to produce sera having the property of neutralizing these toxic substances. These sera were not type-specific, but appeared active against filtrates of all types of pneumococci. They also observed that serum from convalescent human pneumonia cases contained such skin test neutralizing substances.

In 1933 Powell, Jamieson, Bailey, and Hyde,⁷ realizing that the conventional antipneumococcus horse serum falls short of the ideal because of its content of heterophile antigen and lack of heterophile antibody, carried out experiments with various combinations of antipneumococcus rabbit and antipneumococcus horse serum in the treatment of pneumococcus infections in rabbits. They found that such combinations were much more effective therapeutic agents than either serum used singly.

Laboratory investigation and animal experimentation having given such encouraging leads, a clinical trial of the use of such a preparation in the pneumococcus pneumonias of man seemed indicated. A composite serum has recently been prepared for this purpose. In its preparation horses are immunized by intravenous injections of virulent cultures of Types I, II, III, and IV (Type IV of Group IV of Georgia Cooper) pneumococci, and subcutaneous injections of whole culture toxic vaccine of the same types. When by trial bleedings sufficient type-specific protective potency for Types I and II pneumococci and sufficient neutralizing value has been determined, the serum is drawn, refined, and concentrated. Rabbits are immunized by intravenous injection of the same types of pneumococci. Their serum is tested for heterophile antibody, refined, and concentrated. The horse and rabbit antisera are then mixed in such proportions that the heterophile antigen present in the horse serum is precipitated and filtered out, and a final titer reached of 10,000 conventional mouse protective units each of Types I and II, 100,000 skin test neutralizing units,⁶ and 50,000 heterophile antibody units^{*} in each therapeutic dose.^{*} In comparing the finished product with

* Description of preparation taken from information received from Eli Lilly and Company, Indianapolis, Ind., whose generosity in supplying the serum used in this study is gratefully acknowledged.

the hitherto available conventional, concentrated sera of the Felton type, it is at once apparent that they are alike in their content of type-specific protective antibodies against Types I and II, but differ in that in the composite serum heterophile antigen has been eliminated and heterophile and neutralizing antibodies have been added

Experience with the use of this serum in the treatment of a series of cases of pneumococcus pneumonia in Pittsburgh during the season of 1934 to 1935 forms the basis of this report. It was planned arbitrarily to select for this treatment cases of proved pneumococcus pneumonia which came under observation not later than the fourth day of their disease, and which were not obviously complicated. As will appear, a few cases received serum therapy which were later found not to have these qualifications. These latter cases will receive separate consideration. Before instituting serum treatment, in addition to a history, physical examination, blood count, and sputum examination, a roentgen-ray of the chest was taken when possible in order to establish the diagnosis conclusively. Blood cultures were taken at two-day intervals in all cases but one which was treated outside of the hospital. Sputum was regularly typed, but no attempt was made to further differentiate members of Group IV. Following the establishment of the diagnosis, a therapeutic dose of serum was given intravenously at four- to six-hour intervals for approximately 10 doses, or until the fever subsided and showed no tendency to rise again. Prior to giving the serum, intracutaneous and ophthalmic tests were made to avoid dangerous serum reactions. Supplementary treatment consisted only of limitation of diet to liquids including an adequate supply of fruit juice fortified with dextrose, daily enemas as required, and symptomatic medication, such as oxygen and morphine, when indicated. Of 32 cases treated by this method, 24 cases are included in this series as having all the qualifications originally demanded. Brief case outlines follow.

CASE REPORTS

Case 1 J L W, male, Indian, aged 42. Admitted November 19, 1934. Lobar pneumonia, right upper lobe. Onset one day prior to admission. Sputum pneumococcus Group IV. Blood culture negative. Roentgen-ray confirmatory. Serum treatment instituted on third day of disease 24 hours after admission. Five ampoules of serum given in 40 hours. Death occurred on fifth day of disease. Autopsy lobar pneumonia with multiple abscesses of lung.

Case 2 J F, male, white, aged 49. Admitted November 26, 1934. Lobar pneumonia, right hilus. Typical onset one day prior to admission. Sputum pneumococcus Type I. Blood culture pneumococcus Type I. Roentgen-ray confirmatory. Five ampoules serum given within 24 hours after admission. Recovery by rapid lysis.

Case 3 N S, male, white, aged 68. Typical onset, December 8, 1934. Lobar pneumonia, right lower lobe. Sputum pneumococcus Group IV in large numbers. Blood culture not taken. W B C, 24,200. Serum started 17 hours after onset. Three ampoules at six hour intervals. Recovery by crisis.

Case 4 J H, male, white, aged 44. Admitted January 5, 1935. Lobar pneumonia, whole right lung. Onset one day prior to admission. Sputum pneumococcus

Type I Blood culture pneumococcus Type I W B C, 30,650 Roentgen-ray confirmatory Eight ampoules of serum given within 48 hours after admission without terminating illness Type I convalescent whole blood (250 c c) given over fifth, sixth, and seventh days of illness Recovery on seventh day of illness

Case 5 T E, male, white, aged 57 Admitted February 7, 1935 Lobar pneumonia Onset two days prior to admission with pain but no chill Sputum pneumococcus Type II Blood culture negative W B C, 28,900 Roentgen-ray confirmatory Four ampoules serum given within 24 hours after admission Recovery by rapid lysis

Case 6 D K, male, white, aged 40 Admitted February 12, 1935 Postoperative lobar pneumonia, right lower lobe Onset one day following herniorrhaphy Sputum pneumococcus Group IV in large numbers Blood culture negative W B C, 17,600 Roentgen-ray confirmatory Serum started first day Six ampoules serum given Recovery by rapid lysis

Case 7 N K, male, white, aged 55 Admitted February 18, 1935 Lobar pneumonia, right lower lobe Typical onset one day prior to admission Sputum pneumococcus Type III Blood culture negative W B C, 13,000 Roentgen-ray confirmatory Four ampoules serum given within 24 hours after admission Recovery by rapid lysis

Case 8 J M, male, white, aged 72 Admitted March 21, 1935 Lobar pneumonia, left upper lobe Post-tuberculous fibrosis of both apices Onset of pneumonia four hours prior to admission Sputum pneumococcus Group IV and some streptococci Blood culture negative W B C, 28,350 Roentgen-ray confirmatory One ampoule serum given five hours after onset Recovery by rapid lysis

Case 9 M B, male, black, aged 25 Admitted March 29, 1935 Lobar pneumonia, left lower lobe Typical onset seven hours prior to admission Sputum pneumococcus Group IV Blood culture negative W B C, 17,000 Roentgen-ray confirmatory Eight ampoules of serum given in 48 hours Recovery by rapid lysis

Case 10 G B, male, white, aged 42 Admitted April 5, 1935 Lobar pneumonia, left lower lobe Typical onset five hours prior to admission Sputum pneumococcus Group IV Blood culture negative W B C, 22,000 Roentgen-ray confirmatory Eight ampoules of serum given Recovery by rapid lysis (Figure 1)

Case 11 G P, male, white, aged 35 Admitted April 15, 1935 Lobar pneumonia, right upper and middle lobes Nephritis Chronic alcoholism with delirium tremens Onset two days prior to admission, three days before serum Sputum pneumococcus Type I, few Vincent's organisms Blood culture negative W B C, 23,350 Roentgen-ray confirmatory Urine heavy albumin and many casts Blood chemistry N P N 66 mg, Urea N 54 mg Eight ampoules serum in 28 hours Rapid fall to normal in 24 hours Temperature rose following day with development of marked delirium Three more ampoules serum given Developed marked bradypnea, cyanosis and some nuchal rigidity Spinal fluid increased pressure, but otherwise normal Death on sixth day

Case 12 Mrs C F, female, white, aged 35 First seen April 19, 1935 Lobar pneumonia, whole left lung Empyema Typical onset 28 hours before seen Sputum pneumococcus Group IV in great numbers Blood culture negative W B C, 28,000 Roentgen-ray not taken (patient at home) Ten ampoules of serum given in 48 hours Defervescence by gradual lysis to normal, followed by secondary moderate rise due to empyema Pus from pleura pneumococcus Type II Thoracotomy with rib resection Recovery

Case 13 J B, male, white, aged 31 Admitted April 20, 1935 Lobar pneumonia, left lower lobe Typical onset two days prior to admission Sputum pneumococcus Type III Blood culture negative W B C, 14,550 Roentgen-ray con-

mococcus Group IV Blood culture negative W B C, 25,000 Roentgen-ray pneumonia, left hilus Four ampoules serum given within 24 hours Recovery by rapid lysis

Case 22 L S, male, white, aged 54 Admitted May 27, 1935 Postoperative lobar pneumonia, right upper lobe Onset with chill one day following prostatic resection Sputum pneumococcus Type III Blood culture negative W B C, 25,150 Roentgen-ray confirmatory Ten ampoules of serum given in 48 hours Recovery by lysis

Case 23 R S, Male, white, aged 72 Admitted May 28, 1935 Lobar pneumonia, right lower lobe Typical onset two days prior to admission Sputum pneumococcus Type II Blood culture negative W B C, 28,750 Roentgen-ray confirmatory Nine ampoules of serum given in 36 hours Recovery by rapid lysis

Case 24 J M, male, black, aged 53 Admitted June 5, 1935 Lobar pneumonia, whole left lung Onset three days prior to admission with fever, cough, pain, and bloody sputum, but no chill Sputum pneumococcus Type III, streptococci, Vincent's organisms, Leptothrix Blood culture negative W B C, 45,300 Roentgen-ray confirmatory Ten ampoules of serum given in 48 hours Recovery by lysis After one week of practically normal temperature and well being, moderate fever again developed and roentgen-ray showed left lower lobe entirely cleared, but very dense shadow in left upper lobe and considerable infiltration of peribronchial variety in right upper lobe Abscess, tuberculosis, or neoplasm suspected Patient, upon his own insistence, left hospital before accurate diagnosis could be established

Brief outlines follow of those cases which, after serum treatment was instituted, proved to be lacking in certain of the qualifications demanded for admission to the above series

Case A D T, male, black, aged 24 Admitted November 26, 1934, with diagnosis of lobar pneumonia, right upper lobe Onset about one week prior to admission with fever and pain, but no chill Variable signs over right upper lobe Sputum pneumococcus Group IV and Vincent's organisms Blood culture negative W B C, 10,000, 10,500, 10,100 Roentgen-ray shadow over right upper lobe Wassermann 3 plus Six ampoules serum given in first 48 hours with no effect After 12 days in hospital, course of neoarsphenamine given and patient recovered by slow lysis The finding of many Vincent's organisms in the sputum with negative blood culture, comparatively low leukocyte count, lack of any noticeable effect on the course from serum administration in contrast to gradual defervescence over a period of three weeks under neoarsphenamine administration, might well justify a diagnosis of pulmonary spirochetosis rather than pneumococcus pneumonia

Case B C D, female, white, aged 22 Admitted February 6, 1935 Postoperative lobar pneumonia, left lower lobe Onset probably one day following biopsy and cauterization of cervix Sputum not sent until one week after recovery, when it showed streptococcus Blood culture negative W B C, 12,500 on fifth day postoperative Roentgen-ray confirmatory Serum started on fourth day postoperative Three ampoules serum given Recovery on sixth day postoperative Although physical signs and roentgen-ray evidence of pneumonia were present and response to serum administration was typical, there is no proof that this pneumonia was due to pneumococcus infection

Case C H M, male, white, aged 17 Admitted March 6, 1935 Lobar pneumonia, left lower lobe Marked malnutrition Delirious on admission Onset two days prior to admission Sputum bedside direct smear, pneumococcus (?) Blood culture negative W B C, 23,100 Roentgen-ray confirmatory Urine heavy albumin and much pus Six ampoules of serum given Death in 45 hours While pneumococci were thought to be present in the sputum at bedside examination, no

laboratory confirmation of this finding is available. Moreover, inasmuch as the urine was reported to contain a heavy cloud of albumin and a large quantity of pus, it is quite possible that this patient may have been suffering from generalized infection secondary to disease in the genito-urinary tract.

Case D J S, male, white, aged 18. Admitted March 9, 1935. Lobar pneumonia, right upper and lower lobes. Right empyema. Bronchopneumonia and fibrinous pleurisy in left lung. Onset five days prior to admission. Sputum pneumococcus Group IV. Blood culture negative. Culture from empyema hemolytic streptococcus W B C, 22,000. Roentgen-ray confirmatory. Nine ampoules serum given within 48 hours after admission with no apparent effect. Recovery by lysis after surgical drainage. Even though Group IV pneumococci were recovered from the sputum, there was evidence of fluid in the right chest on admission, hemolytic streptococci rather than pneumococci were recovered from the pleural exudate, and defervescence gradually occurred after drainage of the empyema. The streptococcus infection was probably dominant.

Case E H G, male, white, aged 22. Admitted March 9, 1935. Lobar pneumonia. Loculated empyema and fibrinous pericarditis. (These present on admission.) Onset with chill four days prior to admission. (This information questionable.) Sputum pneumococcus Group IV. Blood culture pneumococcus Type II. Pleural fluid pneumococcus Type II. W B C, 20,000. Roentgen-ray confirmatory. Seven ampoules serum given. Several aspirations of chest. Death 48 hours after admission. Autopsy confirmed clinical findings. Due to the fact that the empyema was loculated, adequate drainage could not be obtained.

Case F H R, male, white, aged 31. Admitted May 9, 1935. Lobar pneumonia, whole right lung. Typical onset two days prior to admission. Sputum pneumococcus Group IV, tubercle bacilli, Vincent's organisms. Blood culture pneumococcus Group IV. W B C, 18,150. Roentgen-ray confirmatory. Twelve ampoules serum in 48 hours. Recovery from pneumonia by slow lysis. Sent to tuberculosis sanatorium.

Case G W R, male, black, aged 48. Admitted May 16, 1935. Lobar pneumonia, whole left lung, right upper and middle lobes. Active pulmonary tuberculosis. Diabetes mellitus. Typical onset one day prior to admission. Sputum pneumococcus Group IV and many tubercle bacilli. Blood culture negative. W B C, 15,950. Roentgen-ray confirmatory. Urine sugar 4 plus. Blood sugar 308 mg. Nine ampoules of serum given in 48 hours. Temperature fell by crisis on seventh day, however, a secondary rise associated with symptoms of meningeal irritation occurred two days later, and death occurred on eleventh day. Spinal fluid globulin 1 plus, 60 cells, mostly lymphocytes. Autopsy lobar pneumonia as above, pulmonary tuberculosis.

Case H A C, male, black, aged 60 (?). Admitted July 8, 1935. Lobar pneumonia, whole right lung. Onset three days prior to admission. Sputum pneumococcus Type III. Blood culture pneumococcus Type III. W B C, 50,000. Urine sugar 4 plus, acetone and diacetic acid positive. Blood chemistry N P N 61.6 mg, sugar 652 mg. Roentgen-ray confirmatory. Three ampoules serum given in 15 hours, temperature, pulse, and respiration dropped rapidly to normal. However patient became stuporous and comatose and temperature again rose and patient died of diabetic coma 24 hours after admission. Reports of blood chemistry and urine not received in time to institute treatment.

COMMENT

In the following discussion only the 24 cases of proved pneumococcus pneumonia admitted not later than the fourth day of their disease and not obviously complicated are considered.

One of the outstanding impressions received in observing this group of cases was the relative absence of symptoms and signs of severe toxicity. Although quite aware of the impossibility of accurately measuring manifestations of toxicity, we were struck by the low incidence of marked cyanosis, by the relatively low degree of respiratory embarrassment, the improved quality of the pulse, and the low incidence of delirium and tympanites after serum had been administered.

In evaluating specific therapy for an acute febrile illness of known duration, one of the most important factors is its ability to shorten the course of the disease as well as alter its severity. From a review of the above case abstracts this property of the serum is strongly suggested. It may be rightfully objected that an occasional case of pneumonia may terminate in less than the classical seven days, yet one could hardly anticipate this in as high a percentage of cases as occurred in this series. Of the 24 fully qualified cases which were serum treated, 16 (numbers 2, 3, 5, 6, 7, 8, 9, 10, 13, 14, 15, 16, 18, 20, 21, and 23) recovered by rapid lysis or crisis.

No mortality statistics on the basis of so limited a series warrant any definite conclusions. Experience with the treatment of this disease shows that its mortality varies from season to season and even from month to month. It may be remarked, however, that the death rate from pneumonia in Pittsburgh is always comparatively high, in fact it is usually not exceeded by that in any other of the large cities of the United States. It is equally impossible to maintain adequate control in estimating the value of a curative agent because the number of variables, such as age, virulence of infection, degree of blood invasion, previous state of nutrition and health, stage of disease upon admission, etc., is legion. Nevertheless a comparison of the mortality rate in this series and that in a group of approximately the same number which were treated in this hospital at about the same time without serum is interesting and, we believe, suggestive. The control series was comprised of those proved cases of pneumococcus pneumonia without obvious complications which either entered the hospital in the few weeks before the trial of serum treatment was initiated or during the periods when our supply of serum was exhausted, those which were admitted later than the fourth day of the disease, and those which were private patients of other physicians in the hospital and not under our control. Most of these cases received small doses of quinine in addition to the hygienic and symptomatic treatment outlined above. Of 24 serum-treated cases three died, a mortality of 12.5 per cent. Of 26 cases* treated without serum 10 died, a

*Of these, one case which recovered, and one which terminated fatally were not typed. Excluded from the control series were one case complicated by pyelonephritis and phlebitis, one case by diabetes mellitus, one case by parturition, four cases by asthma, one case by pulmonary fusospirochetosis and lung abscess, one case by rheumatic arthritis, and one case by chronic heart disease with decompensation.

Thus far in the 1935 to 1936 pneumonia season ten additional cases have been serum treated, with nine recoveries (including three with positive blood culture) and one death. These will receive further analysis in a subsequent report covering the current season's experience.

Grateful acknowledgment is made to Miss Edith Culbert for valuable aid in the preparation of accurate records.

mortality of 38.5 per cent. It is true that the average age in the serum-treated group was 47 while that in the control group was 50. However, of five cases aged 60 or more in the serum-treated group one died, a mortality of 20 per cent, while of 10 cases above 60 years of age in the control group six died, a mortality of 60 per cent.

Analyzing the mortality as to type, we find that of three cases of Type I infection treated with serum, one case died, of two cases of Type I infection in the control series, both recovered. There were no deaths among three serum-treated cases of Type II infection, while one case out of three in the control group died. Of particular interest is the comparison in the Type III and Group IV cases, against which the serum contains no type-specific protective antibodies. Of six cases of Type III infection in the serum-treated group, one died, a mortality of 16.7 per cent, while three cases out of eight in the control group died, a mortality of 37.5 per cent. One case out of 12 in the serum-treated series of Group IV infections died, a mortality of 8.3 per cent, while of 11 in the control series five died, a mortality of 45.4 per cent. This marked discrepancy in mortality in the latter two groups gives support to the thesis that heterophile antibody and skin test toxin neutralizing bodies are of considerable value in the control of these infections.

Of four serum-treated cases with positive blood cultures one died. Of nine cases with positive blood cultures in the control series four died. Parenthetically, it is interesting to note that of three fatal cases in the serum-treated series, only one had a positive blood culture, and of 10 fatal cases in the control series only four had positive blood cultures. As opposed to the 25 per cent mortality in the four cases with positive blood cultures in the serum-treated series, there were two deaths among 20 cases or a mortality of 10 per cent in the cases with negative blood cultures. Whereas, in contrast to the 44.4 per cent mortality among the nine cases with positive blood cultures in the control series, there were six deaths among 17 cases with negative blood cultures, a mortality of 35.3 per cent.

If all cases to which serum was administered, regardless of their qualifications, were taken into consideration, the series would consist of 32 cases with seven deaths, a mortality of 21.8 per cent. The Type I mortality would be unaffected. There would be four cases of Type II infection with one death. There would be two deaths among seven cases of Type III infection, a mortality of 28.5 per cent, and two deaths among 16 cases of Group IV infection, a mortality of 12.5 per cent.

If all cases treated without serum, regardless of complications, were included in the control series, the latter would consist of 36 cases with 17 deaths, a mortality of 47.2 per cent. The Type I mortality would be unaffected. There would be five cases of Type II infection with three deaths. There would be four deaths among nine cases of Type III infection, a mortality of 44.4 per cent, and eight deaths among 17 cases of Group IV infection, a mortality of 47 per cent.

FIG 3 Composite chart Cases 2, 3, 5, 6, 7, 8, 9, 10, 13, 14, 15, 16, 18, 20, 21, and 23

It should be noted that, judging from the experience with this series of cases (cases number 12, 17, 19, and E), this serum given intravenously seems to have no anti-bacterial activity against pneumococci that have gained access to the pleural sac

In the early days of the study serum was given at six-hour intervals. Later the interval was reduced to four hours with, we believe, better results. The number of ampoules given varied from one to twelve, the majority of cases receiving eight ampoules. Chill reactions were frequent in the early cases following administration of the first allotment of serum received, none of which, however, proved serious. Since that supply was exhausted such reactions have been remarkably rare. Serum sickness of the usual type, characterized by urticaria, joint pains, and low-grade fever occurred approximately one week after administration in 14, or 56 per cent, of the 25 cases which recovered.

As the most striking effect of the administration of this serum thus far observed appeared to be a prompt, premature defervescence, a composite chart (figure 3) was prepared by plotting the average daily temperature, pulse, and respiratory rate in 16 cases (cases number 2, 3, 5, 6, 7, 8, 9, 10,

13, 14, 15, 16, 18, 20, 21 and 23) responding by crisis or rapid lysis. The curve begins with the records immediately preceding the first dose of serum.*

The question of whether the outcome of the disease is influenced by the stage at which treatment is instituted cannot be answered from this study, since serum treatment was limited to cases admitted not later than the fourth day of their disease. Further investigation is necessary to determine whether this type of serum treatment has value in cases seen late in the course of their infection. The question of optimal dosage also requires further study.

SUMMARY

Experimental observations of various investigators have been cited which indicate that the efficacy of the conventional type-specific antipneumococcus horse serum is enhanced by the addition of heterophile antibody and antibodies which have the property of neutralizing toxic substances in pneumococcus filtrates.

Experience with the use of such a modified antipneumococcus serum in the treatment of a series of 32 cases of pneumococcus pneumonia in Pittsburgh during the 1934 to 1935 season has been outlined and the results analyzed. Comparison has been drawn between the results in this series and those in a similar series treated without benefit of serum administration. While the series is relatively small and dogmatic conclusions therefrom as to effect on mortality are probably not warranted, certain deductions may, we feel, be reasonably drawn.

CONCLUSIONS

- 1 Serum-treated cases appear definitely less toxic than those not so treated.

- 2 The febrile course of a large percentage of cases of pneumococcus pneumonia of all types treated with serum was prematurely terminated.

- 3 The efficacy of the serum in Type III and Group IV cases is particularly striking as these infections have not been favorably influenced by the administration of the available conventional antipneumococcus sera.

- 4 Antipneumococcus horse serum modified by the addition of heterophile antibody and neutralizing antibodies for toxic substances in pneumococcus filtrates constitutes a promising new agent in the therapy of pneumococcus pneumonia.

SOME FACTORS IN THE ETIOLOGY OF THE PSYCHONEUROSES *

By LOUIS CASAMAJOR, M D , *New York, N Y*

THE first factor of importance in the understanding of the etiology of the psychoneuroses is that they are not clinical states in the sense of diseases but rather they are states of mind. These patients come to physicians for treatment, and their symptoms are usually referable to one of the bodily systems, but the physician must recognize that they represent not something which has happened inside the patient but something which has happened to the relationship of the patient to the world in which he has to live. Thus each psychoneurosis is an expression of the reactions of the individual toward certain factors of his life which he is unable to handle in a manner compatible with health.

One might well ask what has health to do with the reactions of a patient to his life's problems? It would have nothing to do with it were it not for the fact that sickness may be an asset to the patient. Sickness is incapacitating surely and takes one to the doctor, but often sickness likewise may have an asset value in that it serves as an excuse that permits one to neglect to do things that would be required of one who is well. The Monday morning headache of the child who has not prepared his home work is the prototype of many neurotic symptoms that may appear later in life—when again the needs of existence appear to be too much for one to meet. The asset element in many of the neurotic symptoms of adult life lies in the fact that they absolve one of the responsibility of acting like a normal healthy individual. We pity the sick, excuse them from many things and afford them special treatment, and it is just this special treatment that the neurotic is searching for with his symptomatology.

Within the scope of such a paper it would be impossible to go into the psychology of the psychoneurotic symptomatology. Here one can only draw the line, somewhat arbitrarily, between conscious, deliberate fabrication of symptoms in which the patient himself does not really believe—which is malingering—and the unconscious assumption of symptoms in whose reality the patient stoutly believes—which is neurosis. Charcot expressed this distinction in his famous dictum "The hysteric is a malingerer who does not lie." This succinct sentence expresses all that I have space to say before I go on to etiological factors.

The *raison d'être* then of the psychoneurosis is the fact that it permits the patient to escape from complete responsibility for himself. Responsibility to others and to the world in which we live is in good measure the product of civilization. The more complex our civilization the greater are

* Presented at the Detroit meeting of the American College of Physicians, March 3, 1936.

the responsibilities of each individual member. One may refer it, as Trotter did, to the herd instinct, but whatever it is there can be no doubt that the average man can not live in comfort and happiness unless he has the good opinion of those in whose company he lives his daily life. We sum these factors up in the expression "public opinion," and each man must bask in some degree of that in order to preserve that good self opinion which is so essential to normal life.

The mores of the group may press most heavily upon an individual, but nevertheless he feels he must conform to them if he is to hold his head up among his fellows. There are ideals in public opinion which most of us feel we must at least compromise with even if we are not inclined to conform to them. There are those who feel this way about religious ideals but their number seems to have diminished in recent years. Even where this diminution has occurred not dissimilar ideals of an ethical and a social nature have taken their place with equal force. Ideals of decency and honesty, of fair dealing and "square shooting," of loyalty and honor, of duty and that rather vague thing which is spoken of as "social consciousness" are just as potent as those other similar ideals which are based on worship and reverence. The taboos attached to these social concepts may not be violated unless one is sick, and neurosis is one of the sicknesses that permit it. Not only must the violation not be in reality but it must not be even in the thoughts and wishes of the individual. Of this he is frequently more afraid than he is of any possible infraction in real life. The former is quite as damaging to self respect and, because it has never reached any real expression, it is all the more frightening and hence productive of neurotic symptoms.

Were life as simple as perhaps it should be, were all our motives as nobly inspired as we would like to have the world believe, no one would be beset with the sort of conflicts which form the basis for the psychoneuroses. Man is a social animal, but he is not only that. More fundamental than the social side of human life is the individual, selfish, egocentric side which expresses itself in the doctrine of "every man for himself and the devil take the hindmost" that determines much more of human conduct than do the social, altruistic motives of which we like to boast. This is the sort of conflict that calls for a resolution in every one of us. That resolution may be an adjustment of the personality compatible with health or, when it breaks down, a psychoneurosis. The individual and the social are often opposing forces which pull the erring human in many ways, and one, at least, of these ways leads to neurosis.

Man plays, at best, a dual rôle in many of his activities, and this would be of little consequence were it not for the fact that both ends of this duality are mutually incompatible. The more incompatible the components of this conflict the greater is the possibility of the conflict eventuating in a neurosis. Such a conflict as that between man as a decent member of a civilized society and man as a mammal, or between man as an idealistic social being and man

as a greedy individualist, requires considerable mental adjustment and adaptation to reach a level of solution. This solution may be one compatible with mental health—an adequate one such as most of us succeed in attaining and maintaining most of the time—or an inadequate one in which the need for sickness plays a part of varying importance. Such inadequate solutions may be benign or malignant. The benign reactions are those which permit the individual to lead something approximating a normal life even though a sick one, which is the psychoneurosis, while in the malignant reactions the patient has cast aside all pretense of a normal life to live in a world of his own fantasy, which is psychosis of the schizophrenic sort.

But we must confine ourselves to the psychoneurosis and try to outline some of the factors which stand in conflict with the social man. Primarily these are things of the instincts. One runs the risk of treading on debatable ground when one speaks of instincts. So much has been said and written on this subject that one can find a plenty of opinion either to establish or deny the importance of these primitive motives. This is not the place to indulge in such a controversy. We must assume merely that there are trends in human and other animal life which are not learned and which are common to most of the members of a species. By instincts one need mean little more than this.

It is convenient to divide instincts into two groups: (1) instincts of self preservation, and (2) instincts of preservation of the species. The former may be called the ego instincts and the latter the sexual instincts. In the discussion of the etiology of the neuroses the sexual instincts have played a very prominent role. Perhaps this may have been too prominent, but it is doubtful if this could be the case. It is doubtful if there exists in animal life a force more potent than sex. In defining sex one must not restrict the definition to those physical activities which tend to eventuate in the preservation of the species. The term sexual must cover all of those activities, physical and mental, which appertain to the phenomenon of human mating. Nothing is more interesting to the majority of the human race than this, and nothing occupies human thought to a greater extent. Plato's description of the sexual urge as "an imperious head-strong power" is as accurate today as ever. It is the motive most fitting of all to come in conflict with the ideals of a self-conscious, repressed society. It is true that improper handling of sexual urges in a mind-bound society by inadequate individuals brings to us the majority of our psychoneuroses, but all psychoneuroses are not based upon sex.

The other instinct of self preservation is just as capable of producing psychoneurotic reactions when improperly handled as is the sexual, and it is of this group especially that I wish to speak. The instinct of self preservation is often of even less respectability than is the sexual. It tends to express itself in motives that may have even less of social value than the other. Such egocentric motives as fear and greed are potent forces in all of us but they are never pretty things. Most of us are even more ashamed of them

than we are of our sexual urges. Potent they are in individual life, but on the social plane they are frequently shameful, hence they are ideally fitted to form the basis for that sort of conflict in the personality that leads to neurosis.

Fear is a normal component of animal psychology. It is a direct expression of the instinct of self preservation. Not only is there fear of death which is but an expression of the wish to live, but there are other fears which constantly beset the individual in a civilized society. Fear of injury, fear of exposure and of shame, fear of loss of position and respect, fear of the future, both here and hereafter, and fear of the loss of the feeling of personal security are quite as competent causes of the psychoneurosis as is anything in the sexual life. Life is necessary for man, but even more necessary often, for civilized man, is comfortable life which is not possible without a high opinion of himself and an adequate measure of approval from public opinion.

Greed is another motive all too human. Frequently we like to call it by other more euphonious names especially when we see it in ourselves. It is difficult to appraise it accurately because it is so universal, and even when one sees it in very pure form, such as in some of the litigation and compensation neuroses, one does not like to call it by its real name. Maybe I should not use the word if I feel it calls for so much defense, but I know of no other that expresses so much of what I mean.

If this were all to the ego plane neuroses, just fear and greed, the problem would be simple indeed, but many other motives enter into the make-up. Euphemism and hyperbole play as important a part in the etiology of the psychoneurosis as they do in the symptomatology. Self-respect which is often only another name for conceit, justice which is often indistinguishable from revenge, and the desire for security which may be but a form of indolence may, any or all, enter into the causation of the ego neurosis and cloud the understanding of it with terms that are difficult to define. And when a money value can be placed upon the neurosis as in the compensation neurosis, and legalistic considerations enter into its interpretation, one is faced with a psychological problem of such complexity that simple direct thinking becomes well nigh impossible.

I had hoped in this paper to describe these ego-plane neuroses in which sexual factors play little if any part. They have been described as "situation neuroses" in an attempt to express the idea that situations in the environment of the patient play the more important rôle in the etiology. This is not altogether the case, for while it is true that external considerations hold a prominent place in the causation, yet the personality of the patient and his instinctive ego urges really do the work of formulating the neurosis just as they do the neuroses of sexual origin.

We saw the ego neuroses in their simplest and truest form in the war neuroses—the so-called "shell shock" of the World's War. Back of all of them lay the good old human mechanism of fear—that fear which we all felt

near the front. Some of these cases appeared in camps in this country and others in France at any point up to the front. The clinical picture was the same no matter where they were seen, for the primary cause was the same—fear, which hit different men at different places.

In civil life we have as frequent ego-plane neuroses the compensation-litigation neuroses with which you are all familiar. Usually these follow injury of some sort and hence are known as “traumatic neuroses.” The nature and severity of the injury have nothing to do with the make-up of the neuroses. The one point they all have in common is that the injury is compensable. I have yet to see a patient with a traumatic neurosis which resulted from an injury sustained while working for himself.

In business life today ego-plane neuroses not infrequently develop. The present business depression is responsible in a way for some of them, but the ego motives of greed and fear of personal and financial insecurity still form the foundation stones of the etiology. It is interesting to note that the depression has not materially increased the number of our psychoneurotics. This is especially true of those people who are on relief. They have hit the bottom and have nothing left to fear. Life can become nothing but better for them, and on a ground work of such a psychology, psychoneurosis can not find soil to grow. They may become dulled and discouraged or they may become social radicals but the psychoneurosis is not a part of their reactions. It is usually those who still have hopes of surmounting their difficulties and eventually triumphing who hold in their makeup the capacity for psychoneurosis. This is especially true when compensation factors occupy a place in the general life picture. The following cases may illustrate some of the points which I have been trying to make.

CASE REPORTS

Case 1 J. M., aged 58. This man, an uneducated Russian Jew, was brought to this country while still a small child and had been earning his own living since he was eight years of age. As a boy he went into the clothing business and worked his way up until he owned his own factory. He prospered and says he made a great deal of money, and during this time he took out a large amount of life and disability insurance.

In 1927 he began to feel badly but kept on with his work because he had always been a hard worker and knew of nothing else to do. He lost considerable weight and finally “collapsed” at his place of business. When examined by his doctor he was found to have diabetes, under treatment he improved. For the first few months he was able to spend only an hour or so a day at his work, and as a result his business suffered. By 1929 his business was in such bad shape that he decided to close it out, which he did without going into bankruptcy, paying his creditors in full. It is of interest to note that during these years of considerable incapacity he never made any claim upon his insurance company for compensation although he was clearly entitled to it. He felt secure in regard to the future and his ability to earn his living at his trade without relying on compensation. In 1930, after he had closed out his business, he took a position as a salesman with another clothing firm and did well. He continued to work hard, and his employers were sufficiently satisfied with him to renew his contract when it expired. Then something happened to business. He saw it melting away before his eyes. He had always been able to make good adjustments

in a world of good business, but he could find nothing to live by in a world of no business

In June of 1931 he had what he describes as a "breakdown" He began to have headaches, pains all over, dizziness and general weakness These symptoms became gradually worse until he had to give up his work after a few months When I saw him in 1933 his complaints were dizziness, easy fatigability, headache, pains in his arms and legs, insecure gait and station and insomnia The neurological examination was entirely negative He was receiving disability compensation at the rate of \$500 00 a month

It was obvious that this man was suffering from a psychoneurosis and not from any organic disease of the nervous system The question of how much incapacity he had is a difficult one to answer unless one could define "incapacity" He had no means of support except his compensation, and if this were withdrawn he probably could not find enough business to do to support him Support was dependent on his being incapacitated He could not do any work because he thoroughly believed he could not work If his business would pick up he would probably be glad to get into it again and then would not need compensation The fact that he did not ask for compensation when he was organically incapacitated with his diabetes proves that he was not of the sort of personality that malingers His neurosis was caused by the business situation in which he found himself plus the compensation which gave him security and paid him well for staying sick

Case 2 J C, aged 47 This was an agitated, depressed looking man who came in complaining that he could not rest, that he worried all the time and felt a fog in his head In order to understand the condition one had to go back into the history to learn something of the background of this man's development He had been born in Italy, the eldest of 10 children At 16 years of age he came to this country and immediately went to work He always worked hard during the day and attended night school until he was 20 years of age He was interested only in his work and his family and took his responsibilities very seriously He supported his mother and helped his nine younger brothers and sisters to get an education, one of whom graduated from medical school After his marriage he devoted himself to his family, and his only interest was in making money for the support and education of his children

He prospered in the contracting business and built a number of houses, some of which he owned Previous to the stock market crash of 1929 he owned two fifty-family apartment houses and six two-family houses as well as other property Then came the crash of October 1929, which was the beginning of his troubles He was in the market pretty heavily and when stock prices fell he wanted to sell out all his holdings, but his bankers and his brokers insisted that he hold on to them They kept constantly calling on him to put up more money and this he did until he had no more left From being a man of considerable property and a comfortable income he was reduced to absolutely nothing except the \$130 00 a month disability compensation he received from an insurance company Then he became depressed and agitated and constantly walked up and down in his home saying he did not know what he was going to do At times he went around to his bank and complained to the officers that they had not treated him fairly, and they would send for his family to come and get him On one occasion they called in the police to remove him

He continued his worrying, slept badly and talked continuously about what fate had done to him In October 1931 he was placed in a State Mental Hospital where he remained for a year There he lost weight and did not improve mentally When he returned to his home he was calmer but his general mental condition was unchanged

The neurological examination was entirely negative Psychiatrically he appeared depressed and somewhat indifferent and he talked only of the past and of his losses

His stream of mental activity was somewhat underproductive. He did not show any persecutory trend except that he felt he had lost his money as much due to bad advice of bankers and brokers as to anything else, which undoubtedly was not a delusion. His orientation and memory were normal.

This man was suffering from a symptomatic depression of a psychoneurotic sort which is quite understandable when one thinks of what he had been through. It is not difficult to understand the make-up of this depression but it is not quite so easy to see what the outcome will be. As he is at the present time and as business is at the present time he is undoubtedly completely incapacitated. Whether he is permanently incapacitated or not probably depends much more on business conditions than upon himself. Should business pick up and this man be able to borrow some money, build houses and rehabilitate himself there is a good chance that he would recover completely. If prosperity does not return soon it is doubtful if he will ever again be a productive member of society.

If one could consider this man alone and not the social, economic and business situations, one would say that there was nothing in this man to incapacitate him. However, one must appreciate the fact that he is living in the world as it is today, and from that point of view one must say that this man is thoroughly incapacitated at the present time for living in the kind of a world we have in this country today. The compensation he receives is all the security he has at present. If that were taken from him he would most likely go into a deeper depression from which recovery would be most doubtful.

These two cases summarize much better than I can express otherwise the points I have been trying to make in this presentation.

SOLITARY ULCER OF THE ILEUM AND ULCER OF MECKEL'S DIVERTICULUM

By PHILIP W. BROWN, M.D., F.A.C.P., and JOHN DEJ. PEMBERTON, M.D.,
Rochester, Minnesota

REPORTS on solitary ulcer of the ileum and on ulcer of Meckel's diverticulum indicate such difficulty in diagnosis, as well as such high surgical mortality that we are endeavoring to present a clearer conception of the problems presented by these two conditions.

There are several excellent reports in the American literature on hemorrhage and perforation attributable to ulcer in or near a Meckel's diverticulum, but little has been written on solitary ulcer of the ileum. In the foreign literature is the paper of Oudard and Jean, who collected reports of 56 cases (37 of ileal ulcer and 19 of jejunal ulcer) in which they noted a 50 per cent mortality among patients whose ulcers were recognized and operated on, while the mortality was 100 per cent if the ulcers had perforated, or if they were not found at operation, or if operation was not undertaken. Aschner and Karelitz reviewed 32 reported cases in which an ileal ulcer was situated at the mouth of a Meckel's diverticulum, with 11 deaths in the 32 cases (34 + per cent mortality). Even relative to ulcer of Meckel's diverticulum, with or without localized evidence of inflammation, Johnston and Renner found reported four deaths in 32 cases (12 + per cent mortality). In some reports ileal ulcer has been confused with what is now recognized as regional enteritis. Recently we have become more alert to the possibility of this nonspecific inflammatory lesion of the small bowel and as a result we have encountered an increasing number of such cases in the past three years. It is only by clinically separating these various lesions, one from the others, that diagnostic accuracy in diseases of the small bowel can be improved. Knowledge that such conditions may exist serves to stimulate development of diagnostic criteria and finally efforts toward working out of the etiology. The importance of thinking of ileal ulcer or of ulcer in Meckel's diverticulum, in contradistinction to regional enteritis, lies not so much in diagnosis as in surgery, usually, the area of enteritis is readily located whereas an ileal ulcer may be accompanied by so few signs of peritoneal involvement as to be found only by very careful exploration of the bowel.

Our study is based mainly on the surgical records of 10 patients who had solitary ulcer of the ileum and of eight patients who had ulcer of Meckel's diverticulum. There are many points common to both conditions but it is simpler to discuss them separately. In addition, we have obtained data from records of necropsy.

* Presented at the Detroit meeting of the American College of Physicians, March 2, 1936.

From the Mayo Clinic, Rochester, Minnesota.

SOLITARY ULCER OF THE ILEUM

There should be more reports on ileal ulcers than now are available. The feeling has existed that it is futile to diagnose lesions of the small bowel, and there has been a tendency to advise either to "observe further" or to "explore the small bowel." In diagnosis of chronic obstructing lesions, the roentgenologist has been of much assistance. But ileal ulcer is a clinical problem, roentgenology, as well as laboratory aids, has been chiefly of negative value in ruling out other conditions. The one exception, relative to laboratory aids, is detection of occult blood in the stool, which, if proper precautions are observed, is of real diagnostic value.

In reviewing the records of necropsy of The Mayo Clinic for the past 15 years, data were found on only one case in which death had been caused by perforation and bleeding of an ileal ulcer. This patient, a parietic, was in a hospital for the insane, and was apparently in fair physical health until he complained of vague abdominal pain which culminated abruptly, in 24 hours, with a rapidly fatal hemorrhage from the bowel. At necropsy an ulcer was found in the ileum, 80 cm. from the ileocecal valve. In examination of three other subjects, who had died of debilitating or infectious diseases, a small superficial ileal ulcer was found but seemed to be only incidental. In examination of a fifth subject, who had died following ileosigmoidostomy, an ileal ulcer was found six inches (15 cm.) from the ileocecal valve. This patient had been operated on in the "pre-liver days" in the hope of benefiting his pernicious anemia by excluding the colon. Apparently similar ileal ulcers, either single or multiple, have been observed occasionally in examination of subjects who had died of pernicious anemia, aplastic anemia or leukemia. The records of necropsy disclosed only one case of solitary jejunal ulcer, excluding the cases in which jejunal ulcers were associated with antecedent gastroduodenal operations. This one case was that of a patient the primary cause of whose death was Hodgkin's disease and who also suffered from psoriasis. At necropsy, a perforating jejunal ulcer was found which contributed to the final outcome. (These five cases are not included in table 1.)

Among our surgical records we have found none of a case of solitary jejunal ulcer not associated with gastric surgery. In their comprehensive review, Oudard and Jean discussed 53 cases of ulcer of the small bowel which they had collected from the foreign literature and added three of their own. They found 37 cases of solitary ileal ulcer and 19 of jejunal ulcer. Barber, in 1926, reported a case of acute perforation of a jejunal ulcer in which successful operation was performed. Other than this case, there is very little that we can find in the American literature on jejunal ulcer.

Clinical Notes. The 10 patients included in our clinical study of solitary ulcer of the ileum (table 1) consist of seven males and three females. Four of the patients were 24 to 28 years old, one, 35, three were 43, 47 and 47, respectively, and two were 58. Their symptoms covered a period of from

TABLE I
Summary of Cases of Solitary Ulcer of the Ileum

Case	Age, years, and sex	Duration of symptoms, years	Chief symptoms, site of pain	Nausea and vomiting	Stools		Blood			Preopera- tive diag- nosis	Surgical findings, type of operation and date	Pathologic examination	Result
					Tarry	Occult blood	Hemoglobin, gm per 100 c c	Erythrocytes, millions per cu mm	Leukocytes, per cu mm				
1	58 M	3	Attacks of severe epigastric pain Many mild attacks	Once	0	Test not done	*	*	*	Intestinal obstruction	Stricture lower ileum due to annu- lar constricting ulcer which caused angula- tion and obstruc- tion of ileum Lat- eral anastomosis 1917	No tissue	Well
2	58 F	18	Increasingly severe attacks of epigas- tric pain culminat- ing in constant pain in umbilical region	0	0	0	*	*	*	Chronic in- testinal ob- struction	Ulcer 3 feet from ileocecal valve pro- ducing marked dilata- tion of proximal ileum Lateral anas- tomosis 1918	No tissue	Well (?)
3	47 M	3	Attacks of severe epigastric pain, worse shortly be- fore admission Pain extended through to back	+	0	0	*	*	*	Perforated peptic ulcer	Two inches provi- mal to ileocecal valve was perfor- ated, ileal ulcer sealed off by coils of ileum Contained several ounces of thin pus Lateral anastomosis Post- operative fistula needed repair 1916	No tissue	Well

TABLE I—Continued

4	43 F	4	Attacks of severe epigastric pain and tenderness in right lower quadrant Pain extended through to back	0	0	Test not done	*	*	*	Ileocecal tumor	Ulcer in lower end of ileum causing obstruction Lateral anastomosis 1927	No tissue	Well
5	47 M	8	Tarry stools every six months Some gas and distention No pain	0	0	+	7 0	3 5	7000	Bleeding lesion of small bowel	Spleen enlarged three to four times normal Half way between duodenum and cecum, stricture due to annular ulcer Dilatation of proximal ileum Resection and anastomosis 1930	Inflammatory annular ulcer containing lymphoid tissue	Well
6	35 M	7	Attacks of sharp pain left to right at level of umbilicus Pain extended through to back Shortly before admission, weak and pale	0	0	+	7 3	3 13	6900	Bleeding lesion of small bowel	Ulcer 3 feet from ileocecal valve with dilatation of proximal ileum Resection and anastomosis 1935	Subacute simple inflammatory ulcer 1 cm in diameter	Well
7	28 M	5	Vague dyspepsia Attacks of deep, bursting pain around umbilicus Pain extended through to back	0	0	+	8 8	4 37	6200	Ileitis (?) Meckel's diverticulum (?) Duodenal ulcer (?)	Two feet proximal to ileocecal valve, angulated loop with obstruction Resection and enterostomy 1934	Annular ulcer of ileum at mouth of a Meckel's diverticulum No gastric mucosa in diverticulum	Well

seven months to 18 years with an average of more than six years. In seven cases the first symptoms were moderate to severe attacks of abdominal pain which was situated in the lower part of the epigastrium, around the umbilicus, or in the right lower quadrant. The pain was described as cramping, colicky, or as a deep, bursting pain usually accompanied by nausea and vomiting. The degree of pain eventually was found to be related to the degree of inflammation and obstruction. In five cases the pain extended into the small of the back or to the region between the shoulders. In addition to the attacks of pain, there was an irregular type of dyspepsia which had vague features of peptic ulcer, cholecystitis, or appendicitis. Taking of food sometimes initiated the distress, or again seemed to relieve it, while alkalies afforded no constant relief. One patient related that his appendix had been removed without improvement resulting. Another had undergone abdominal exploration, but the abdomen had been closed again, a report had been given the patient that there was a mass in the lower right portion of the abdomen, and anti-syphilitic treatment had been advised. A third patient said that cholecystostomy had been of no avail. A fourth, in whose case splenic anemia had been diagnosed, received no benefit from splenectomy. Of three patients, whose earlier symptoms were pallor and weakness, two had passed black, tarry stools, while the most anemic patient had not been aware of gross loss of blood from the bowel. One of these three eventually had attacks of lower abdominal cramp associated with nausea and vomiting, although the other two had only mild distention from gas, with no symptoms of moment other than the anemia.

Undoubtedly the striking symptom in six of the 10 cases was the severe secondary anemia, which was evidenced by a concentration of hemoglobin ranging from 20 to 55 per cent and a number of erythrocytes ranging from 2,700,000 to 4,370,000 per cubic millimeter of blood. The stools of all six patients were found to give a positive test for occult blood. Four had been aware of bleeding from the bowel, but of greater moment are the two, the value for whose hemoglobin was 20 per cent and 30 per cent, respectively, who had not known of any loss of blood. In examination of three patients, associated splenomegaly was found and this led to the possible diagnosis of splenic anemia, one of the patients as has been noted above, had undergone splenectomy.

In all instances, aside from anemia or blood in the stools, the laboratory data were negative.

Surgical Findings Surgery, for the type of ileal ulcer that we have encountered at the clinic, has had a more favorable outcome than that related in other reports which have been based on a series of cases in which the preponderance of ulcers has been of the perforating type. In our 10 cases, there were two postoperative deaths attributable to peritonitis secondary to the surgical difficulties but not attributable to preexisting general peritonitis. In both fatal cases, that portion of the ileum which contained the ulcer had been resected. In four of the cases in which the results were successful

resection was performed, while in the remaining four, anastomosis around the obstructed portion sufficed to effect cure. In one of the latter four cases, the patient remained well for seven or eight years, at the end of which period her physician reported that she was again suffering some abdominal difficulty, the exact nature of which is not known to us.

Notes on Pathology In nine of the ten cases the ulcer was situated from 2 to 36 inches (5 to 91 cm) proximal to the ileocecal valve. In the tenth instance it was estimated to be in the ileum about half way between the duodenum and the cecal end. In nine of the 10 cases there was more or less evidence of dilatation and thickening of the ileum proximal to the ulcer. In none of the cases was there record of enlarged lymph nodes in the mesentery. Of the six specimens available for microscopic study, three (figures 1 and 2) were described as merely "subacute simple ulcers" about 1 cm in diameter, while the other three were classified as "annular constricting ulcers" (figures 3 and 4). In one of these, much lymphoid tissue was noted but in none was any heterotopic tissue found. Evidences of tuberculosis were not found. The significance of these pathologic findings lies chiefly in the fact that it is a simple ulcer of the small bowel which may produce bleeding, perforation, or obstruction just as is true of peptic ulcer. All of the six ulcers of the patients who had been bleeding were resected, whereas in four cases the element of obstruction without demonstrated hemorrhage or anemia led to the simpler procedure of lateral anastomosis around the obstructing portion.

In two cases the ulcer was situated in the ileum, at the mouth of a Meckel's diverticulum, which raises the question if the ulcer was related to possible heterotopic mucosa in the diverticulum, such as was reported in the comprehensive study by Aschner and Karelitz. They reported two cases in which the patients were infants and found in the literature reports of 21 other cases in which gastric mucosa was present in the diverticulum, also they included 12 additional cases, in which, however, microscopic study of the diverticular mucosa had not been made. They postulated that since gastric mucosa of Meckel's diverticulum can secrete acid and ferments, stimulation of this heterotopic mucosa may be a factor in producing the ileal ulcer. In our case 7 (table 1), examination of the diverticular mucosa gave no evidence of the presence of gastric mucosa (figure 5) but only ileal mucosa. In case 9 (table 1) there was likewise only ileal mucosa, which gave evidence of chronic inflammation and subacute superficial ulceration. Although these are the only cases in our series in which Meckel's diverticulum occurred, it does seem as if the ileal ulcer was the chief lesion and the diverticulum was merely incidental. This evidence is not offered as against the possible relationship of heterotopic gastric mucosa to an ileal ulcer at the mouth of the diverticulum but merely to justify these two particular cases as examples of solitary ulcers of the ileum.

From another angle, and anticipating the second section of our paper, none of the eight patients who had inflamed, hemorrhagic Meckel's divertic-

ula had ulcer of the ileum although in five of the eight cases, gastric mucosa was found in the diverticulum. Hence, in our cases in which gastric mucosa was found in the diverticulum an ulcer had not developed in the adjacent ileal mucosa

FIG 1 (Case 6, table 1) Subacute, simple ulcer of ileum, measuring 1 by 1 cm

FIG 2 (Case 8, table 1) Subacute, simple ulcer of ileum, measuring 2.5 by 1.5 cm

Comment The problem of solitary ulcer of the ileum has been tersely stated by Moiroud "Its pathology is obscure, its symptomatology is indefinite, and often perforation with peritonitis is its first revealing sign" Concerning our few cases, the last phrase could be changed to read, "and often secondary anemia with or without abdominal pain is its first revealing sign"

FIG 3 (Case 10, table 1) Subacute, constricting, annular ulcer of ileum

The various theories that have been advanced in explanation of the cause of peptic ulcer have been brought forth for solitary ileal ulcer but with no better conclusion relative to the one than to the other In 28 cases of perforated ileal ulcer, Oudard and Jean noted that six of the patients had suffered severe abdominal injury and seven had undergone severe stress just prior to the onset of symptoms No such history was obtained in our cases although there occurred no cases of acute perforation

It is strange that the lower end of the ileum is, second to the duodenum, the most vulnerable portion of the small bowel It is known that an ileal ulcer may develop when the error has been made of utilizing a loop of ileum rather than one of jejunum in the establishment of a gastro-enteric stoma Likewise, most of the Meckel's diverticula are in this last 3 feet (91 cm) of ileum All but one of 12 ileal ulcers (two seen at necropsy, not included in table 1, and 10 at operation) were found in this segment Is it possible that this portion is more vulnerable because the gradient of the entire bowel

FIG 4 (Case 10, table 1) A section of the ulcer represented in figure 3

is lowest at this point? ¹ May heterotopic tissue exist in the ileum as it does in some Meckel's diverticula? ² While this theory has been suggested, it does seem logical, as one would expect, that the ulcer should heal spontaneously after destruction of the heterotopic cells and that it should not persist as a chronic ulcer

--

FIG 5 (Case 7, table 1) Ulcer in ileum at mouth of a Meckel's diverticulum which contained ileal mucosa

Another query is the following Why is bleeding so common in these cases? Although ten cases are too few to permit of any conclusions, yet certainly secondary anemia was the striking symptom in two-thirds of this number Also, how can one explain the associated splenomegaly which was present in three of the six cases in which bleeding occurred and which also was noted in two of the eight cases in which there were bleeding ulcers of a Meckel's diverticulum? No patient gave any evidence of hepatic damage, nor would there seem to have been enough infection in the ulcer to produce infectious splenomegaly Dragstedt reported the case of a boy 17 years of age who was found to have an ileal ulcer at the mouth of a Meckel's diverticulum, in this case splenomegaly was noted but shortly disappeared after resection of the bleeding ulcer The patient who has secondary anemia

usually is not found to have splenomegaly although it occasionally occurs in association with the primary hypochromic anemia of women¹⁰ We have the impression that secondary anemia as a result of long-continued loss of blood from the bowel may produce splenomegaly Our data are not sufficient to support this but it may be that the size of the spleen has not been carefully noted in all cases Even though splenomegaly may occur only infrequently, it is important to bear in mind so as to avoid making a diagnosis of splenic anemia and thereby lead to splenectomy The rule of examining a series of stools for occult blood should help prevent this error Experimentally,⁷ splenomegaly has been produced as a result of chronic loss of blood from the gastrointestinal tract, myeloid metaplasia of the spleen was found to have occurred This would seem analogous to the findings in our five cases in which splenomegaly occurred

ULCER OF MECKEL'S DIVERTICULUM

The incidence of Meckel's diverticulum is about 2 per cent, with males predominating in a ratio of 2 : 1 The number of diverticula which produce symptoms is not easy to estimate They may be a factor in obstruction, by invagination with resulting intussusception, by producing a twist or by ensnaring a loop of bowel, especially if a remnant of the vitelline duct remains Others of these diverticula may undergo inflammatory change with resulting hemorrhage or perforation Johnston and Renner collected the data on 78 cases of this type There was microscopic proof of heterotopic mucosa in the diverticulum in 64 cases, in 50 of which definite ulceration was present In the remaining 14 cases there was gross evidence of ulcer but microscopic examination was not made Three-fourths of the 50 patients who had ulcers had suffered from bleeding from the bowel, and three-fifths of the 50 gave evidence of varying degrees of perforation

Our knowledge of this condition is again obtained from records of operation and of necropsy Data concerning the latter are not included in table 2, but from study of them Carlson has just completed a thesis on Meckel's diverticulum which covers the experience of the past 10 years His study concurs with previous reports as to the incidence of 2 per cent and as to the 2 : 1 ratio of males to females In 27.6 per cent of his 152 cases heterotopic tissue was found Mucosa from various parts of the gastrointestinal tract was found in any and all combinations, or identification was made of a single type of mucosa from some one part of the tract from the cardia to the colon, one diverticulum even contained only islets of Langerhans In none of the 152 cases was there evidence of ulceration, nor was the diverticulum related to the cause of death

In surgical records of the corresponding 10 years 85 cases of diverticulum were noted In 30 instances the surgeon merely recorded the abnormality as an accidental finding and the pouch was not removed In 47 of the 55 cases in which diverticula were resected, there was reason to think

TABLE II
Summary of Cases of Hemorrhagic Ulcer of Meckel's Diverticulum

Case	Age, years, and sex	Previous surgery	Duration of symptoms, years	Pain	Nausea and vomiting	Stools		Blood			Pre-operative diagnosis	Surgical treatment, date	Pathological report on diverticulum	Result
						Tarry	Occult blood	Hemoglobin, gm per 100 cc	Erythrocytes, millions per cu mm	Leukocytes, per cu mm				
1	6 M	Appendectomy, benefit	1/3	None	0	+	Test not done	12.6		8000	Meckel's diverticulum (?)	Resection for diverticulitis Enterostomosis 1933	Gastric mucosa with diverticulitis	Well
2	7 F	Appendectomy, no benefit. Resection part of ileum, no benefit	5	Attacks of diffuse abdominal pain	Not known	+	Test not done	46	3.3	8300	Meckel's diverticulum or polyp	Resection for diverticulitis 10 inches from ileocecal valve 1926	Gastric mucosa with chronic inflammation	Well
3	9 F	None	1	Severe attacks of pain lower quadrant and umbilical region	+	+	Test not done	13.7	5.38		Lesion of small bowel	Resection for diverticulitis 1930	Gastric mucosa with inflammation	Well
4	15 M	Appendectomy, benefit	12	Attacks of epigastric pain	+	+	+	66	3.69	8300	Lesion of small bowel	Resection for diverticulitis 18 inches from valve Splenomegaly (grade I+) 1926	Diffuse diverticulitis with gastric mucosa but no acid cells	Well
5	22 M	None	9	None. Mild aching right lower quadrant	0	+	Test not done	17.2	4.94		Meckel's diverticulum	Resection for diverticulitis 36 inches from valve 1935	Ulcer at base containing polypoid gastric mucosa	Well

TABLE II—Continued

Case	Age, years, and sex	Previous surgery	Duration of symptoms, years	Pain	Nausea and vomiting	Stools		Blood			Pre- operative diag- nosis	Surgical treat- ment, date	Pathological report on diverticulum	Re- sult
						Tarry	Occult blood	Hemoglobin, gm per 100 c c	Erythrocytes, millions per cu mm	Leukocytes, per cu mm				
6	30 M	None	24	Vague symptoms of ulcer Pain right lower quad- rant three days before admission	0	+	Test not done	12.1	3.05	6400	Subacute appendicitis	Resection of ileum with marked in- flammatory di- verticular mass Appendectomy 1935	Diverticulitis of ileal mucosa	Well
7	44 F	Appendectomy and chole- cystectomy, no benefit	10½	None Vague ab- dominal distress	0	+	+	37	2.18	4000	Duodenal ulcer	Resection for di- verticulitis 24 inches from valve Spleen resected (235 gm) 1935	Jejunal mucosa	Well
8	61 M	None	10	Severe abdominal pains	+	+	Test not done	48	4.46	18500	Obstruc- tion small bowel	Entero-anastomo- sis Resection of diverticulum Much inflama- tion (site not stated) 1930	Ileal mucosa with marked inflammation	Well

that the diverticulum might be related to the patient's complaints. These diverticula varied from the definite type, such as a large pouch filled with hard feces and impacted in the pelvis, to the smaller, more innocent appearing off-shoots, resembling segments of normal ileum, which were removed in the course of eliminating all possible sources of trouble. Kernohan, of the Section on Surgical Pathology, has studied for us this group of 47 diverticula. He reported as follows: normal ileal mucosa, 15 cases, inflammatory ileal mucosa, 22, excess lymphoid tissue in ileal mucosa, 1, excess lymphocytes in ileal mucosa, 1, gastric mucosa with acid cells, 3, and gastric mucosa (one containing carcinoma), 5.

These data would not suggest that diverticula which contain heterotopic mucosa are more likely than others to undergo inflammatory change. As previously has been noted, Carlson found 27.6 per cent of healthy heterotopic tissue in otherwise normal diverticula while in this smaller group of 47, which were removed because possibly they explained the patients' symptoms, only 16 per cent contained heterotopic tissue. Probably of considerable importance is the group of 22 patients in which varying degrees of inflammatory reaction were observed. This will constitute part of a further study in our endeavor to learn more about the symptomatology and diagnosis of diseases of the small bowel.

Clinical Notes. The remaining eight cases of the 55 (table 2) are those of particular interest because they were characterized by secondary anemia and bleeding from the bowel. These are the eight cases mentioned in the introduction to this paper. Johnston and Renner found that 89 per cent of their 78 patients were 16 years of age or less. Although our group of eight cases is far too small to be comparable, yet it is of some clinical importance to note that half of the patients were more than 20 years of age (22, 30, 34, and 61 years), while the others were less than 16 years of age (15, nine, seven, and six years). The usual duration of symptoms was about the same in this group of cases as in those of ileal ulcer, ranging from four months to 24 years, although the average duration in the cases of diverticulum was higher (about nine years), the increase in the average duration is accounted for by the one patient who had some vague symptoms for 24 years but had not been ill enough to warrant operation until the recent development of more acute distress.

Bleeding from the bowel was the striking and constant finding in all eight cases, although on admission the blood count was normal in two because bleeding had not occurred for some time. Three of the eight patients made little or no complaint other than of weakness and of a history of dark to tarry stools. It will be recalled that in three of the 10 cases of ileal ulcer, anemia and weakness were the early or only symptoms of trouble.

In addition to the intestinal hemorrhages, five of the eight patients had suffered from attacks of abdominal pain. One located the pain in the epigastrium, one, across the lower part of the abdomen and around the umbilicus, and a third had pain in the right lower abdominal quadrant. In two

cases, pain was recorded only as "attacks of severe abdominal pain" In three of them, the pain was explained at operation as probably being attributable to partial obstruction, and in these cases nausea and vomiting had occurred

Results of physical examination and laboratory findings were again meager, just as in the cases of ileal ulcer In most instances, roentgenologic studies of the stomach and colon were made and, of course, abnormality was not found Examination of the blood furnished one of the two objective positive findings and in six cases revealed secondary anemia of an extent depending on how recently hemorrhage had occurred For no apparent reason the stools were examined for occult blood in only two cases and the test was positive in both

Careful study of these eight patients, together with the apparent exclusion of disease of the upper and lower ends of the digestive tube, of a splenohepatic syndrome, and of blood dyscrasia, led to a fairly accurate diagnosis of "lesion or obstruction of the small bowel" in three instances and to an even more accurate opinion in three more that a Meckel's diverticulum probably was present In case 7 (table 2) duodenal ulcer was held to be the most likely diagnosis and, in case 6 (table 2), subacute appendicitis Neither of the last two was a grave error, as it was realized that surgical indications were present It often has been emphasized that frequently it is impossible to be sure of the diagnosis, but of far greater importance is the nicety of judgment required to determine that a condition is surgical This in turn, emphasizes the responsibility of the surgeon to be prepared for, and to look for and to cope with, an unusual condition if all is not as was anticipated preoperatively

As previously has been noted, the puzzling associated splenomegaly in two of the eight cases is of much interest In one, hemorrhages had occurred 12 years prior to operation but no further gross bleeding was observed for the succeeding nine years In the other case, gross bleeding had been noted for only the eight preceding months On admission the concentration of hemoglobin was 66 per cent and 37 per cent, respectively Probably the same explanation for the splenomegaly holds in these two cases as held in the three cases of ileal ulcer in which splenomegaly occurred

Surgical Measures and Results At operation the diverticulum in four cases was 10 to 36 inches (25 to 91 cm) proximal to the ileocecal valve, in the remainder the site was not specified In all, the diverticulum was resected and the ileal defect closed In two cases, entero-anastomosis seemed advisable, for closure of the defect produced undue narrowing of the lumen No deaths occurred and these eight patients had not had further trouble at the time of writing of this paper

Notes on Pathology Microscopic study of these eight diverticula revealed the following (1) gastric mucosa with diverticulitis, (2) gastric mucosa with chronic inflammation, (3) gastric mucosa with inflammation, (4) diffuse diverticulitis with gastric mucosa but without acid cells, (5)

polypoid gastric mucosa and at its base a shallow, ulcerated area 5 mm in diameter (figure 6), (6) ileal mucosa with marked inflammation of the diverticulum, (7) jejunal tissue, and (8) diverticulitis with ileal mucosa and ulceration of the entire mucosa

Again, one is dealing with too few cases to permit conclusions, but it may be more than coincidental that five of these eight patients who suffered from intestinal hemorrhages were found to have inflammatory gastric mucosa in the diverticulum, and the diverticulum of one other contained jejunal mucosa

FIG 6 (Case 5, table 2) Meckel's diverticulum containing polypoid gastric mucosa, with ulcer at the base

SUMMARY AND CONCLUSIONS

In none of 10 cases of solitary ulcers of the ileum was there found an associated Meckel's diverticulum containing gastric mucosa which might have been a factor in producing the ulcer. Of eight cases of inflammatory, hemorrhagic ulceration of a Meckel's diverticulum, in five gastric mucosa was found in the diverticulum and in one, jejunal mucosa. Possibly heterotopic mucosa is more likely to be found in cases in which bleeding is a feature. In contrast, in 47 additional cases in which a diverticulum had been resected, bleeding did not occur and only eight diverticula were found to contain gastric tissue. In 12 of the 18 cases there were sufficient clinical data to justify a preoperative diagnosis of a lesion of the small bowel. In three others the element of obstruction was outstanding and led to a diagnosis of intestinal obstruction. In two cases the condition was mistaken for peptic ulcers and in one, for subacute appendicitis.

Although definite clinical diagnosis is impossible, yet unexplained secondary anemia associated with a history of intestinal bleeding or with blood in the stools, and associated with roentgenologic evidence of a normal stomach and colon, should arouse the suspicion that there is an ulcer in the ileum or in a Meckel's diverticulum. Although attacks of midabdominal pain are customary, yet they may not occur. These observations should be sufficient to cause the clinician to advise surgical exploration. Hence there is need of close cooperation between clinician and surgeon in order that early diagnosis may lead to prompt surgical treatment. It should not be assumed that operation is urged on the evidence of a single intestinal hemorrhage or that all patients who have unexplained secondary anemia are too hastily subjected to exploration.

TABLE III

Condensed Data Concerning 18 Cases in Which Hemorrhagic, Ulcerative Lesions of the Ileum Existed

	Sex		Age, years	Pain	History of intestinal hemorrhage	Anemia	Occult blood in stool	Splenomegaly	Surgical result	
	Male	Female							Cured	Died
Solitary ulcer of the ileum (10 cases)	7	3	24 to 58	8	4	6	6*	3	8	2
Ulcer of Meckel's diverticulum (8 cases)	5	3	6 to 61	5	8	6	2†	2	8	

* No test made in two cases

† No test made in six cases

Pictures (table 3) of the two hemorrhagic, ulcerative lesions of the ileum which are the subject of this paper, represented by our 18 cases, may be described as follows:

Solitary Ulcer of the Ileum Usually the patient is an adult aged 20 to 60 years, of either sex but more likely a male, who gives a history of having had attacks of abdominal pain for about six years. This pain is situated in the region of the umbilicus and often extends through to the small of the back or to the region between the shoulders. The patient usually is pale and although he may have been aware of intestinal hemorrhages, this is not always so, possibly because of minute, steady bleeding, lack of observation, or color blindness. Studies of the stomach, duodenum, colon, and liver are normal. The blood count may be normal but often discloses secondary anemia. The examining physician should exercise care not to be misled by the finding of an enlarged spleen. The test for occult blood in the stool is usually positive. Less often, the syndrome presented by a male, who has

secondary anemia, who has no abdominal distress, and all studies of whom give negative results, except for a positive test for blood in the stool, should suggest ileal ulcer

Ulcer of Meckel's Diverticulum The same general picture applies except that the age level is lower and that among children this condition rather than ileal ulcer is more likely to be the cause of tarry stools and anemia

ERRORS IN THE INTERPRETATION OF CARDIO-VASCULAR SYMPTOMS AND SIGNS ¹

By PAUL D. WHITE, M.D., F.A.C.P., *Boston, Massachusetts*

ERRORS often lead the way to new knowledge. Some of the most important advances in medicine have developed from the recognition and study of errors. Many details of our present rapidly progressing understanding of the diagnosis of cardiovascular disease have arisen from our analysis of errors in the interpretation of cardiovascular symptoms and signs. It is of some of these that I shall speak to you today.

The appraisal of cardiac symptoms, the most important part of cardiovascular examination and the part that requires no use of hands or instruments, is, and always has been, the most imperfect and neglected. Why this is so is strange, but it is a fact which cannot be overemphasized in the present state of medical training and practice. Too often the history of the patient is relegated to a relatively untrained person when it would be safer to turn over any other part of the examination. Or the physician is too hurried, or tired, or preoccupied to do a proper job. In ancient days the presentation of symptoms was usually too brief, leaving out important clues, in recent years there has been a tendency to bury the clues in a mass of details which are often irrelevant. The chronological development and relationships of the chief symptoms are the essentials which with past and family history permit in most cases a correct diagnosis of the cardiovascular condition, even before the physical examination is begun. I shall first present errors in the interpretation of the three chief cardiac symptoms—pain, dyspnea, and palpitation.

A. SYMPTOMS

1. Pain

Mrs. E. C. M., 54 years old, housewife, entered the Massachusetts General Hospital on April 5, 1933, to have treatment for persistently recurring nocturnal heart attacks by paravertebral alcohol injection of the sympathetic nerve ganglia and rami.

Five years before she had begun to be troubled by momentary attacks of sharp, shooting pain originating just over the heart to the left of the sternum and radiating across the chest to the right and occasionally up over the left chest, almost to the clavicle. These transitory pains were not associated with exertion but seemed to come more when she was resting after a hard day and in the evening when in bed. She consulted her doctor who gave her tablets of nitroglycerine for the attacks, which seemed to give relief. This was at the time of the menopause. Ever since then this trouble had recurred at intervals, more frequently during the few weeks prior to her admission to the hospital, when she also noticed almost constant heartache, some dyspnea on hurrying, and blueness of her fingers and lips. Her ankles seemed to swell slightly at the end of the day. Her doctor digitalized her but she said that she had to omit the drug because of her inability to retain it.

* Read at the Detroit meeting of the American College of Physicians March 3, 1936.

About one year before entrance to the hospital she was troubled by another and more important symptom, consisting of precordial and substernal oppression in attacks at night awakening her and causing her to sit up, lasting for a few minutes at a time, and not responding quickly to nitroglycerine. On one occasion she was given morphine for relief. During the three weeks before entrance to the hospital these nocturnal attacks had increased in frequency and severity, and had been accompanied by a feeling of impending death, cold sweat, and rapid heart beat. She had, however, continued to do her housework as before.

Her past history revealed no important illnesses. She had six healthy children. Her mother and one sister had died of tuberculosis.

Physical examination showed a well developed and well nourished middle-aged woman with good color, normal breathing, no edema, and no abnormal neck pulsations. Her heart was normal in size, sounds, rate, and rhythm. There were no murmurs. The pulse rate was 80. The blood pressure varied from 154 to 165 millimeters of mercury systolic and from 90 to 100 diastolic. The lungs were normal.

Electrocardiogram showed normal rhythm and total inversion of Lead III.

Roentgen-ray examination showed some increase in the transverse diameter of the heart, which was recorded as greater than the long diameter.

The urine and blood were normal except for very slight albuminuria and slight secondary anemia. There was no bile in the urine. The stool was normal. The Hinton reaction was negative and the basal metabolic rate was minus 10 per cent.

On April 5, the day of her admission to the hospital, I saw her for a few minutes and wrote the following opinion: "Brief questioning does indicate the apparent occurrence of severe angina pectoris (decubitus) dating back three weeks (mild for two or three years before that). Examination shows no abnormalities except for slight hypertension. Further study—more careful history, electrocardiogram, roentgen-ray, Hinton reaction—are essential before final diagnosis. Paravertebral alcohol injection may well be indicated but I would advise postponing it for a few days until studies are completed. Try amyl nitrite for attacks." The surgeon wrote the following note in the record: "I believe that this patient is a suitable case for paravertebral alcohol block as her cardiac pain is so severe and she is getting so little relief from her medical measures. The only difficulty is the bilateral nature of the pain."

On April 7, 1933, we questioned her more carefully, realizing how rare severe angina pectoris is in a middle-aged woman with little or no hypertension and no story of substernal oppression on effort, and we gave the following verdict: "Further history this morning reveals the vitally important fact that rapid regular heart beating at more than twice the usual speed always accompanies the anterior chest discomfort and apparently precedes it. *This is extremely significant for it changes the diagnosis from coronary disease with angina pectoris to paroxysmal tachycardia with little or no heart disease.* She is already better in here resting. Sedatives and quinine sulphate (3 grains three times daily) will be much more likely to help her than any other drugs. I expect the Hinton reaction will be negative. For completeness we shall have a basal metabolic rate determination. Certainly there is no need at present for paravertebral alcohol injection unless the paroxysms grow very much worse and are refractory." One week later on the new therapy she was feeling very well, completely free of heart attacks. She was discharged from the hospital much improved on April 15.

Three months later, on July 3, 1933, she came to my office with no complaints except for very slight heart twinges for a second at a time on two days the previous week. She was taking quinine. Examination including electrocardiogram and fluoroscopy showed nothing amiss except for slight hypertension (170 mm systolic and 95 diastolic).

In October she reported the occurrence of a spell of racing of the heart lasting

a half hour after a recent fatiguing day. She had omitted the quinidine but thereupon resumed it. She no longer was afraid of the attacks—they had become simply disagreeable. Her blood pressure was 155 systolic and 90 diastolic.

I have continued to see this patient at intervals ever since, the last time on February 10, 1936, three weeks ago. She continued in good health (with infrequent palpitation) except for a series of acute attacks of typical gall stone colic with vomiting from August to November of last year (1935), completely relieved by the uneventful removal of her gall-bladder containing a large stone. She continued to have infrequent brief paroxysms of tachycardia up to the time of operation but none in the three months thereafter. The blood pressure continued to be slightly elevated (170 systolic and 95 diastolic on February 10, 1936). The electrocardiogram, including the chest lead, has been normal.

There are several morals to this tale. The most important one, of course, is the establishment by careful history taking of the correct diagnosis whereby the patient was not tagged with the label of a serious ailment and unnecessarily treated therefore. It is by no means the first time that such an error has occurred, I myself have encountered several other cases, the last one only a few weeks ago. The most notable patient of the sort that I recall was Jonnesco's first special case of supposed angina pectoris submitted to cervical sympathectomy who was still alive and in a good state of health many years afterwards, a review of the history of that case establishes this point*. There the history was all right but its interpretation was in error.

A second point of importance in this case is the change in the patient's reaction to the paroxysms of tachycardia. In a person untrained medically the first paroxysm of tachycardia usually causes great fear and discomfort, sometimes this happens even in a doctor. At such a critical time, or soon after, if a physician pronounces a verdict of heart disease and especially of angina pectoris, and warns against exertion and prescribes nitroglycerine, it is a very easy matter for the patient to develop a cardiac neurosis superimposed on the paroxysmal tachycardia. The palpitation due to the tachycardia becomes more disagreeable and in a nervously sensitive person even painful. The constant repetition causes a great dread and finally there is the addition of the fear of impending death and of a cold sweat at the time of the paroxysm, and of neurocirculatory asthenia with dyspnea and constant heartache and disturbed peripheral circulation between attacks, as in my case. When the patient is reassured and loses her fear of the attacks, only the disagreeable palpitation remains, and the fear of impending death and the cold sweat and other symptoms vanish. So it is, too, sometimes in the case of angina pectoris, although the more severe nature of this ailment more often justifies and causes these additional symptoms. As a matter of fact the great majority of my cases of angina pectoris have had neither the sense of impending dissolution nor cold sweating.

Here I would add an aside, namely, that there are cases of paroxysmal tachycardia or paroxysmal auricular fibrillation with coronary disease who

* JONNESCO, T. *Le sympathique cervico-thoracique*, Masson et Cie, Paris, 1923.

do have real angina pectoris (a sort of status anginosus) during their rapid heart beating, but such patients are usually seriously crippled by angina pectoris on effort to start with. They are generally benefited by quinidine therapy but they live short lives after the beginning of such a history. The patient whose story I have recounted was not one of these.

There is a third point of interest. My patient for some years had temporary flashes of precordial pain when quiet, beginning at the time of her menopause. Such pain is almost always an excessive reaction of a nervously sensitive patient to an extrasystole. In such a case there is often tenderness on palpation of the precordium. Apparently in patients who have had painful reactions to paroxysmal tachycardia there may be developed a conditioned reflex to tachycardia that isn't even paroxysmal, that is, to a slight elevation of the heart rate of 20 or 30 or 40 beats, a sinoauricular tachycardia due to excitement or effort, so that even the rehearsal of the "sad story of illness" may precipitate one of these heart attacks, accompanied sometimes by tears.

A fourth point of importance is the patient's reaction to therapy. Quinidine was almost a specific, and it may very well be that some of the cases labeled angina pectoris who have been benefited by quinidine have had either painful sensations due to premature beats or paroxysmal tachycardia which have been controlled by the drug and which have been wrongly interpreted as angina pectoris due to coronary disease. In our case nitroglycerine was thought to have helped the transient pains but not the more prolonged heart attacks, it may conceivably have acted a little like exercise or atropine by raising the intrinsic heart rate and so abolishing extrasystoles. Digitalis, on the other hand, usually aggravates the uncomfortable symptoms produced by extrasystoles or paroxysmal tachycardia and may cause these disturbances of rhythm in the first place, as it did in myself experimentally twenty years ago.

The variations from the usual normal findings in the electrocardiogram and roentgen-ray picture in this patient of mine tended at first to cause further suspicion of heart disease. I shall mention them simply because they too are morals in this particular tale. Both the total inversion of Lead III and the reversed relationship of the measurements of the transverse and long diameters are unimportant findings in an individual who is fat, whose diaphragm is high, and whose heart lies horizontally, as in my case. Often in such cases the inclusion in the measurement of two or three centimeters of a triangular shadow of pericardial fat at the cardiac apex adds to the gross error.

The last point I would mention in my case is the possible relationship of the gall stone to the heart attacks. In the first place the stone did not cause the precordial distress although such a site of gall-bladder pain can occur, as I have recently experienced regretfully in a case wrongly diagnosed coronary thrombosis. When in my patient whose history I recounted above the gall stone did cause pain, that pain was upper abdominal and associated with vomiting. However, it is conceivable that the paroxysmal tachycardia

may have been a reflex manifestation of the gall stone or it may have been a reflex from something else if it was a reflex at all. At any rate it was not evidence of any rapidly progressive heart disease.

Before leaving the subject of heart pain I shall simply recount the 28 conditions mentioned by Dr. James Herrick, in a paper last year,² that he has himself found to have been confused with coronary thrombosis, which as we all know has recently been considerably overdiagnosed: paroxysmal angina pectoris, cardiac arrhythmias, cardiac neuroses, neurocirculatory asthenia, malingering, acute pericarditis, luetic aortitis with or without aneurysm, dissecting aortic aneurysm, pleurisy, pneumonia, carcinoma of bronchus or lung, massive collapse of the lung, pneumothorax, pulmonary embolism, herpes zoster, arthritis of costochondral articulation, shoulders, or spine, bursitis, gall stones, peptic ulcer, carcinoma of stomach or duodenum, acute gastritis, spastic colitis, diaphragmatic hernia, tabetic crisis, and impending diabetic coma.

2 **Dyspnea** is often misinterpreted. The common breathlessness of neurocirculatory asthenia in a nervously tired person or in one who is "soft" and physically unfit has been often treated as cardiac dyspnea with restriction in exercise and with digitalis therapy, when almost the opposite measures are indicated. A careful history should at once correct this error of interpretation and treatment with the support of the finding on examination of no reason or evidence of myocardial weakness. The most common error in this respect is to be misled by the dyspnea of neurocirculatory asthenia when there is also present actual organic heart disease without failure. Long experience and good judgment are sometimes essential in the proper analysis of such a case. An extremely helpful clue when present is sighing respiration, which is never primarily due to heart disease. A patient who comes into your office and seats herself with a sigh saying "Well, here I am, doctor" reveals at least part of the diagnosis in the first few seconds of her interview.

Dyspnea of pulmonary origin is less commonly confused with cardiac dyspnea, but the error is often enough made to warrant much care in analysis. Chronic bronchitis with emphysema and weakness of the left ventricle with pulmonary vascular congestion and emphysema are the two conditions which in an elderly person, especially in the winter, are likely to be mistaken for each other. And sometimes they are actually superimposed. The history of respiratory infection, the presence of heart disease, roentgen-ray evidence, and the quick response to adequate digitalis therapy are the important clues, by their proper use the differential diagnosis is generally easy.

It should be observed that a chronic as well as an acute asthmatic state may be caused by congestion of the lungs secondary to heart disease. This is not widely appreciated.

One important error of interpretation that used to be made frequently but which is now uncommon is illustrated by the following case. A man 55

* Jr. Med. Soc. New Jersey, Oct., 1935, XXXII, 590.

years old is awakened at night by a severe pain in the epigastrium and lower anterior part of the chest. He gets up, takes hot water and soda bicarbonate, and belches gas. After a half hour without relief a doctor is called. He gives morphine subcutaneously with slight relief. A half hour later the patient vomits several times. Another hypodermic injection of morphine is given for the persistent pain which finally dies away after some twelve hours. The next evening the patient is wheezy and coughs a little. He prefers to sit up in bed. His lungs show scattered râles and emphysematous breathing. He may become definitely and even seriously asthmatic. His temperature is 101 degrees.

Both doctor and patient may be content with the one time "obvious" diagnosis of acute indigestion complicated by bronchitis or bronchopneumonia with asthma, but careful analysis and experience suggest the true diagnosis of coronary thrombosis with myocardial infarction followed by left ventricular dilatation with failure and acute pulmonary edema, the electrocardiogram will confirm the suspicion of coronary thrombosis in nearly every case. It is the morphine in such patients that may be wholly or at least in part responsible for the vomiting.

When there is marked mitral stenosis the most common symptom is dyspnea on effort, or in attacks (with or without asthma) or constantly. Such dyspnea is certainly to be ascribed to pulmonary vascular engorgement with too little room for air, as is evident by roentgen-ray examination and in fatal cases by autopsy finding of the marked engorgement of even the lung capillaries. But, granted all this, it is still the rule wrongly to attribute this dyspnea to heart, or rather myocardial, failure. To be sure, the dyspnea and pulmonary engorgement are due to the heart disease but they aren't due to myocardial failure. Rather the reverse. Actually the left ventricle is small, under no strain, not dilated, and not failing. The right ventricle is large and strong and also not failing, provided there is no increase in systemic venous pressure (as shown by normal neck veins, non-engorged liver, and no dependent edema). The answer is to be found in the disproportion between the strength and activity of the right ventricle and the narrow size of the mitral valve orifice. More blood is pumped into the lungs and left auricle in a given unit of time than can pass through the mitral valve—it is a mere matter of mechanics. It is thus obvious that digitalis will not help in such a case *unless it will reduce the heart rate* and thereby decrease the blood flow into the lungs. Fortunately in most cases of the sort digitalis does that very thing and hence is helpful. This is true in practically all cases of auricular fibrillation where the ventricular rate is at first rapid and uncontrolled. It is sometimes even true when the rhythm is normal, but far less frequently. At least the drug should always be tried. The slower the pulse rate in such cases the less the pulmonary congestion, and any measures besides digitalis that keep the heart from beating fast should be utilized.

There is one more important point concerning dyspnea that I shall mention. A good many individuals with heart disease and weakness are

troubled by insomnia. Very often this insomnia is frankly due to nervousness and very often to orthopnea secondary to pulmonary congestion, but there are borderline cases, and nervousness alone should not be blamed for the insomnia and treated as such, until the situation has been carefully analyzed. Digitalis and diuretic drugs may prove to be specific remedies for the insomnia in such patients.

3 **Palpitation** is due to the consciousness of forceful, rapid, or irregular heart action. It is never in itself a sign of heart disease and should never be prognosed and treated as such until the patient has been carefully studied. It may initiate a cardiac neurosis or even neurocirculatory asthenia unless properly handled at the outset. The most common condition associated with palpitation, that is more than the simple awareness of extrasystoles or short paroxysms of tachycardia, is neurocirculatory asthenia, of which it is frequently the chief symptom. Much has been written of the chance of confusing thyrotoxicosis, with its frequently disturbed heart rhythm and palpitation, with heart disease, but not so much has been said of confusing neurocirculatory asthenia with thyrotoxicosis. I shall recount briefly such a case.

An athletic young man, 20 years old, had a gruelling experience during the World War in 1918 and developed palpitation with a rather rapid pulse, nervousness, insomnia, exhaustion, and a precordial aching with a little dyspnea. When the war was over he rested and gradually recovered good health but three years later while studying hard in law he had a return of these same symptoms along with a feeling of tightness of the collar. Although worried about his health for a long time then, he did not consult a doctor because he was afraid that a serious diagnosis would be made. Finally after a year or two he did go to a physician who told him that he had an "athletic heart," and prescribed digitalis and bromide, the former drug did not help him, the latter did. Still not feeling well he consulted another doctor who made the diagnosis of thyrotoxicosis. Medical treatment of the condition seemed ineffective and finally partial thyroidectomy was done, at first he felt somewhat better but while still convalescent he had a year of heavy strain looking after his sick mother and later after his sick sister. Feeling poorly, with a return of all his old symptoms he consulted more doctors who suspected tuberculosis and advised treatment therefor which was carried out for a brief time. Then he returned to hard work with intense nervous strain and tried to save money on which to marry. He would return home exhausted every evening, but he continued to work hard and to worry about his work and his finances. His symptoms increased. He became panicky and finally consulted a doctor once more. Recurrent thyrotoxicosis was diagnosed and a second thyroidectomy was done four years after the first. Two months after the operation he felt somewhat improved and was married. His home life was very happy and his wife was sympathetic. His mental strain decreased and he no longer feared death, but he has never felt strong since this second operation. In a few years he began to feel nervously tense again, all his old symptoms recurred. Thyrotoxicosis was suspected once more but his basal metabolic rate was normal.

On examination last year I found this man, then 37 years old, to outward appearance in good health, very alert and breathing normally except for an occasional sigh. His reflexes were exaggerated. The thyroid gland was not enlarged, the neck showed an excellent scar. There was no abnormal pulse in the neck. The heart was normal in size, sounds, and rhythm. There were no murmurs. There was no evi-

dence of congestive failure. The pulse was regular at 120. The blood pressure was 145 systolic and 100 diastolic. Fluoroscopy showed a normally shaped, though unusually active, heart; a normal aorta, and normal lungs. Electrocardiography showed sinoauricular tachycardia with normal chest lead.

This man has improved in the past year on vigorous reassurance, regular exercise, ample rest, restricted work, omission of tea and coffee, small amounts of alcohol and tobacco, and the occasional use of bromides. It is obvious that his diagnosis is now and quite probably always has been, neurocirculatory asthemia, whatever that is, and not thyrotoxicosis, tuberculosis or heart disease. Cases somewhat like his are very common though not always so striking.

B. SIGNS. I shall now very briefly present a few cases illustrating common errors in the interpretation of cardiovascular signs.

1. Cardiac Enlargement. It is quite a common error for an over-active heart to be misjudged in size, especially by an inexperienced observer. The forceful apex impulse produces a widespread movement of the anterior chest wall which may be seen and felt several centimeters beyond the cardiac apex itself. If the outermost point of this impulse vibration is taken as the left edge of the heart, and especially if the measurement is made following the curve of the chest rather than tangentially from the midsternal line, a gross and misleading error results. The maximal point of the apex impulse is to be taken as the position of the cardiac apex itself, using the much neglected and sometimes scorned but nevertheless valuable method of percussion for control, at least until a roentgen-ray examination is available.

It is a less common error to underestimate the heart size. There are to be sure still a few individuals who speak of normal heart size when the maximal apex impulse and left border of dullness are located in the left nipple line but fortunately their number is steadily decreasing. Rarely the nipple line may be near enough to the sternum to be the proper position for the left edge of a heart of normal size but almost always it is one to two centimeters too far to the left, the so-called midclavicular line should be used as a guide.

On a few occasions it is possible to misjudge the heart size grossly on hasty examination when a fairly forceful impulse is felt near or in the midclavicular line in patients with mitral valve disease whose hearts are very large and whose powerful right ventricles may displace the anterior chest wall while the true apex impulse is in or near the left anterior axillary line. I have recently made this error twice in the same patient whom I examined in April 1934 and again in December 1935—I had forgotten the first error. This was the case of a young woman with mitral stenosis and auricular fibrillation and a very large heart. It is of considerable interest and importance in such cases to observe that the characteristic diastolic murmur of mitral stenosis is often and in fact usually limited to the immediate vicinity of the true apex impulse in the axilla, if cardiac auscultation is not carried out to that region the diagnosis of mitral stenosis may be missed. And again I would urge that careful percussion be also done in the third left interspace to detect marked increase in size of the infundibulum of the right

ventricle and prominence of the root of the pulmonary artery, particularly in cases with suspected mitral stenosis

2 Now a few words about **heart murmurs** I shall limit my remarks to two particular murmurs and I shall give two cases in illustration

(a) A boy, eight years old, is seen in the third month of his first attack of rheumatic fever. He is still moderately ill with a slight elevation of temperature in the afternoon, occasional mild rheumatic pains and nose-bleeds, malaise and slight leukocytosis. He had a pericardial friction rub for a few days a month ago. Observation shows a pale listless child lying in bed in no discomfort. No abnormalities are found on examination except for a regular rapid heart action of 120, a moderately enlarged heart, and blowing systolic and rumbling mid-diastolic murmurs at the cardiac apex. There are no thrills. There is no evidence of congestive failure in lungs, liver, neck or dependent parts of the body. The diagnosis is made of subacute rheumatic infection, rheumatic heart disease, and mitral stenosis and regurgitation. He is thought to show early mitral valve disease with deformity, including stenosis.

An acute exacerbation of the rheumatic infection occurs and the boy dies four months after trouble started. Autopsy shows no deformity of any heart valve, but an enlarged dilated heart with myocardial rheumatic lesions (Aschoff bodies), small vegetations on the line of closure of the mitral valve, and acute fibrinous pericarditis.

Having been caught like this on a good many cases over a period of 10 years Dr Bland, Dr Jones, and I a few years ago began to suspect the truth and gradually assembled data which we published in the December 1935, number of the *American Heart Journal*. We believe that this paper is a very important one. The moral to the tale is that during a severe infection, especially rheumatic fever which attacks the myocardium, dilatation of the left ventricle may give rise to a mitral diastolic murmur (and in some cases even an accompanying thrill) which we used to think was pathognomonic of mitral stenosis, in the absence of free aortic regurgitation producing the so-called Austin Flint murmur. I believe that the murmur is due to the relative mitral stenosis (dilated left ventricular cavity and undeformed mitral valve) whether there is any aortic regurgitation or not. In the series of cases to which I am referring now particularly there was no aortic regurgitation. Hence when during acute or subacute rheumatic infection a mitral diastolic murmur is found to appear in the course of weeks or months it should be interpreted as I have done above and not considered to be evidence of real mitral stenosis, if it was heard before the infection or if there was a previous rheumatic infection some years earlier, then we are dealing with another matter and quite likely do have a mitral valve deformity with stenosis. It is important to remember that from this study close to two years must elapse after the beginning of a rheumatic infection of the heart before there is an appreciable stenosis of the mitral valve. Patients showing the mitral diastolic murmur due to left ventricular dilatation during acute or subacute rheumatism may die or they may recover—it is an important sign of myocardial infection and weakness. Those cases that recover may show a gradual transition in a period of years to true mitral stenosis, but sometimes they lose their murmurs altogether. When the mitral diastolic mur-

murmur disappears with recovery we must not say that we are mistaken ever to have heard the murmur, nor can we say that valvular disease and deformity have been cured (as has sometimes been declared erroneously)

Parenthetically it may be added that other diseases besides acute rheumatic infection may cause temporary mitral diastolic murmurs as the result of left ventricular dilatation, this is especially the case in severe anemia due to any cause

(b) A physician, 53 years old, consulted me in September 1926, because on a recent life insurance examination a systolic heart murmur had been found and he had been passed only with a higher age rating. He felt perfectly well but wanted me to tell him the significance of the murmur. He was a very healthy appearing, heavy man with good color and normal breathing. The only abnormalities were slight cardiac enlargement, a moderately loud blowing systolic murmur widely heard all over the precordium but maximal at the apex, without palpable thrill, and with a few premature beats. The blood pressure was 140 millimeters systolic and 90 diastolic. Electrocardiogram showed slight left axis deviation. I made a diagnosis of cardiac enlargement and mitral regurgitation, of unknown cause. He was advised to lose weight, to avoid fatigue, and to report for annual examinations. Lost to sight for nine years, he consulted us again last fall because of a history of attacks of acute pulmonary edema at night following a few months of rather poor health with dyspnea on effort after a grippe attack last spring. He was found in serious congestive failure. His heart was somewhat more enlarged than it was nine years earlier, the loud systolic murmur was much as before but more intense and as loud at the aortic valve area as at the apex, and now an aortic systolic thrill was easily felt. The aortic second sound was audible but less loud than an accentuated pulmonary second sound. The diagnosis of aortic stenosis was now evident with congestive failure therefrom.

The aortic stenosis was undoubtedly the cause of the widespread loud systolic murmur heard nine years before. The diagnosis was missed then, but now that we have had such experiences repeatedly we are becoming wiser and making the correct diagnosis earlier, before all the so-called classical signs appear. The etiology of the aortic stenosis in this case is in doubt as it is in many other patients. Rheumatic infection is obviously the cause in some and probably it is in a good many others, infection in middle aged men may be the cause in a few. Calcification often found is probably nearly always a complication, usually appearing late in advanced cases, and not itself the only cause of marked aortic stenosis. It should be possible to diagnose aortic stenosis by physical examination before there is enough calcification to show well by roentgen-ray study—the roentgen-ray diagnosis can be made only in advanced cases.

3 Finally, I shall have a word to say about errors in the interpretation of congestion including dropsy.

A married mill worker, 30 years old, mother of one child, was referred to me in January 1933, because of persistent dropsy. For two and one half years she had had gradually increasing anasarca, which had failed to yield to medical treatment consisting of rest, digitalis, and diuretic drugs. Several doctors had diagnosed heart disease and congestive failure. My examination revealed a slender woman with

marked edema of both legs extending to the hips and up to the waist with some fluid in the peritoneal and right pleural cavities, some engorgement of the neck veins with venous pressure of 16 centimeters, small regular pulse of 84 with blood pressure of 105 millimeters systolic and 70 diastolic, and heart normal in size with good sounds and no murmurs. Electrocardiogram showed low voltage of QRS and T-waves in all leads. Roentgen-ray examination revealed normal sized heart and aorta with little or no pulsation of right border but active pulsation of the left and upward displacement of the left leaf of the diaphragm with systole. These findings established the diagnosis of chronic constrictive pericarditis, and the operation of pericardial resection was carried out by Dr. Churchill in April 1933. A spontaneous diuresis began three days after the operation and within one month the dropsy had completely vanished with a loss of twenty and one-half pounds. She has been in excellent health ever since, having resumed work in the mill.

Here is an example of venous congestion due not to heart disease and failure but to the mechanical interference of a thick callous constricting pericardium. The same effect is produced by marked tricuspid stenosis in rare cases. Comparably, as I have already said, when there is pulmonary vascular congestion in marked mitral stenosis, it is not primarily myocardial failure that is responsible, but the mechanical influence of the valvular defect. This viewpoint is of great importance in the proper understanding and treatment of vascular congestion not due to myocardial failure.

I have herewith presented a number of cardiovascular symptoms and signs that are likely to be misinterpreted. Through our diagnostic errors in the past, caused by such misinterpretation, important advances have been made. We should search diligently for more errors in the future for there is still a great deal for us to learn therefrom.

THE INITIAL VENTRICULAR COMPLEX OF THE ELECTROCARDIOGRAM IN CORONARY THROMBOSIS¹

By L. FELDMAN, M.D. *Chicago, Illinois*

THE changes in the final ventricular complex, the T-wave, and in the S-T segment of the electrocardiogram in coronary thrombosis have been extensively studied, both experimentally and clinically, since the early works of Herrick,¹ Smith,² and Pardee.³ As a result, it has been generally accepted that characteristic changes do occur in the majority of the cases, following an attack of coronary thrombosis.

In contrast, the changes in the initial ventricular complex have, up to recent years, received much less attention. Smith² and Weain⁴ observed that in coronary thrombosis the initial ventricular complex may not rarely be of a very small amplitude. The former observed such a reduction of the amplitude following coronary ligation in animals. Oppenheimer and Rothschild⁵ found arborization block in a number of their cases of coronary thrombosis that were studied postmortem. Various grades of intraventricular conduction disturbances have been reported to have appeared following coronary thrombosis.

That Q may become prominent in myocardial infarction was first observed by Pardee,⁶ and later by Wilson,⁷ Parkinson and Bedford,⁸ and by Levine.⁹ Fenichel and Kugel¹⁰ suggested that a large Q in coronary thrombosis was probably due to involvement of the posterior portion of the ventricular septum, and that large Q deflections in other leads may have a similar clinical significance.

On the other hand, many articles^{11, 12, 13, 14} have appeared showing that a large Q₁ may also be encountered in such conditions as coronary sclerosis, hypertension, obesity, pregnancy, rheumatic heart disease (without right axis deviation), and not rarely as a variation of the normal electrocardiogram. Wilson¹⁵ and his associates recently described certain changes in the initial deflection of the ventricular complex in association with coronary thrombosis. They classified these changes as belonging to Q₁ and Q₂ groups. The former was most frequently observed in association with the T₁ type of electrocardiogram, and the latter with the T₂ type, as classified by Parkinson and Bedford.⁸

The Q₁ group is characterized by "the presence of a conspicuous and, in most instances, rather broad Q in Lead I, the absence of Q in Leads II and III, the small amplitude of the largest of the initial deflections in Lead I, and the presence of a conspicuous S in Leads II and III. In some instances

* Received for publication January 14, 1936.

From the Department of Medicine, Mount Sinai Hospital, Chicago, Illinois.

one or more of these characteristics may be absent or poorly developed. Nevertheless, all of these curves display a family resemblance.

The Q_3 group is characterized by "the absence of Q in Lead I, the presence of a conspicuous Q in Leads II and III, and relatively small amplitude of the initial ventricular deflection in Lead II." Here, too, the authors stress the fact that not all curves show all the characteristics mentioned. They add "Curves in which Q is absent in Lead II, as well as in Lead I, and in which T is inverted in Lead III only, are not infrequent in myocardial infarction, they are not rare, however, in young individuals in whom there is no reason to suspect cardiac disease."

The absence of characteristic changes in the S-T segments or in the T-waves in some of the authors' curves is attributed by them to the long interval that elapsed between the occurrence of the infarction and the recording of the tracings.

Winternitz¹⁶ described changes in the initial ventricular complex of the electrocardiogram in coronary thrombosis. His first group is not unlike the Q_1 group of Wilson¹⁵. His second group is characterized by negativity of the principal deflections in all leads. The amplitude is low and the main deflection may be Q or S . His third group is typified by intraventricular conduction disturbance, resembling arborization block.

Barnes¹⁷ studied a group of cases and he found that coronary thrombosis is frequently followed by electrocardiographic changes that conform to the Q and T patterns. He concluded that the combined consideration of the changes in the initial and in the final ventricular complex yields more information regarding coronary thrombosis than does the study of either change alone.

Durant¹⁸ studied 74 cases of coronary thrombosis, and he found that 38 cases (51.3 per cent) showed changes in the initial ventricular complex of either Q_1 or Q_3 types. He concluded that the relative permanence of these changes greatly enhances their value in the recognition of old myocardial infarcts.

Since various conditions, such as rheumatic fever, pericarditis, coronary sclerosis, anoxemia, large fatigued hearts, digitalis, uremia, pneumonia, etc., are known to produce changes in the S-T segment and in the T-wave very much akin to those seen in coronary thrombosis, the uncovering, by the authors mentioned above, of changes in the initial ventricular complex that may be produced by the latter condition should be of great value.

MATERIAL STUDIED

One hundred and eight electrocardiograms of patients with coronary thrombosis were reviewed. The diagnoses were based on good clinical evidence. Service cases had the opinions of the attending staff, and private cases had frequently the opinion of a cardiac consultant, although characteristic changes in the electrocardiogram, when they occurred, were taken

into consideration in reaching a decision. In most instances the patient was seen and an electrocardiogram taken some hours or days after the onset of symptoms. Only very few patients were seen weeks after, unless they experienced a new attack before completely recovering from the first. Very frequently the tracing was repeated in a few days, less frequently was a third one taken, and in practically none was a serial study made. Of the 34 patients that died, eight were studied postmortem.

Eleven electrocardiograms showed no changes of any kind. Forty-five cases displayed various changes in the S-T interval and in the T-wave significant of coronary thrombosis, but had no changes in the initial ventricular deflection. Fifty-one cases exhibited Q patterns associated with T-changes. There was one case which showed a marked left axis deviation with a good-sized Q_1 , without changes, recent or old, in the final ventricular complex. She died soon after admission, no autopsy was obtained. Twelve cases showed extremely low Q-R-S complexes.

CURVES OF THE Q_1 GROUP

Using the criteria of Wilson¹¹ and his associates, we classified 19 cases as belonging to the Q_1 group. Almost all of these had in association changes of the T_1 type. The six curves in figure 1 represent the typical changes and the variations of this group, showing that the family resemblance prevails.¹⁵

FIG 1 Electrocardiograms of six patients displaying initial ventricular deflections of the Q_1 type

Figure 1A typifies this group. There is a conspicuous Q in Lead I. In Leads II and III the first ventricular deflection is upward and is followed by a deep S-wave. The initial deflections are small in Lead I. T_1 is sharply inverted, and the S-T₂ and S-T₃ intervals are elevated and rounded. The patient was a man 40 years old who had a typical attack three weeks before the tracing was taken. He recovered.

Curve 1B was taken three days after the attack in a man 56 years old,

who nine months previously was seen with a severe attack of coronary thrombosis. He survived the second attack, dying suddenly two months later. This curve is similar in general outline to that shown above, although it differs from the latter in some detail, the amplitudes of the initial deflections in Lead I are comparatively large, S_3 is comparatively small, and S_2 is widened and rather inconspicuous. $S-T_1$ is elevated, $S-T_2$ is elevated and rounded, giving a monophasic curve, and $S-T_3$ is depressed. It is possible in this case that the somewhat atypical changes in the initial ventricular complex may be due to the ancient infarction. That the Q may persist for such a length of time following the attack was stressed by Wilson.¹⁵

Tracing 1C is also quite different in detail from the typical. While Q_1 is prominent, R_1 is quite large. S_2 is lacking and S_3 is small. T_1 is sharply inverted, and $S-T_2$ interval is slightly depressed. This tracing was taken seven weeks after the attack in a man 57 years old. He recovered. The time interval, here too, is probably responsible for the variation, for the tracing is more characteristic of an old infarct than of a fresh one.

Figure 1D is that of a man 59 years old, taken four days after the onset of an attack, and one day before his death. Except for a large R_1 it is typical of the group under consideration. There is also intraventricular conduction disturbance. The changes in the $S-T$ intervals are highly significant of coronary thrombosis in the acute phase.

Curve 1E represents still another variation of this family group. The very low amplitude of the initial ventricular deflections and the conspicuous S_2 and S_3 qualify this electrocardiogram for the Q_1 group, in spite of the absence of Q_1 . The absence of the latter is probably due to the low voltage in Lead I. The $S-T$ intervals are not markedly altered, probably due to the time interval since the attack, which happened three weeks previously. This was a woman 59 years old, dying the day after the tracing was taken. This curve is similar to that shown by Wilson¹⁶ (see his figure 8) which is of a man 44 years old, with coronary thrombosis. Autopsy showed occlusion of the anterior descending branch of the left coronary artery. The infarcts invaded the anterior and lateral walls of the left ventricle.

Tracing 1F is also slightly different from the typical in this group. The very small Q in Lead I, the small S in Lead III and the inconspicuous S in Lead II are all probably due to the low voltage. $S-T_1$ is altered, while the final complexes in the other leads show no conspicuous changes. It is a tracing of a man of 60, one week after the onset. He recovered.

Except for the duration of Q_1 and its relative amplitude in comparison with the succeeding upstroke, the initial ventricular deflections of some of the curves typical of this group are very similar to those of left axis deviation, due to preponderate hypertrophy of the left ventricle (figures 1A and 1D). It is also possible that left ventricular hypertrophy, which is common in patients of the class subject to coronary thrombosis, may have played a part in determining the form of the initial ventricular deflections, especially large S_2 and S_3 . Wilson,¹ however, shows that myocardial infarction may

produce such curves. He cites a case (see his figure 4) having an electrocardiogram taken before and after the attack of coronary thrombosis. The latter showed the development of large S_1 and S_2 , and a very small initial deflection in Lead I. Q_1 is not definite but suggestive. He cites another similar case (see his figure 5), thus proving that infarction may produce such changes in the form of the initial ventricular complexes.

CURVES OF THE Q_1 GROUP

Twenty records were classified into the Q_1 group, all of which were associated with T_1 type changes. The six curves in figure 2 are representatives of this class.

FIG 2 Electrocardiograms of five patients showing initial ventricular deflections of the Q_1 type. Tracings E and E_1 are of one patient, taken three days apart.

Figure 2A is typical of this type of curve. The characteristic features are: absence of Q in Lead I, the presence of a conspicuous Q in Leads II and III, and the relatively small amplitude of the initial ventricular deflections in Lead II. In Lead III, Q is often the largest and, at times, the only initial deflection. It is a tracing of a man of 58 years, taken two days after the attack, from which he survived. There are definite S-T and T changes of the T_1 type.

Curve 2B is that of a man 43 years old, taken two days after the attack, from which he recovered. The curve is similar to the previous one, with the exception of a conspicuous R in Leads II and III. The changes in the final ventricular complex are those of type T_1 .

Tracing 2C is of a man 63 years old, one day after the attack. The Q in Lead II is not as prominent as in the previous curves, but the amplitude of the initial ventricular deflections is more typical. The R in Lead II is quite notched. The S-T and T changes are characteristic of the T_1 type. The patient improved, but continued to show marked myocardial insufficiency.

Figure 2D is a typical tracing of the group under consideration. It is of a man 67 years old, four days after the attack and one day before death.

There is also evidence of intraventricular conduction disturbance, and the changes in the final complex are those of an acute phase of infarction

Curves 2E and 2F are of one patient, a man 48 years old. The former was taken two days following the attack. This curve is not typical of the class under discussion. The Q_2 is small, R_2 quite large, and Q_3 very small. The S-T intervals show only slight changes. The latter curve was taken three days later and five days following the attack, Q_3 has become prominent, T_3 more inverted, and T_2 flattened. The initial ventricular complexes in the other leads did not change. This curve is an example of the appearance of a large Q_1 and inverted T_3 following coronary thrombosis.

Curves of this description are not rare in coronary thrombosis^{6, 7, 8, 9}. There were 12 other such curves in our 108 records. However, as mentioned above, they may also be seen in conditions other than coronary thrombosis^{11, 12, 13, 14, 15}.

PERSISTENCE OF QRS CHANGES

Since our cases were seen mostly days after the infarction, the persistence of the changes in the initial ventricular complexes could not be studied. Those cases seen by us weeks after the attack and a few, months after, were again in the throes of a new attack on admission, thus precluding any conclusions. Wilson¹⁵ and his associates express the opinion that the changes in the initial ventricular complex of the types described are often more persistent than the characteristic changes in the final deflection of the ventricular complex, and that they may be helpful in recognizing an old myocardial infarction. They cite a case in whom Q_2 and Q_3 were present five and one-half months after the infarction, while the T reverted to normal long before.

Wallace¹⁰ cites a case showing persistent Q_1 and Q_2 almost one year after the acute attack of coronary thrombosis and months after the changes in the final ventricular complex had disappeared.

CORRELATION WITH POSTMORTEM FINDINGS

Wilson¹⁵ and his associates, in discussing the correlation of the Q_1 and Q_3 type of electrocardiogram with the location of the infarct, concluded that while infarction in the anterior wall of the left ventricle and the adjacent septum was generally associated with ventricular complexes of the Q_1 - T_1 type, it may be accompanied by curves of the Q_2 - T_3 type, or possibly by no definite electrocardiographic changes of any kind. They also found instances both in their own series and in those reported in the literature, where curves of the Q_1 - T_1 type were produced by infarction of the posterior wall of the left ventricle.

Barnes,¹⁶ in correlating the changes in the initial ventricular deflections with the site of the myocardial infarct, concludes that tracings typical of the Q_1 - T_1 group are found to be associated with infarction of the anterior wall of the left ventricle and the adjacent septum. Infarction of the posterior

wall of the left ventricle and the adjacent septum is accompanied by curves of the Q_3 - T_1 group

Eight cases of our series were autopsied. The location of the infarcts and the changes in the coronary arteries were carefully studied by Dr. I. Davidsohn, with the following results:

FIG. 3. Electrocardiograms of six patients that were studied postmortem.

Figure 3A is that of a man 68 years old, who died one week after the attack. It belongs to the Q_3 - T_1 group. The opening of the right coronary artery was completely occluded by a thrombus. The left coronary artery showed a moderate degree of sclerosis. Acute myomalacia of the posterior wall of the left ventricle and the posterior half of the septum was found. There were pericardial adhesions posteriorly.

Figure 3B is that of a woman 69 years old, who died three weeks after the attack. The tracing was taken one week after the onset, and it belongs to the Q_3 - T_1 type. There was a complete occlusion of the left circumflex artery, with myomalacia of the posterior wall of the left ventricle and, to a lesser degree, of the posterior half of the septum.

Figure 3C. This was a man 45 years old. The tracing belongs to the Q_3 group. The first attack came six weeks prior, and the second two days before the tracing was taken. He died two days later. There was occlusion of the entire descending branch of the left coronary artery, with an aneurysm of the left ventricle at the apex. There was also recent thrombosis of the right coronary artery near its mouth, with acute myomalacia of the posterior wall of the left ventricle, right ventricle, and the posterior half of the septum. T_1 is diphasic, T_2 is inverted, and S - T_2 is elevated. The changes in the initial ventricular complex fit in with posterior infarction, while the changes in T_1 and T_2 may be remnants of the anterior infarction.

Figure 3D is a tracing of a man 57 years old, one week after the attack. He gave no history of any previous attacks. There is only Q_3 present, which is slurred and atypical. There is depression of all the S - T segments. He died two weeks later. There was an obliterating thrombosis of the

anterior descending branch of the left coronary artery, with an aneurysm of the left ventricle at the apex. More recent thrombosis of the right coronary artery near its orifice with acute myomalacia of the posterior wall of the left ventricle was also present. The more recent infarction possibly is responsible for the Q_3 (Fenichel and Kugel¹⁰), while the diphasic T-waves may be a vestige of the older damage.

Figure 3E. A woman 62 years old. The tracing was taken two weeks after the attack. She died three weeks later. There is a small Q_1 and a deep Q_2 . The changes in the final ventricular complex are not readily discernible. There was a thrombosis of the left descending coronary artery and of the circumflex branch, also acute myomalacia of the anterior wall of the ventricle, and, to a lesser extent, on the posterior wall.

Figure 3F is a tracing of a woman 50 years old. She had severe nocturnal dyspnea with collapse two weeks before the tracing was recorded. Death occurred three weeks after the onset. The electrocardiogram shows right axis deviation with conspicuous Q_1 , T_1 and T_3 are inverted. There was a thrombosis of the first part of the anterior descending branch and of the circumflex branch of the left coronary artery. There was also an occlusion of the right coronary artery 3 cm from its origin. Fairly recent myomalacia of the apex, the adjacent septum, the posterior wall of the left ventricle, and the posterior half of the septum resulted.

Figure 4D is a tracing of a man 60 years old, taken three days after the attack. He died three weeks later. The tracing does not belong to either of the groups under consideration. The changes in the final ventricular complex are significant, but not typical of any particular type. There was thrombosis of the circumflex branch of the left coronary artery, with acute myomalacia of the posterior wall of the left ventricle.

Figure 4E. A man 61 years old. The tracing was taken three days after the attack and two days before death. Except for the low amplitude and slurring, there are no significant changes in the initial ventricular complex. The T changes are of the T_3 type. There was a thrombosis of the circumflex branch of the left coronary artery, atheromatous changes in the descending branch of the left coronary artery, and also in the right coronary artery. Early myomalacia of the posterior wall of the left ventricle resulted.

Hence, four cases showing infarction of the posterior wall of the left ventricle had tracings of the Q_2 - T_2 type. In two cases having both anterior and posterior infarctions the electrocardiograms did not conform to any type. However, the right axis deviation in one of them (figure 3F) is rather significant. One case of posterior infarction failed to show changes conforming to either the Q_1 or Q_3 type. Finally, the last case of posterior infarction showed typical T changes, the initial ventricular complex was of low amplitude and markedly slurred, but without any Q waves.

OTHER CHANGES IN THE INITIAL VENTRICULAR COMPLEX

There were 12 cases in our series showing extremely low initial ventricular complexes. These changes, helpful in the diagnosis of coronary thrombosis, were described previously^{4,5,10}. The first three tracings in figure 4 represent such changes.

FIG. 4. Electrocardiograms of six patients. A, B, C, and D display low amplitude of the QRS deflections. D and E were studied postmortem, and F shows bundle branch block.

Figure 4A is that of a man 42 years old, taken three days after an attack. The S-T and T changes are not unlike those described by Barnes²¹ as occurring in coronary thrombosis complicated by pericarditis. The patient recovered.

Figure 4B. This is the tracing of a man 67 years old, taken three weeks following an attack and three days before death. The curve conforms to the Q_3 - T_3 type.

Figure 4C is that of a man 60 years old, taken six days after the attack. He improved.

Figure 4F shows bundle branch block of the common variety. We had six such tracings in our series. This patient was 69 years old. The tracing was taken 10 days following the attack, and one week before death. Such changes in conduction are helpful in the diagnosis of coronary thrombosis^{5,15}.

SUMMARY

One hundred and eight electrocardiograms of patients with coronary thrombosis were studied with particular reference to the changes in the initial ventricular complexes.

Eleven tracings showed no changes in either the initial or the final ventricular complexes.

Forty-five cases showed changes in the final ventricular complex (S-T and T-waves) only.

Fifty-one records (47.22 per cent) displayed conspicuous Q-waves in association with characteristic changes in the S-T segments and T-waves.

Nineteen of these, belonging to the Q_1 group and almost always associated with the final ventricular deflection of the T_1 type, displayed often a conspicuous Q-wave in Lead I, while the other Q-R-S deflections in this lead were small. In Leads II and III, the first deflection of the ventricular complex is upward and is often followed by a large S deflection. However, Q_1 may be very large and S_2 and S_3 may be small or absent.

Twenty tracings of the 51 were classified into the Q_3 group and were accompanied by the final ventricular deflection of the T_3 type. The characteristics are usually a large Q-wave in Leads II and III, but no Q in Lead I. There is frequently a relatively small amplitude of the initial ventricular deflections in Lead II.

There were twelve curves showing Q-T₃ only. In one case this finding was inconspicuous two days after the attack, only to become prominent three days later.

Since various other conditions may be associated with changes in the S-T segments and T-waves, the presence also of changes in the initial ventricular complex is of additional value in the diagnosis of coronary thrombosis.

Changes in the initial ventricular complex without accompanying changes in the final ventricular complex are rare in acute coronary thrombosis. Such a curve would speak, instead, for an old infarction.

Most of the cases that had posterior infarctions showed tracings of the Q_3 - T_3 type, while the rest, either having multiple infarctions or a single posterior one, displayed curves that did not conform to either Q_1 or Q_3 groups. The number of autopsies being small, no definite conclusions can be drawn.

Other changes in the initial ventricular complex, such as marked reduction in amplitude, or the development of intraventricular conduction disturbances, may occur in coronary thrombosis.

LATE RECRUDESCENCE IN ENCEPHALITIS LETHARGICA WITH SUCCESSION OF NEW MANIFESTATIONS AT INTERVALS OF YEARS, THE PROBLEM OF PROGNOSIS *

By ALFRED GORDON, F A C P , *Philadelphia, Pennsylvania*

It is pretty well established that the virus of encephalitis lethargica may invade any area of the central nervous system but has a special affinity for the striatal region in the mid-brain. The Parkinsonian symptom-group is the usual clinical expression of this localization. As to the so-called sequelae, the literature shows a multiplicity of phenomena. The sensory system, the special sense organs, the motor system, the vegetative nervous system, the psychic functions—all may show morbid alterations. Some of these various manifestations are rare or very rare, while others are common. Hyperkinetic phenomena are the most frequent. Since, in some cases, the postencephalitic sequelae are chronologically not far distant from the original malady, and since usually when they do occur, they remain fixed, it might seem a logical deduction that the pathological substratum, which is directly responsible, is fixed and shows no tendency to extension and further involvement. On the other hand there are cases in which aggravation of the preexisting symptoms occurs and also the appearance of new manifestations. Such observations, of course, can only signify a progressive and extensive development of the original lesions, due in all probability to the persistence of the encephalitic virus in the nervous tissue. The clinical histories of many such cases indicate that the virus may remain active in the nervous tissue for a considerable time, that it is capable of causing new anatomical lesions and extensions of preexisting ones. They also indicate that there is no certainty as to whether the virus is ever completely eliminated, and if its elimination is possible, within what period of time it may be accomplished. It is uncertain also, should the virus be eliminated, whether the lesions can regress, and to what extent and with how much consequent amelioration of the clinical manifestations. Our present therapeutic resources do not include any method of neutralizing the virus in order to obtain a regression of the anatomical lesions and consequently a modification in the course of the syndrome. The postencephalitic manifestations should not be considered merely as sequelae, but as forms of a genuine chronic evolution in the presence of a virus which is still active.

The present contribution has for object to put on record additional data demonstrating the grave possibility that the apparent subsidence of an encephalitic invasion does not necessarily indicate a finished process, and that

* Received for publication September 27, 1935

Patients presented before the Philadelphia Neurological Society

the virus may exist in a latent state even for many years, during which the clinical manifestations remain unaltered and fixed. Recrudescences may develop, not only after the acute state, but also many years later, and new phenomena may appear in the domain of extrapyramidal, pyramidal, bulbar and cerebellar domains, or at any level of the central nervous system. The succession of pathological manifestations in the same individual at intervals of years demonstrates the fact that the so-called sequelae are not of evolutionary character, but late and definite reactivations of the original infectious process, especially characteristic of lethargic encephalitis. These observations have a very considerable and serious bearing on the prognosis in this grave affection. They prove that it would be erroneous to assume a final position as to the course of lethargic encephalitis even after the Parkinsonian syndrome became definite. Besides the main object of this presentation, namely to suggest the importance of a reserved prognosis, attention is also called to some new and unusual features which have not yet been recorded in the literature as very late occurrences in lethargic encephalitis of long standing.

CASE REPORTS

Case 1 M. P., a newspaper dealer, 35 years old, 15 years earlier had a condition characterized by sudden onset, somnolence, fever, and double vision. He was bed-ridden for four weeks. He then presented the attitude general fixation, facies and fine tremor of the hands and lips, characteristic of the Parkinsonian syndrome following an acute attack of encephalitis lethargica. The condition remained unaltered for six years, when he developed the oculogyric manifestations from which he is still suffering. The eyes roll up suddenly and may remain in that position for between one and 10 hours. An emotional upset may precipitate an attack, but emotion is not the exclusive exciting factor. Physical fatigue may do likewise. On the other hand the upward deviation of the eyes may occur even after a good rest or early in the morning, before he commences to work. Sometimes the attack occurs while the patient is in his conveyance, distributing papers. The patient is absolutely unable to overcome this condition. All possible efforts on his part to bring the eyes down are futile. In his work he is obliged to be accompanied by someone as he is unable to continue his work and cannot walk by himself while the eyes are in the upward position. Seven months ago, that is over 14 years after the acute attack, he developed another additional disorder. Almost at every meal, while masticating his food, there occurs a sudden rigidity and immobility of the tongue, and the patient is unable to roll the food from side to side. This may last as long as five or ten minutes. These paroxysms have been quite frequent of late. Three months ago he developed another additional symptom, namely sudden closure of his eyes which, like the other symptom, may set in without warning. Any effort on his part to reopen the eyes is useless. This manifestation lasts a shorter time than the upward movements of the eyes, but, like the latter, it equally incapacitates him and interrupts his work.

The previous medical history of the patient is essentially negative. Lues is improbable since the Wassermann reaction of blood and spinal fluid is negative. Urinalysis is negative. Eye grounds are intact. There is no organic involvement of the ocular muscles. The circulatory system is normal. The reflexes, sensations, pupillary reactions are all intact. There are no pathological reflexes.

To sum up, we are dealing with a typical case of Parkinsonian syndrome subsequent to an attack of lethargic encephalitis 15 years earlier. Since

then, at different periods up to the present and at intervals of years between each other, the patient has developed three different phenomena, namely six years after the onset of encephalitis, the oculogyric phenomena, five years still later, the attacks of rigidity and immobility of the tongue, and much later (about three months ago) attacks of uncontrollable closure of the eyelids with hypertonicity of the orbicularis palpebrarum muscles

Case 2 S S, girl, 20 years of age, seven years ago developed a typical attack of lethargic encephalitis (somnia and fever). Shortly afterwards she observed a stiffness of the jaw and later an impediment of speech. The condition progressed for a time and then remained stationary. The speech disorder presented certain unusual features. Briefly, while speaking the tongue protrudes between the teeth, rolls curls and moves to the right side, at the same time two deep furrows appear on both sides of her mouth. (For details of this unusual postencephalitic manifestation, the reader is referred to the *ANNALS OF INTERNAL MEDICINE*, 1933, vi, 895.) There is no evidence of aphasia, paraphasia, or anarthria. Because of the dysfunction of the tongue, the food remains in the mouth a long while, and there is also pronounced salivation. The palate and pharynx are intact. Simultaneously with the speech-disorder appeared myoclonic contractions of the muscles of the left hand, so that the fingers would flex and extend alternately. Somewhat later a tremor was observed in the same hand. During a period of four years this speech manifestation and the tremor of the left hand were the only postencephalitic sequelae. At the end of the fourth year the patient began to observe a gradually oncoming weakness of the right upper extremity. At that time both knee-jerks were increased, but there were no other pathological reflexes. One year ago, that is six years after the acute attack, for the first time she noticed a tendency to turn her head to the left. This condition gradually increased in frequency and intensity so that, at present, a typical spasmodic torticollis is established. The former paretic condition of the right arm has greatly increased within one year, so that she is compelled to use her left hand almost exclusively. Moreover, the right leg, in addition to the increased knee-jerk, presents now an extensor plantar reflex, a condition which was not present two years ago. A general somatic examination is essentially negative. Blood, spinal fluid, urine, show no special disorder worth mentioning. The mental state is normal.

To sum up, the following course of events has been observed in a period of seven years. At first a typical picture of encephalitis lethargica. Shortly after the acute period, there developed an unusual speech disorder which persists at present, also myoclonia and tremor of the left hand. The next abnormal symptom (four years later) was a paretic state of the right arm which progressively increased. Next, in the chronological disorder (in the fifth year), was the extensor plantar reflex on the right side and finally a progressive spasmodic torticollis became established. The clinical symptoms, therefore, indicate an involvement of the extrapyramidal and pyramidal systems. The speech disorder, with particular disturbance of the function of the tongue in the act of speaking, may be the result of a nuclear involvement in the medulla or rather of an interruption in the structural connection of the striatum with the important bulbar segments of the central nervous system.

Hypertonia or dystonia and hyperkinesia are met with frequently in the postencephalitic period. The muscular phenomena may be generalized or

limited to circumscribed areas. They may be due to an irregular muscular function confined to the peripheral agencies. An improper and abnormal use of the many small muscles which enter into the formation of syllables and words in speech, and therefore in the enunciation of words, may be the cause of the speech disorder. The hyperkinesia in the form of the torticollis is another clinical evidence of a new invasion of the striatal connections.

In this case, as in the first, we observed several encephalitic sequelae, developing at very long intervals between each other, demonstrating the existence of latent or silent periods of years' duration after the acute attack of infection. Therefore a final fixed stage in the disease under discussion is not admissible.

CONCLUSION

Two cases are reported which are instructive from the standpoint of prognosis in encephalitis lethargica. Even years after the onset of this disease recrudescences may occur attacking any part of the central nervous system. The so-called sequelae are an indication of chronicity of the pathological processes and persistence of the virus.

CASE REPORTS

RENAL DWARFISM, A CASE REPORT

By J F ROBERTS, M D, *Toronto, Canada*

THE relationship between chronic interstitial nephritis in childhood and the occurrence of infantilism, late rickets, and dwarfism as sequelae, was first clearly defined by Fletcher¹ in 1911. Thirty years previously Lucas² had noted the frequent association of albuminuria with late rickets but had regarded the albuminuria as functional. Renal dwarfism, however, has only been recognized as a definite clinical entity since 1920, when Barber³ introduced the name, and defined it as "a condition of stunted development, associated with bone deformities of the 'late' rickets type, due to an insidious chronic interstitial nephritis of obscure etiology." The terms, renal dwarfism, renal infantilism, and renal rickets have been variously used for this group of cases, depending on whether dwarfism, infantilism or rickets was the predominating clinical feature. At present there are about one hundred examples of this condition recorded.

Attention has recently been drawn, by Ellis and Evans,⁴ to the importance and frequency of other abnormalities occurring in the urinary tract in this condition, namely, hypertrophy of bladder and dilatation of ureters and kidney pelvises, without any malformation or lesion to account for the obvious obstruction. In their report of 20 cases which came to postmortem, 14 showed these changes, but no organic lesion was found, and the author suggested a disorder of the neuro-muscular mechanism controlling the urethro-vesical sphincter, as the responsible factor.

More recently Ellis⁵ has reported a case with similar dilatation of the urinary tract, in which a definite organic obstruction of the nature of a valve in the posterior urethra was found, to account for the back pressure.

The following case report has a threefold purpose, first, to report a case of renal dwarfism, second, to call further attention to the association of this syndrome with an unexplained dilatation of the urinary tract, as described by Ellis and Evans, in contrast to that reported by Ellis, and, third, to direct attention to changes in the pituitary gland with a view to their possible bearing on the development of the dwarfism.

CASE REPORT

D K, a male, first came under observation at the Hospital for Sick Children in May 1926 at the age of eight years, with symptoms of cystitis and pyelitis of two weeks' duration, and a history of polydipsia and polyuria dating from 12 months of age, excessive in character both day and night. At birth he was normal in size and development. At four years he had measles and at six, whooping cough.

* Received for publication October 3, 1935.

From the Department of Pathology, University of Toronto.

On examination he was described as poorly developed and emaciated with normal intelligence, an irritable cough and slight naso-pharyngitis. The bladder was distended to the umbilicus. The urine showed 1+ albumin and a specific gravity of 1.002 on three examinations. Pus and *B. coli* were identified. Blood examination showed hemoglobin 65 per cent, red blood cells 3,900,000, white blood cells 34,000. Differential count 82 per cent polymorphonuclears and 18 per cent lymphocytes. He was discharged one week later, much improved.

The next note was that at the age of 13 years and again about one year later at 14 he had attacks of short duration, described as cystitis. He was finally admitted to the Toronto General Hospital in December 1934, at 16 years of age because of difficulty in breathing of two days' duration. History obtained from relatives at this time stated that for the past two months it had been noticed that he appeared tired all the time and drowsy. This was sufficiently marked to keep him from school, for the first time. He complained of cramps in his legs, numbness of his hands and after laying down objects held by the fingers, they would stay "flexed" for a short time. For the past month he had had a head cold, a non-productive cough and considerable nasal discharge. Since one year of age he had drunk large quantities of water and passed large quantities of urine throughout the same interval. For the week prior to admission his polydipsia had markedly decreased. The breathing difficulty began two days ago and his physician took swabs and administered 60,000 units of diphtheria antitoxin. The swabs were negative. It is noted that this boy began school at eight years, was quite bright as a student never missing an examination. He played with, and acted like, boys of his own age, but he has not grown for the last seven years. The family history was negative.

On examination he was described as a small red haired boy appearing of about half the stated age, conscious, very hoarse, breathing with considerable difficulty. The respirations were rapid and stertorous, with prolonged expiration. Râles were heard in both lungs. Examinations of the heart and of the abdomen were essentially negative. The external genitalia were undeveloped, with no pubic hair, and the testicles undescended. The nervous system was negative. No urine could be obtained. The blood showed a hemoglobin of 70 per cent, red blood cells 4,200,000, white blood cells 24,000. Non-protein nitrogen, 111 mg per cent. CO_2 combining power 10 per cent, fasting blood sugar 0.07 per cent, serum S.N.P. 2+. The Wassermann was not taken. The patient died in a generalized convulsion shortly after admission to hospital, before further examination could be carried out.

Summary of Postmortem Findings. Symmetrical dwarfed male of juvenile appearance without secondary sex characteristics. Measured 134 cm in length and was estimated to weigh 85 lbs. Trunk, head and limbs well proportioned and symmetrical. Skin soft, smooth and elastic with moderate amount of subcutaneous fat. Teeth in good condition. No skeletal deformity. Testicles undescended, no pubic hair. Redundant prepuce. Brain weighed 1450 grams, slight edema, vessels normal. The pituitary gland only half filled the sella turcica. It was small, rounded, weighed 0.20 gram and showed no evidence of tumor. The anterior and posterior lobes were of normal proportions to each other. The accessory nasal sinuses were free of infection. The mucosa of the trachea, larynx and epiglottis was reddened, edematous, irregularly eroded and covered with a pseudomembranous deposit. The thyroid was small, weighing only 10 grams but was normal in appearance. The thymus was of normal appearance and weighed 14 grams. The lungs showed an early bronchopneumonia at both bases. The heart appeared normal, showing no hypertrophy. The aorta, radials and femoral arteries showed no abnormality. There was a slight amount of clear fluid in the peritoneal cavity. Spleen, liver and gastrointestinal tract were normal. Adrenals large, weighing 8.75 grams each, but of normal appearance. The testes were in the inguinal canals, small, soft, each the size of a lima bean, weighing together 4.5 grams.

Genito-Urinary Tract The kidneys were slightly larger than usual, flabby and embedded in a considerable amount of fat. The right measured 11 by 6 by 2.8 cm., and the left 10.2 by 5 by 2.8 cm. The capsules were adherent, the surfaces, nodular and cystic. On the cut surface the kidney tissue, largely replaced by large, cyst-like dilatations of the calyces containing a cloudy fluid, appeared as a tough white shell. The cortex and medulla could not be differentiated. There were no abscesses or streaky suppuration as seen in acute pyelonephritis. The pelves were large dilated sacs, and both ureters were widely dilated, measuring up to 3.5 cm. in circumference. There was no obstruction in the ureters and each could be readily traced into the bladder. The bladder wall was greatly hypertrophied, trabeculated. The mucosa was pale, smooth with occasional areas of congestion.

No obstruction was found in the prostatic urethra, although the urethra was transected after examination from the bladder end. The penis was removed and the urethra opened carefully but no point of obstruction could be found.

Microscopically the kidney showed great reduction in the number of glomeruli, those in the outer cortical zone being completely fibrosed, while in the deeper portions those remaining showed marked variation in size with pronounced thickening of the capsular membrane. There was marked separation and extensive loss of tubules due to a great increase of fibrous tissue. Some of the remaining tubules contained hyaline casts. In several areas there were focal collections of lymphocytes and polymorphonuclear leukocytes, and in addition lymphocytes were scattered diffusely throughout the interstitial tissue. The blood vessels were not markedly thickened.

The pituitary gland showed a symmetrical atrophy, the relative proportions of anterior to posterior lobe being essentially the same as in the normal hypophysis. In the anterior lobe, the acidophilic cells were abundant but not evenly distributed, there being a definite tendency to clumping without any specific relation to blood sinuses. The chromophobes were increased in number, being equal to if not greater than, the number of acidophile cells. There were relatively few basophiles distributed about the peripheral portions of the lobe, but they were more abundant in the region of the stalk.

Search of the thyroid and adjacent tissues revealed one large parathyroid gland measuring 4 by 2 mm. Microscopically the cells were all of one type, the large clear chief cells. No acidophilic (oxyphil) cells were seen. A few scattered collections of fat cells were present.

The testis showed a definite increase in the number of interstitial cells. The seminiferous tubules, however, were juvenile in type, the lining cells being limited for the most part, to a single layer of epithelial cells, the spermatogonia and Sertoli cells. In some instances spermatocytes of the secondary layer could be made out, but no further stage of spermatogenesis was evident.

A section of the spinal column at the level of the first lumbar vertebra showed between the cartilaginous plate and the cancellous bone an irregular line of endochondral osteogenesis. The normal arrangement of the cartilage cells in columns was partially destroyed. The bony trabeculae were irregular and thicker than normal, showing water marking to quite a marked degree, each containing a central core of irregular moth-eaten bluish staining matrix and an outer smooth layer involved in patchy areas by small buds of cellular connective tissue containing osteoclasts. The marrow appeared normal.

Microscopically all the other organs were without any significant pathological change.

DISCUSSION

Of the many interesting pathological features of this case one of the most striking was the occurrence of an unexplained dilatation of the urinary tract.

Undoubtedly some obstructing factor or mechanism was present, and its apparent site was obviously at the bladder neck or below this level, as the bladder was uniformly hypertrophied. Unfortunately, in our case the entire urinary tract, including the urethra, was not removed in continuity, the urethra being severed just below the prostate. Consequently, though careful examination of the prostatic urethra, and subsequently the penile urethra, failed to establish any cause for the obstruction, the possibility, as pointed out by Poynton and Sheldon,⁶ that the method of removal destroyed the evidence, such as a valve or incomplete septum at the site of transection, is naturally to be considered. These authors believe that most of these cases are the result of definite organic obstruction rather than a functional disorder of the neuro-muscular mechanism controlling the urethro-vesical sphincter, as suggested by Ellis and Evans.

That clinical evidence of such an obstruction in the posterior urethra may be entirely lacking, was shown by Hinman and Kutzman⁷ who collected 50 reported cases of congenital valvular obstruction of the posterior urethra. They found that frequently the characteristic symptoms such as dribbling, incontinence, and dysuria did not become obvious until infection of the dilated urinary tract occurred. This was borne out by the case of Ellis, but in our case, though infection was undoubtedly present, at no time were symptoms of obstruction present, even as a terminal event.

The suggestion that infection may be the primary factor was mentioned by Mitchell⁸ as a possible explanation of these cases of dilatation without any organic lesion. Obviously this is in contrast to the usual sequence of events, and the origin of the infection remains therefore to be explained.

The many other cited causes which might lead to obstruction, such as congenital torsion of the penis, phimosis, atresia of the urethra, congenital hypertrophy of the vera montanum, cysts of the urethral mucosa and prostate were not operative in this case. Mitchell quotes Sawyer as having had two cases in which he attributed the obstruction to a long prepuce. In our case there was a redundant prepuce, but such a cause is untenable, in view of the fact that many such conditions are present in infancy and unless complicated by some other factor, such as phimosis, do not lead to obstruction.

The kidney findings in this case suggest the changes of both chronic interstitial nephritis and ascending infection. It is obviously difficult, however, to determine what part in the production of these lesions was played by each of these two conditions, nor is it possible to say which was the primary factor.

Due to the insidious onset and long protracted course of the disease, these children do not, as a rule, come under observation until either lack of development or bone deformities become evident. The early history of thirst and polyuria provides interesting data for speculation. There is some evidence according to Mitchell that congenital nephritis may occur, and Ellis suggests that both the dilatation and nephritis may have that origin. He further points out that if the chronic nephritis is a result of back pressure in previously normal kidneys, the type of obstruction which would produce such a result would appear to be one of slight degree.

The solution of the entire problem lies in a much earlier and closer examination of these children before the advanced changes in the urinary tract so obscure the picture that the true etiological basis cannot be determined.

The dwarfism occurring in these cases has been almost universally attributed to an altered metabolism as a result of the long standing renal insufficiency. Its mode of production has never been explained. Throughout the literature, little or no reference has been made to the pituitary gland, beyond the statement that in some instances it was either normal or smaller than normal. The first clear suggestion came from Hutinel⁹ who described a typical case of renal rickets which at postmortem did not show any interstitial nephritis and he regarded the dystrophy as due to an alteration of the glands of internal secretion, particularly the hypophysis.

In Ellis and Evans' series, the pituitary was mentioned only in case 7, in which a cyst was found on the superficial aspect of the pars intermedia. R. W. B. Ellis stated in his case that the appearance of the pituitary was within normal limits. A roentgenogram on the skull of a case reported by Zundell¹⁰ showed a normal pituitary fossa. Feiling and Holyoak¹¹ noted that in their case, though no definite abnormality could be seen, the sella turcica was small and ill-developed.

In those cases of dwarfism where the pituitary is primarily at fault, the anterior lobe deficiency is inherited and in most cases there is a definite family history. Moreover the cases are recognized early. On the other hand, the dwarfism occurring in these renal cases is not apparent for some time. Usually they are normal at birth and continue so until about the seventh year after which time the retardation in growth slowly becomes evident.

In the light of our present knowledge, interpretation of the findings in the pituitary, though suggestive, are inadequate and naturally open to much criticism. They are, however, extremely interesting, and for that reason merit consideration.

If, as Bell¹² points out, the cellular constituents of the anterior lobe represent different stages in the activity of a single cell type, namely the acidophilic cells indicating the secretory phase, the basophilic a storage phase and the chromophobes the resting or exhaustion phase, the predominance here of the chromophobic cells might be interpreted as indicative of an exhaustion phase in the gland. What, if any significance can be attached to the peculiar clumping of the acidophilic cells is impossible at present to say. Their numbers showed no definite increase or decrease.

Rasmussen¹³ has shown in numerical counts on normal glands that the chromophobes may constitute as high as 57 per cent of the anterior lobe cells, with an average of approximately 52 per cent, and a comparatively wide range of variation. Also that the chromophile series may show considerable variation, though not to so marked a degree. In view of these normal variations any approach from the numerical angle, in disease states, must be made with caution before assigning to the results any pathological significance.

These observations were made, however, on normal adult glands, and it does not follow that equivalent conditions obtain in the actively growing period of the first decade.

The suggestion is made that this exhausted and atrophied gland may be the result of a secondary effect exerted upon it by some single or complex product arising as a result of the slowly increasing metabolic disturbance, consequent on the renal disease. A point is reached when there is a relative anterior lobe insufficiency, that is, the demand exceeds the supply, and consequently there is a slow but progressive retardation of somatic, genital and osseous growth.

The bone changes in these cases are interesting, particularly as regards their frequency, mode of origin, and the question whether they are identical with those described in true infantile rickets.

The high incidence and sudden onset of the bone deformities have been well described by Barber,¹¹ Parsons,¹² Lathrop,¹⁰ and Mitchell. The average age at which they develop would seem to be about the ninth year, and their importance is reflected in the fact that their presence may be the first evidence of the true underlying condition. Of these deformities, genu valgum is the most frequent and most important. Barber further points out that the deformities are uncommon in the first few years of life, and in many instances have only appeared at puberty. In the case described by Ellis the typical deformity occurred relatively early, at four years and 10 months, while in our case there was no clinical evidence of any bone deformity, and it was not until examination of a section taken from the vertebral column at postmortem, that definite bone changes were found. Unfortunately, important clinical data such as serum calcium and phosphorus estimations and radiological studies of the long bones were not obtained, attention being particularly directed toward the treatment of the acute uremic state.

Most of the discussion and speculation directed toward an understanding of the fundamental problems in the so-called cases of renal rickets have to do with the chemical changes in the blood, with particular emphasis laid on the relative concentrations of the inorganic phosphorus and calcium.

The usual finding has been a raised serum phosphorus due to the extreme functional disability of the kidney to excrete phosphate, and a lowered serum calcium consequent on the hyperphosphatemia (Peters and Van Slyke¹⁷). Based on this altered ratio, Lathrop, and Shepley, Park, McCollum and Simmonds¹⁸ have suggested that renal dwarfism is a type of low calcium rickets which results from the effects of high serum phosphorus on serum calcium and calcification. The studies of Boyd, Courtney and MacLachlan,¹⁹ Schoenthal²⁰ and Parsons support this view. On the other hand, Hunter²¹ states that "The theory that phosphate retention, due to the renal defect is primarily responsible for the changes in the bones is clearly unsatisfactory." He further points out that in rickets there is a disturbance of exogenous metabolism resulting in a deficient calcification of osteoid tissue, because of a lack of proper metabolism of calcium and phosphorus in the absence of vitamin D, whereas, in renal rickets, though the bone changes may be identical with true rickets, here vitamin D is not lacking and the changes in bones are due to a disturbance of endogenous metabolism of calcium and phosphorus, for which the renal insufficiency, as a result of the chronic nephritis or its equivalent chronic renal obstruction, is responsible.

Two very interesting studies dealing with parathyroid involvement in these cases were made by Smyth and Goldman²² and Langmead and Ori.²³ The former authors, reporting a case of renal rickets, parathyroid dysfunction and metastatic calcification in a boy of 14 years, the underlying cause of which was a congenital urethral obstruction, found that the retention of acid phosphate constituted the first important change in the blood chemistry and, while agreeing with the theory based on the high level of blood phosphorus, suggest that the raised serum phosphorus stimulates the parathyroid glands (parathyroid hyperplasia) resulting in dwarfism and demineralization of the bones. Langmead

and Ori suggest as an explanation of the bone changes that although the chronic renal disease occurring in renal dwarfism may cause true rachitic changes in bones the most characteristic osseous changes seen radiographically are due to osteoclastic resorption, the result of secondary parathyroid activity

Mitchell, from his extensive review of the literature concluded that clinically the bone changes were identical with those seen in the usual infantile rickets but that radiologically and histologically they appear somewhat different With regard to the latter, Brockman's study of the histological changes would seem to indicate that although both show the irregular line of ossification with formation of irregular bony trabeculae, destruction of cartilage cells increased number of blood capillaries, and replacement of red marrow in relation to the trabeculae, with fibrous tissue, in renal rickets these changes are much more marked, with slight differences sufficiently evident to distinguish between them

In our case we feel, therefore, that the changes described do not warrant any definite conclusion as to the possibility of their being rachitic in type but that they merely indicate a general inhibition of growth

SUMMARY

- 1 A case of renal dwarfism is reported
- 2 The interesting finding of a marked dilatation of the urinary tract and hypertrophy of the bladder, unsuspected clinically, is discussed
- 3 The urinary retention appeared to occur at the level of the urethro-vesical sphincter No obvious organic cause for the obstruction was found
- 4 Of particular interest were the marked changes in the pituitary gland, and the hypothesis is suggested that the dwarfism may be due to a secondary effect on the pituitary of some product of altered metabolism arising as a result of the long standing renal insufficiency
- 5 Definite microscopic changes in the bone of the vertebral column are described and are interpreted as evidence of a general inhibition of growth

ACUTE FULMINATING MENINGOCOCCUS INFECTION WITH BILATERAL CAPILLARY HEMORRHAGE OF THE ADRENALS AS THE MOST STRIKING GROSS PATHOLOGIC LESION, A CASE REPORT¹

By F H FOUCAR, F A C P, Lt Col, Medical Corps, U S Army

THE case I shall report died 12 hours after the onset of the final illness, one-half hour after admission to the Walter Reed General Hospital. The antemortem diagnosis was Rocky Mountain spotted fever. As no antemortem laboratory work of any kind had been done and as only a very superficial physical examination had been possible, the microscopical studies on the autopsy material were undertaken to substantiate or refute the original diagnosis. The final diagnosis was not made until after a careful microscopical examination of the body tissues had been completed. The author deems the case especially valuable as an illustration of the solution of a problem in postmortem diagnosis.

CASE REPORT

W H, a white male, aged 20 years. A member of the Civilian Conservation Corps, attached to Camp A2, Beltsville, Md. He always had been in good health and exceptionally strong and active. He worked Saturday, Sept 21, 1935, until noon when he was given a pass for the weekend. According to the statement of the patient's brother the patient was perfectly well until Sunday evening. Sunday evening, September 22, the patient "suddenly came down with chills and fever, and brown spots appeared over his body, he complained of pain in his joints." The family physician was called who made the diagnosis of Rocky Mountain spotted

¹ Received for publication December 2, 1935

From the Laboratory Service, Walter Reed General Hospital, Washington, D C

fever Monday morning, September 23, the patient's brother transported him in an automobile from Landsdowne, Md, to Camp A2, arriving at the Camp Dispensary at 8 30 a m. At this time the patient presented the picture of a hemorrhagic purpura involving practically the entire body. He was conscious, answered questions intelligently and did not appear to be in great pain. He was immediately transferred to the Walter Reed General Hospital, Washington, D C.

The patient was admitted to the Walter Reed General Hospital, Monday, September 23, at 9 45 a m. He presented what was described by the Ward Surgeon as a hemorrhagic discoloration of the skin over the entire body. Conjunctivae hemorrhagic. Pupils equal in mid-dilatation. Lips cyanosed. Pulse almost imperceptible. The heart sounds were distant and the blood pressure too low to determine. The patient became comatose within 15 minutes after admission. He vomited about 250 c c of "greenish mucus." He died at 10 15 a m, one-half hour after admission to hospital.

Autopsy, W R G H. Autopsied September 23, 1935 at 10 45 a m, 30 minutes after death. The following is an abstract of the protocol.

Body that of young adult white male, length 174 cm, weight 77 kg. Well nourished, voluntary musculature exceptionally well developed. Right pupil 6 mm in diameter, left 5 mm. No exophthalmos. There is marked subconjunctival hemorrhage, bilateral. The left deltoid region presents two large vaccination scars. The cutaneous surface of the body shows a diffuse erythema, ham colored, most advanced over face, neck, arms and extensor surfaces of forearms. Ears cyanosed. The thighs and legs are only slightly "flushed." The palmar surfaces of the hands and feet are of normal hue. After removal of the viscera and consequent drainage of blood, the cutaneous erythema faded considerably leaving scattered bluish petechial areas over the forehead and surrounding the mouth.

Thymus rest 25 gm. Thyroid 25 gm. Congested.

Lungs Right 450, left 400 gm. Upon the pleural surface of all lobes both lungs are scattered small bright red points of hemorrhage, 1 to 2 mm in diameter. *Heart* 370 gm. The epicardial surface presents scattered points of hemorrhage. The wall of the left ventricle is 1.9 to 1.4 cm in thickness, cut surfaces grayish-red, consistence firm. The aortic ring is 6.5 cm in circumference. The valves are normal. The heart contains fluid blood. The coronaries are normal. Aorta intima smooth, glistening and of a normal ivory hue.

Abdomen There are widely scattered, small points of hemorrhage over the stomach, jejunum and ileum and over both leaves of the mesentery of the small gut. There is no increase in fluid in the peritoneal clunk. Stomach Slightly dilated. Mucosa grayish-red, rugae preserved. No eschars, no ulcers. The lumen of the stomach contains 250 c c of grass green fluid without appreciable odor. Jejunum Wall slightly edematous, mucosa pink, glistening and shows normal markings. The mucosa presents a few petechial hemorrhages, 2 to 4 mm in diameter. The lumen contains a small amount of semi-solid pale yellow material. Ileum Contracted, contents scant in amount and of pale yellow hue. The mucosa of the lower ileum presents six to eight oval areas measuring from 1 to 3 cm in length, long axes paralleling the long axis of the bowel. The oval areas are grayish, finely granular and lusterless, edges sharp. Vermiform appendix Normal in the gross. Colon The ascending, transverse and descending colon are contracted, mucosa pale, moist and glistening. There are a few scattered petechial hemorrhages, 2 to 4 mm in diameter, bright red in color, located in the mucosa. The rectum and sigmoid contain fluid feces, no gross blood. The mucosa lining the rectum is pale gray and presents scattered petechiae and innumerable pin-point hemorrhages. The lymph nodes in the mesentery of the small gut are enlarged to the size of split peas, pinkish-gray and shotty to the feel. Liver 1630 gm. No gross pathology. Spleen 160 gm. Consistence firm. Cut sur-

faces flat, glistening and of a deep plum color. Corpuscles not visible in the gross. Pancreas 110 gm. Normal in the gross.

Adrenals. The adrenals furnish a striking gross appearance. The combined weight of the two adrenals is 25 gm (normal 12 to 15 gm). They are of normal contour, firm and of a dark slate color. The cut surfaces show marked capillary hemorrhage throughout the cortices and invading the medullary portions. The cut surfaces of the adrenals are flat and of a reddish brown hue. Small islands of grayish translucent medullary parenchyma are visible. Both adrenals present the same gross picture (Figures 1 and 2).

Kidneys. Right 170, left 180 gm. Cut surfaces show moderate congestion. Urinary bladder, prostate, seminal vesicles, vasa deferentia and testes. Normal in the gross.

Calvarium. Normal. **Dura.** Moderate edema. **Brain.** 1370 gm. Consistence quite soft. The pia is congested. The ependyma is smooth and glistening. There is marked congestion of the small vessels beneath the ependyma covering the floor of the fourth ventricle. **Pituitary.** Normal. The circle of Willis and cerebral arteries present normal walls and contain fluid blood.

The outstanding gross findings are (1) cutaneous erythema with purpuric areas, (2) scattered points of capillary hemorrhage upon the serous surfaces of the viscera, (3) hyperplastic Peyer's patches and enlarged mesenteric lymph nodes, (4) bilateral capillary adrenal hemorrhage, (5) congestion of the pia arachnoid.

Considering the above gross findings singly the diagnoses suggested are Rocky Mountain spotted fever, typhoid fever, bilateral capillary hemorrhage of the adrenal, possibly toxic as in diphtheria, possibly septic, bulbar palsy. The final diagnosis was not made until the above possibilities were eliminated.

As suggested by the gross pathological findings, the following bacteriological examinations were made:

(a) Cultures from the nares and the nasopharynx upon Loeffler's medium were negative for the diphtheria bacillus.

(b) Culture from the heart's blood was overgrown by *B. coli*.

(c) Culture from spleen showed no growth.

(d) Cultures from the contents of the lower ileum, caput coli and from the surfaces of the Peyer's patches all were negative for bacilli of the typhoid-dysentery groups.

Blood serum of the deceased was agglutinated against *B. proteus* X-2, proteus X-19 and proteus Kingsbury, all agglutinations were negative.

Blood taken from a subcutaneous venule of the cadaver shows the following differential count: lymphocytes 38, monocytes 17, neutrophils 45 per cent. The lymphocytes are all of the small type. The neutrophils are 28 per cent band forms and 17 per cent segmented forms. The granulocytes present advanced degenerative changes. Gram stain of blood film shows no microorganisms.

Microscopical examinations were made of all the organs of the body, stained both by H. E. and Giemsa. Especial attention was paid to the reaction of the blood vessels of the skin, brain and heart in view of the original diagnosis of Rocky Mountain spotted fever^{1,2}. There is no endothelial swelling or hyperplasia and no thrombosis. The perivascular reaction is limited to the skin where there is engorgement of the venules in the zone between the corium and hypodermis, the congested subpapillary venules present an irregular piling up of the adventitial cells including a considerable number of mast cells and an occasional lymphocyte. The capillaries supplying the sweat glands and the papillae of the hair follicles show no pathologic changes. None of the histiocytes or endothelial cells include Rickettsia. There are no perivascular nodules in the heart, and sections of the testes show normal histology. The histopathology of Rocky Mountain spotted fever was fresh in my mind due to a case autopsied recently. Dr. R. D. Lillie of the National Institute of Health kindly studied

FIG 1 *Adrenals* combined weight 25 gm Dark slate color in the gross

FIG 2 *Adrenal* cut surfaces flat, reddish-brown, markings greatly obscured

the slides I made in the case I am now reporting and found nothing suggestive of Rocky Mountain spotted fever

The micro-sections of the lower ileum show hyperplasia of the Peyer's patches, the germinal centers are prominent and present small areas of karyorrhexis and beginning necrosis (figure 3) No bacteria are revealed by the Giemsa stain The

FIG 3 Lower ileum $\times 105$ H E Stain Shows the marked hyperplasia of the Peyer's patches

lymph nodules in the mesentery of the ileum present large germinal centers, the sinusoids do not show the large swollen phagocytic reticular cells found in the lymph nodes in cases of Rocky Mountain spotted fever

Adrenals The surrounding fat presents a diffuse, very slightly marked infiltration with erythrocytes. The arteries show normal walls, the veins are congested. The adrenal capsule is thin and intact. The zona glomerulosa is fairly well represented. Beneath the capsule there is marked capillary hemorrhage extending inward in broad rays and wedge-shaped areas. The remnants of cortex are well preserved, the cells rich in lipoids. The zona reticularis is entirely replaced by hemorrhage (Figure 4). The medullary portion is for the most part destroyed by hemorrhage though there are scattered islands of parenchyma remaining. The intact portions of the medulla show capillary congestion, edema, and small agminations of lymphocytes and plasma cells. Sections stained by Giemsa and by Gram reveal no microorganisms. Sections stained by Levaditi show no treponemata.

The microscopic examination of thyroid tissue reveals large acini filled with deeply stained, homogeneous colloid, epithelium flattened. No apical vacuoles. No lymphoid reaction.

The parathyroid section includes a lobule composed of high cylindrical clear cells. The majority of the lobules present alveoli composed of small clear cells, the large polygonal oxyphilic cells are very few in number.

Pituitary No pathologic changes other than venous capillary congestion.

Brain Sections were taken from the medulla at the level of the decussation of the pyramids and at the level of the inferior olive and sensory decussation, also from the cortex of the forebrain (left precentral gyrus), the basal ganglion left, including the internal capsule, caudate nucleus and ependyma lining the lateral ventricle. The sections were stained by H. E. and by Giemsa. The microscopic picture shows congestion of the veins and capillaries in the arachnoid, edema of the molecular layer which includes swollen astrocytes. There is capillary congestion throughout the gray substance and a few small hemorrhages into the perivascular spaces of His. No ring shaped hemorrhages. No thrombosis. No cellular infiltration of the spaces of Virchow-Robin and no perivascular cellular "cuffing."

Sections of the brain stained by Gram show many small Gram-negative diplococci arranged in small groups and in scattered pairs, mostly extracellular though a few of the diplococci are included in the bodies of adventitial cells. The Gram negative diplococci are coffee bean shaped, without capsules and are found in the cellules of the arachnoid over the ventral surface of the medulla and over the outer surface of the forebrain (Figure 5).

Gram stain made of the sections of the skin and adrenal reveal no bacteria.

Diagnoses Acute fulminating meningococcus infection with general purpura and massive bilateral capillary adrenal hemorrhage. *Death* occurred before the onset of a suppurative meningeal reaction.

The bilateral adrenal hemorrhage is very striking, and at one period in the study of the case I was tempted to call the adrenal hemorrhage the cause of death without searching further for a cause of the general pathologic process. The histogenesis³ of the adrenals and the dual function^{4,5} of these organs should be reviewed by those who are interested in the adrenal lesions encountered in the case I have just presented. The subject of bilateral adrenal hemorrhage had been brought to my attention by Lavenson⁶ and by Pearl and Brunn.⁷ The adrenal hemorrhage in the cases cited by these authors is of the thrombotic type, secondary to a local inflammatory reaction in the case of Lavenson, possibly syphilitic in the case cited by Pearl and Brunn. The bilateral adrenal hemorrhage in the case I have reported in this paper is of the capillary type, suggesting a toxemia as in diphtheria or a fulminating septicemia. The case of Rocky Mountain spotted fever recently autopsied at this hospital presented unilateral adrenal hemorrhage of the thrombotic type. Whether or not the adrenal damage

FIG 4 *Adrenal cortex* $\times 810$ H E Stain Shows marked capillary congestion and hemorrhage and destruction of the cortical parenchyma

in the case I have just reported had any direct bearing upon the rapidly fatal termination, is problematical. Biasse⁸ (quoted by Pearl and Brunn) states that massive bilateral adrenal hemorrhage causes an initial hyperadrenalemia followed by hypoadrenalemia resulting in death.

The original diagnosis of the case I have just presented was Rocky Mountain spotted fever, suggested by the cutaneous eruption and no doubt by the fact that cases of this disease had been recently encountered in this section of the United States. In the course of my microscopical examinations I excluded Rocky Mountain spotted fever as the final diagnosis. The negative Weil-Felix reaction here means nothing because of the very short period of time elapsed since

FIG 5 *Arachnoid*, ventral surface of the medulla oblongata, level of the pyramids $\times 2050$ Gram stain. Shows Gram-negative diplococci in clumps without associated inflammatory reaction other than presence of few lymphocytes and wandering histiocytes.

the onset of the illness. Cecil⁹ quotes Wolbach as follows: "In Rocky Mountain spotted fever the rash appears usually on the third to fifth day of the fever. The rash appears first on the wrists, ankles and back, then on the forehead, arms, legs, chest and abdomen. The efflorescence requires 24 to 36 hours. The macules are at first bright red, rapidly become darker and after a few days the eruption is definitely petechial." In the case just presented the eruption came on within a few hours following the initial chill and was general and purpuric from the start.

A typical case of Rocky Mountain spotted fever is presented by Masson¹⁰. This case will serve well as a model in both the diagnosis and differential diagnosis between Rocky Mountain spotted fever and other exanthemata, giving as it does the incubation period (5 days), the mode of onset, the appearance and

distribution of the eruption and the dates and titers of agglutinations of the patient's blood serum against proteus X-19 In Masson's case of Rocky Mountain spotted fever the eruption first appeared upon the wrists and ankles during the third day of the illness and was of the red macular type, on the fourth day of the illness the "rash" became generalized, involving the face, trunk and extremities including the palms and soles

As all of us had overlooked meningococcus infection as a possible etiologic factor in the case I have presented, I shall quote several of the accepted texts on the subject of epidemic meningitis

Osler's¹¹ definition of cerebrospinal fever is "an infectious disease occurring sporadically and in epidemics, caused by the meningococcus, characterized by inflammation of the cerebrospinal meninges and a clinical course of great irregularity The affection is also designated as spotted fever Meningococci may be in the blood without meningitis resulting In malignant cases there may be no characteristic pathological changes, the brain and cord showing only extreme congestion The intestine sometimes shows swelling of the follicles" According to Nelson¹² "In fulminating cases the skin, serous membranes and particularly the adrenals show hemorrhages and microscopically the cutaneous blood vessels have been seen to be crowded with meningococci The Peyer's patches and the mesenteric lymph glands are commonly swollen and the intestinal mucosa may be hemorrhagic Petechial hemorrhages may be seen on all serous surfaces"

Referring to the notes I made during May 1919, while I was in charge of Army Laboratory No 1, Neufchateau, France, I find that many cases of meningitis were hospitalized as respiratory diseases, and the final diagnosis of meningitis was made when the patients had been isolated in the influenza wards of Evacuation and Base Hospitals French pathologists during the early part of the World War reported cases of meningococcic septicemia without meningeal involvement During Sept 1918 a case of bronchopneumonia was admitted to Base Hospital No 6, the sputum of this case yielded a pure culture of the meningococcus, type IV (Pasteur type B)

Boyd¹³ states "In a case of extremely acute meningococcic septicemia in a child which I studied, the only lesion was an extensive bilateral hemorrhage of the adrenals"

Stevens¹⁴ discusses the fulminating type of cerebrospinal fever which he says is comparable to the malignant forms of other specific infections, not uncommon in some epidemics and occasionally met with sporadically The patient is suddenly stricken, sometimes without the least warning, and quickly passes into a state of collapse A severe chill, headache, stupor, soon followed by coma, moderate fever, a feeble pulse and an extreme prostration are the usual symptoms and the usual course A purpuric eruption is present in some cases Death is inevitable and may take place within 12 hours Autopsy reveals hyperemia of the membranes of the brain but no pus

Dr A Magruder MacDonald, the Coroner of Washington, D C, told me that in the epidemic of cerebrospinal meningitis during the winter and spring of 1934 to 1935, there was a high percentage of fulminating cases with a course of from 12 to 24 hours, autopsies revealed no purulent meningeal reaction in these cases

A recent report¹⁵ of a case very similar to the one I have just presented has come to my attention. By a happy coincidence the case referred to in this paragraph is from the Navy, while my case was under the Army jurisdiction. The Naval case was admitted to the U S S "Relief" from a battleship, March 9, 1935 and died two and a half hours later. As far as could be determined the patient, a white male, aged 18 years, was sick only five hours prior to his death. The antemortem leukocyte count was 5000 with 71 per cent small lymphocytes. The blood film was loaded with Gram-negative diplococci. The antemortem spinal fluid was entirely negative, cell count three. The antemortem blood culture was positive for the meningococcus (type not specified). The autopsy findings in this case show congestion of the meninges but no purulent exudate, there are petechial hemorrhages in the serosa covering all the viscera. The statement is made that "the adrenals are swollen and appear hemorrhagic."

SUMMARY

The case presented is that of a young adult white male who became ill suddenly during the evening of Sept 22 this year. The onset of the illness was marked by a chill, followed by pain in various joints. By morning a general purpuric erythema had developed. The radial pulse became imperceptible, coma developed and the patient died 10 15 a m, Sept 23. The total illness was of less than 12 hours' duration. Autopsy revealed bilateral adrenal capillary hemorrhage as the most striking gross finding. Micro-sections of the brain stained by Gram showed Gram-negative intra- and extracellular diplococci located in the cellulose of the arachnoid. There was no purulent reaction of the meninges. The final diagnosis, based on the microscopic autopsy findings, is acute fulminating meningococcus infection.

CONCLUSIONS

It is misleading to over-emphasize the importance of any single gross autopsy finding, such as the cutaneous erythema, the petechial hemorrhages in the serosa of the viscera, the bilateral capillary hemorrhage of the adrenals, the hyperplastic Peyer's patches and the congestion of the brain, all of which were well marked gross autopsy findings in the case I have presented. In any case presenting a skin eruption, the character and distribution of the eruption and the time required for complete efflorescence must be taken into consideration. The importance of considering meningococcus infection as a possible cause of death in an illness of less than 12 hours' duration is emphasized.

LIPOIDAL HISTIOCYTOMA (FIBROXANTHOMA), REPORT OF A CASE

By GEORGE M LEWIS, M D, *New York, N Y*, and WILBERT SACHS, M D, *Jersey City, N J*

THE origin and nature of the xanthoma cell is in doubt¹ Because of this, its significance is not fully understood Many observers have noted the rather widespread occurrence of xanthoma-like cells in dermatoses not usually considered among the true xanthomas In using the term fibroxanthoma, a combination of a fibroma with a xanthoma is implied Aschoff and Kammer² consider that such a unification exists and classify fibroxanthoma as a type of the true xanthomas Pinkus and Pick³ contend that the process is more likely due to the ability of tumors of the connective tissue group to become enriched with lipoids For this reason, they prefer the term fibroma xanthoma or, better still, fibroma lipoidicum We doubt that it is a disease *sui generis* because it apparently has no characteristic clinical features

CASE REPORT

J S, aged 36, a policeman, was first examined in January 1934, regarding a lesion of six months' duration on the right knee Four years before, he was struck by a trolley-car and severely injured Besides several dislocations and internal injuries, he sustained many contusions and abrasions, among which was an abraded area at the site of the present lesion Healing was delayed and a small infiltrated area remained Six months before his first visit, he tripped on a subway stair and

* Received for publication August 21, 1935

From the Skin and Cancer Unit, New York Post-Graduate Medical School and Hospital, Columbia University

bruised the same area of skin on his right knee. Following this, a lesion appeared and became progressively larger until it reached its present size (figure 1). Bleeding was at times profuse, so that it was necessary to wear a bandage to prevent his clothes becoming soiled.

Examination disclosed a walnut-sized, dark-red nodule, elevated above the surface of the skin. Its surface was uneven and in one part was covered with a crust. There was very slight infiltration at the base. Palpation of the lesion revealed a slightly harder consistency than one would expect from its appearance.

From the clinical characteristics, the lesion was considered either sarcoma or pyogenic granuloma. Because of the possibility of malignancy, it was felt advisable

FIG 1 Photograph showing the lesion on the right knee

to excise the lesion. This allowed a complete histologic study to be made. After surgical removal, the wound was closed with three interrupted sutures.

Pathology In the center of the specimen was an infiltrate occupying one-half the section and extending throughout the upper, mid, and deep cutis down to the fat (figure 2). This infiltrate was composed of closely packed cellular elements. The area was circumscribed and sharply differentiated from the normal tissue on either side.

Throughout the infiltrate were coarse and fine strands of connective tissue. Within these were many blood and lymphatic vessels. In the mid and upper cutis these vessels were more numerous and were markedly dilated, some were filled with blood elements.

At the margins of the section, the epidermis was markedly and irregularly acanthotic. The rete pegs encircled the cellular infiltrate and extended down almost

FIG 2 Low power photomicrograph showing the lesion as a whole ($\times 10$)

FIG 3 High power photomicrograph showing histiocytes with fatty changes ($\times 500$)

to the deep cutis. Overlying the cellular mass, the epidermis was thinned into a narrow band of three or four layers of cells, composed of one basal cell, one or two prickle cells, and one horn cell. The rete pegs and papillary bodies were absent. Over the center, the epidermis was entirely missing and the cellular mass extended to the surface.

The infiltrate was composed of large cells, some being round and some polygonal, they were about in equal proportion (figure 3). The cell outlines were distinct and the nuclei were large and round, with chromatic fibers loosely arranged. There were definite nucleoli. Many of the cells contained two or three nuclei. The spongio-plasm was fairly clear but the hyaloplasm was only faintly visible, giving a foamy appearance to the cell body.

Besides the presence of xanthoma-like cells, granuloma pyogenicum was differentiated from fibroxanthoma by the absence of granulation tissue and the presence of a different stroma, sarcoma was ruled out by the absence of variously-sized connective tissue cells, by the fact of the lesion being well circumscribed and demarcated and by its orderly arrangement.

SUMMARY

A case is reported in which the clinical findings were suggestive of either granuloma pyogenicum or of sarcoma. The histology was that of fibroxanthoma. Examination of the patient one year following the removal of the lesion revealed no evidence of local recurrence.

THE AMERICAN BOARD OF INTERNAL MEDICINE

During the recent session of the American Medical Association at Kansas City, Missouri, May 11 to 15, 1936, the American Board of Internal Medicine was given final official approval by the Advisory Board for Medical Specialties, the Council on Medical Education and Hospitals and the Section on Practice of Medicine of the American Medical Association.

The Section on Practice of Medicine, American Medical Association, held a special executive meeting for this purpose, preceding the scientific program, Wednesday morning, May 12, 1936 with Dr William J Kerr, chairman of the section, presiding. Present on the platform were the four representatives from the Section on the Joint Committee of Organization, Reginald Fitz, Ernest E Irons, John H Musser, and Walter L Biering as well as Dr James Alexander Miller, recent president of the American College of Physicians.

The plan of organization of the Board with an outline of the methods for certifying specialists in internal medicine was presented by the chairman of the Joint Committee, Walter L Biering, after which Dr James Alexander Miller made a statement on behalf of the American College of Physicians that the College appreciated the privilege and opportunity to sponsor this movement and cooperate with the Section in the organization of the American Board of Internal Medicine.

The resolution of approval by the Section on Practice of Medicine, American Medical Association, was presented by Dr James A Paullin and supported by Dr S Marx White, after which it was unanimously adopted.

The historic significance of this action was manifest to all who were present. Within one year after the Regents of the American College of Physicians at the Philadelphia session in 1935 adopted the resolution to underwrite the necessary expense and join with the Section on Practice of the American Medical Association in the organization of a qualifying board for the certification of internists in the United States and Canada, the purpose was accomplished.

The American Board of Internal Medicine comprises nine members with five representatives from the American College of Physicians. Jonathan C Meakins, O H Perry Pepper, David P Barr, William S Middleton and G Gill Richards, and four members representing the Section on Practice of Medicine, American Medical Association, Reginald Fitz, Ernest E Irons, John H Musser and Walter L Biering.

The first meeting of the Board will be held in Chicago, during the month of June, at which time officers and personnel of special committees will be selected, and plans of procedure regarding methods of qualification and certification adopted. All the activities of the Board will be given the fullest publication in the *Annals of Internal Medicine*.

THE IMPORTANCE OF POTASSIUM IN THE TREATMENT OF ADDISON'S DISEASE

THE work of Harrop^{*} and of Allers,[†] and others has shown that the adrenalectomized dog may be kept alive indefinitely without the use of cortical hormone by the administration of sufficient quantities of sodium in the forms of sodium chloride and of either sodium bicarbonate or sodium citrate. Recent work of Allers has indicated that if the potassium intake be kept to a very low level, these animals, maintained on a high sodium intake, will not only live but will show entirely normal plasma electrolyte levels.

Adrenalectomized animals maintained on this high sodium, low potassium regime have shown themselves very much more sensitive to the action of a variety of toxic substances than are normal animals. They have been found to be highly sensitive to the action of insulin, of histamine, and of thyroxine. Important observations have now been published which indicate that they are also highly sensitive to the effect of any increase in the potassium intake.

This sensitivity of the adrenalectomized animal to potassium is especially significant since the effect produced is very similar to the acute crisis seen in the untreated animal following adrenalectomy. The prostration of the animal is accompanied by a fall of serum sodium levels and a rise in serum potassium. The color, viscosity, sedimentation rate and clotting time of the blood resemble similar determinations made on the blood in acute crisis following adrenalectomy. Intravenous injections of large amounts of sodium chloride, sodium bicarbonate and glucose plus large amounts of cortin serve to restore these animals to normal.

The importance of these similarities between the crises produced by increasing the potassium intake and those occurring spontaneously is enhanced by the consideration of data indicating that in Addison's disease in periods of crisis the serum potassium rises as the serum sodium falls. The administration of large doses of cortin tends to reverse these phenomena. It would appear, therefore, that the level of potassium in the serum is as intimately concerned with the mechanism of crisis and as much under the regulation of the cortical hormone as is the level of serum sodium.

The practical application of this principle to the control of Addison's disease has been under investigation in the Mayo Clinic and the results obtained in three patients have been published.[‡] It was found that when the intake of potassium was kept at 1.6 gm per day the sodium and chloride intake could be reduced from such figures as 8.1 gm sodium and 10.9 gm

* HARROP, G. A., SOFFER, L. J., NICHOLSON, W. M., and STRAUSS, M. B. Studies on the suprarenal cortex. IV. The effect of sodium salts in sustaining the suprarenalectomized dog, *Jr. Exper. Med.*, 1935, 111, 839-860.

† ALLERS, W. D. The influence of diet and mineral metabolism on dogs after suprarenalectomy, *Proc. Staff Meet. Mayo Clinic*, 1935, 10, 406-408.

‡ WILDER, R. M., SNELL, A. M., KEPLER, E. J., RYNEARSON, E. H., ADAMS, M., and KENDALL, E. C. Control of Addison's disease with a diet restricted in potassium: a clinical study, *Proc. Staff Meet. Mayo Clinic*, 1936, 11, 273-283.

chloride to 6 gm of sodium chloride daily without seriously altering the levels of serum sodium or serum potassium and without producing clinical evidence of crisis

On the other hand when the patients were in normal condition on a régime of high sodium and chloride and low potassium it was found that if the potassium intake were raised from 1.6 gm to 4 gm there developed a prompt outpouring of sodium and chloride in the urine, the serum sodium fell and symptoms of crisis developed which required active treatment with cortin and intravenous salt

Comparable increases in the potassium intake do not cause any marked change in the serum sodium in normal persons, though if the intake of sodium is high, administration of potassium salts may be followed by some increased urinary excretion of sodium. The action of the natural cortical hormone is apparently protective. Within what limits the administration of cortin will protect against the action of potassium in Addison's disease is not yet fully determined

Wilder has pointed out that the normal diet contains variable amounts of potassium, many common foods such as meat, fish, potatoes, etc yielding as much as 400 mg per 100 gm. It is entirely possible, therefore, that an accidentally increased intake of potassium in the diet may account for some of the hitherto unexplained crises of patients under treatment with a high sodium intake alone. It would seem important therefore to add to the requirements for successful treatment of Addison's disease that dietetic measures be taken to ensure a potassium intake of not more than 1.6 gm a day

REVIEWS

The Diagnosis and Treatment of Variations in Blood Pressure and Nephritis By HIRMAN O MOSLINTHAL, M D 616 pages, 15.5 × 24 cm Oxford University Press, N Y 1930, 1931 Price, \$9.00

This volume is divided into two parts, the first dealing with blood pressure and the second with nephritis. In the first part the physiologic dynamics controlling blood pressure, methods of estimating arterial tension, tests for functional efficiency of the circulation, blood pressure as applied to life insurance, the effects of certain everyday habits and daily routine upon the blood pressure, hypotension and hypertension are discussed. The author points out that moderately elevated blood pressures remaining at the same level do not have the same significance as those which progressively become higher. He classifies cases of hypertension according to the elevation of the systolic or diastolic pressure or both, and attributes the first to a large pulse volume or to a general rigidity of the arterial wall, the second to an associated myocardial insufficiency, the last to a primary increased peripheral vaso-constriction or more commonly to an increase in the tone of the arteries between the heart and arterioles with secondary arteriolar constriction—the cases in this latter group being considered those known as essential hypertension. In regard to the severity of the vascular lesions secondary to or associated with hypertension, the author points out the present confusion in the use of the terms benign and malignant and suggests that better terms would be "mild," "progressive," or "severe." The etiology, symptomatology and treatment of essential hypertension are discussed.

The second part of this volume is devoted to what the author prefers to call Bright's disease, since he feels that nephritis can no longer be considered a disease of the kidney alone, and since furthermore certain conditions included in the non-suppurative renal diseases are not inflammatory in origin. Included in this portion of the book is a discussion of the various types of pathological lesions found, methods of testing renal function, symptoms and signs of impaired function, and treatment. The author has divided treatment into that directed at the pathological lesion and that directed at the symptoms and signs exhibited by the patient. He stresses the point that each patient presents an individual problem. There are separate chapters on edema, anemia, blood pressure and uremia. A classification is offered.

Drs Daniel R Barr, Ernst P Boas, Harold M Frost, C Ward Crampton, Edward C Schneider, Benjamin I Ashe, S Edward King, and James J Short have made contributions to this volume. There is an extensive bibliography.

W S L, JR

Synopsis of Diseases of the Heart and Arteries By GEORGE R HERMANN M D Ph D 344 pages, 13 × 20 cm C V Mosby Company St Louis 1936

This synopsis of cardiovascular disorders is intended for the student and general practitioner. It contains no reference lists but from time to time the names of outstanding investigators are mentioned in the text. It is well indexed. It contains chapters on modern instruments used in the clinical study of the heart, cardiologic roentgenology, and electrocardiography. This book is recommended to those wishing more information on this subject than is to be found in the textbooks on general medicine, and who do not wish to purchase or who have not the time to read one of the more extensive treatises on cardiovascular diseases.

W S L, JR

The Medical Treatment of Gall Bladder Disease By MARTIN E. REHFUSS, M.D., and GUY M. NELSON, M.D. 465 pages, 15 × 24 cm W. B. Saunders Company, Philadelphia 1935 Price, \$5.50

Any comprehensive presentation of the medical treatment of gall bladder disease is timely, for today the results of even expert surgery are often discouraging. Moreover, the mechanism of gall bladder disease is not reversed or changed by surgical treatment, such treatment merely removes the result of a pathological process without affecting its cause. In the light of our present knowledge Rehfuß and Nelson feel that like the diabetic, the chronic biliary sufferer needs an adjustment of his method of living, a recognition of certain dietary procedures, and equally important a systematic check-up of his condition.

The book is well arranged and proceeds in orderly fashion first by stating the problem and then the methods whereby it may be attacked. The physiology of gall bladder activity is reviewed briefly. The important points in the clinical study of the gall bladder patient are described.

The authors believe that the primary problem in the treatment of gall bladder disease is a medical one, although surgical therapy is often necessary as a part of the general program. Certain cases they consider clearly candidates for surgery, but on the other hand they point out that there are exceptions to the rule that gall stones in themselves are an indication for surgical treatment. Careful consideration of the patient's status as a surgical risk is necessary. The clinical similarity to gall bladder disease of pancreatitis, appendicitis, and coronary disease should lead to a careful analysis of clinical data in each case before a final decision is reached.

In discussing the medical treatment, the authors stress the value of considering that in each patient with gall bladder disease one or more etiologic factors are chiefly at play and must be especially combated. The three major etiologic factors they consider to be metabolic defects, infections, and stasis. Diet regulation, the removal of focal infections, the use of vaccines, the employment of duodenal drainage, etc. are more or less appropriate therapeutic methods according to the etiologic factor which predominates in the individual case.

There is a very full discussion of diets, drugs, and special therapeutic methods. General hygiene, rest, exercise, work and diversion are considered from the point of view of the gall bladder patient.

S. M.

The Stomach and Duodenum By GEORGE B. EUSTERMAN, and DONALD C. BALFOUR. 958 pages, 17 × 25 cm W. B. Saunders Company 1935 Price, \$10.00

This book is an excellent example of a cooperative effort on the part of competent men working in unison for the benefit of all of us. They supplement each others' knowledge and in that way are able to present the fundamental facts of diseases of the stomach and duodenum as well as their relationship to other diseases. The gastro-duodenal field is surveyed and brought up to date from all points of view, medical, surgical, physiological, pathological and roentgenological, and the result is an excellent book for internist, surgeon, general practitioner and student.

The authors and contributors have endeavored to confine their discussions to such phases as have more or less direct clinical application, and thus to emphasize the real purpose of coordinated practice, namely, that the benefit of all knowledge, whether clinical, experimental, surgical or pathological, be made available to the individual patient. They have omitted mention of conditions, anomalies, or therapeutic procedures with which they are not sufficiently familiar to cause their opinion to have weight, but on the other hand they have paid the greatest attention to diseases of frequent occurrence such as duodenal ulcer, gastric ulcer, dyspepsia, gastritis, hemorrhage, nutritional disorders, vitamin deficiency states, etc.

The first five chapters may be looked upon as reviews from the historical, physiological, experimental, surgical pathological and pathological points of view. They give the reader that fundamental knowledge upon which a satisfactory clinical approach can be substantially based. The general problem of dyspepsia is classified into four groups. These are the organic, reflex, systemic and functional. Then follows the investigation of the patient. Test meals are discussed and their diagnostic significance evaluated. An illustrated chapter is devoted to roentgenologic diagnosis. Anesthesia for surgical procedures involving the stomach and duodenum are duly considered.

The chapters on duodenal ulcer are excellent. Other phases of duodenal disease such as duodenitis malignant and non-malignant tumors of the duodenum, tuberculosis of the duodenum, chronic dilatation and obstruction of the duodenum, fistulas and injuries of the duodenum, duodenal parasites, diverticula, paraduodenal hernia are considered. Gastric diseases are similarly discussed and it is interesting to see that the subject of gastritis is still a controversial one. Gastric ulcer and cancer, as would be expected, consume many pages. In the chapter on surgical treatment of carcinoma of the stomach, excellent step by step illustrations of various operative procedures are included. The importance of early diagnosis is stressed and the possibility of more and more five year cures is shown to depend upon early diagnosis, proper surgical technic and proper pre- and postoperative care of the patient.

Achlorhydria assumes added significance in view of recent advances in the understanding of it. A chapter is devoted to the medical treatment of inoperable carcinoma of the stomach, a subject upon which we always need enlightenment. The subject of diaphragmatic hernia is discussed. Apparently what was interpreted as an increase in its incidence is due entirely to the awareness that the condition exists and to better diagnosis.

The important subjects of perforation and hemorrhage and their treatments as well as the problem of gastric retention due to duodenal and pyloric obstruction are considered thoroughly. A chapter is also devoted to that moot question of carcinomatous transition of gastric ulcer and another to anemia following operations on the stomach.

It is apparent, therefore, that we have here perhaps the most complete treatise on the stomach and duodenum in the English language. The work is systematically and skillfully arranged following a plan which devotes one-third of the book to general and fundamental considerations, one-third to a discussion of the duodenum in practically all its phases and the final one-third to a similar discussion of the stomach, except for the last chapter which discusses the nature of postoperative pulmonary disease. Both stomach and duodenum are considered in the same sequence.

The bibliography is selective, comprehensive and authoritative. The illustrations are splendid. The book can be highly recommended. S M

Lobar Pneumonia and Serum Therapy By FREDERICK T. LORD, M.D., and RODERICK HERRON, M.D. 91 pages. The Commonwealth Fund, New York. 1936. Price, \$1.00.

This small book, written with special reference to the experience of the Massachusetts Pneumonia Study, will be of interest and value to all those engaged in the care of pneumonia cases. It deals first with the underlying immunological problems and then in a very practical and specific way with such topics as the selection of cases for serum treatment, the technic of typing, the methods and precautions useful in serum therapy, dosage, and reactions. In the last chapter new data are added concerning the results of serum therapy.

The presentation will be clear to any intelligent practitioner and at the same time the observations recorded will be valuable to those fully conversant with the previous literature of this subject. M C P

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following gifts to the library of the American College of Physicians

- Dr Oliver T Osboine (Fellow), New Haven, Conn—3 books, "What Everyone Ought to Know," "Mouth Infection" and "Evaluation of Symptoms",
Dr Jacob Gutman (Fellow), Brooklyn, N Y—Sixth Supplement to his book, "New Modern Drugs," previously donated to the College,
Dr Jacob Buckstein, New York, N Y—1 book, "Peptic Ulcer",
Lt Col Thomas W Burnett (Fellow), M C, U S A—1 reprint,
Dr Arthur R Elliott (Fellow), Chicago, Ill—18 reprints,
Dr Hubert C King (Fellow), Lakewood, Ohio—1 reprint,
Dr E B Krumbhaar (Fellow), Philadelphia, Pa—16 reprints,
Dr Albert Soiland (Fellow), Los Angeles, Calif—6 reprints,
Dr Pauline Williams (Fellow), Richmond, Va—2 reprints,
Dr W Lawrence Cahall (Associate), Philadelphia, Pa—1 reprint,
Dr Richard J Clark (Associate), Boston, Mass—3 reprints,
Capt James H Forsee (Associate), M C, U S A—5 reprints,
Dr William Freeman (Associate), Worcester, Mass—10 reprints,
Dr Ralph H Kuhns (Associate), Chicago, Ill—1 reprint,
Dr Fred J McEwen (Associate), Wichita, Kan—1 reprint,
Dr G Louis Weller, Jr (Associate), Washington, D C—4 reprints,
Dr F Eugene Zemp (Associate), Columbia, S C—4 reprints

The North Carolina State Medical Society met in Asheville May 4 to 6, under the presidency of Dr Paul H Ringer (Fellow), Asheville A luncheon by North Carolina members of the American College of Physicians was given Tuesday, May 5, in honor of Dr Ernest B Bradley, President of the College, at which 36 Fellows out of a State membership of 66 were present In addition to President Ringer, four ex-Presidents of the State Society were present, Dr L B McBrayer, Southern Pines, Dr M L Stevens, Asheville, Dr Isaac Manning, Chapel Hill, and Dr Paul P McCain, Sanatorium, as well as Dr Wingate M Johnson, Winston-Salem, President-Elect of the Society, all Fellows of the College Dr Bradley spoke briefly explaining the progress of the Committee on the Certification of Internists

Under the Presidency of Dr James E Paullin (Fellow), the Medical Association of Georgia recently held its 87th Annual Session Dr William B Castle (Fellow), recipient of the Phillips Memorial Award of the American College of Physicians for 1933, delivered the Abner Wellborn Calhoun Lecture

Dr J Frederick Panton (Fellow), Buffalo, N Y, has been appointed Associate in Medicine at the University of Buffalo School of Medicine for the academic year, 1936 to 1937

Dr A U Desjardins (Fellow) Rochester, Minn, is Chairman of the American committee in charge of the First International Congress on Fever Therapy to be held at Columbia University, New York City, September 29 to October 3, 1936 The subjects to be discussed will include physiologic and pathologic changes as well as the

treatment of gonorrhea, both in the male and in the female, gonorrheal and non-specific arthritis, syphilis in its various stages, neurologic conditions such as multiple sclerosis, chorea, paresis, tabes, skin diseases, etc. This meeting will be held under the Chairmanship of Baron Henri de Rothschild of Paris France. There is a French committee headed by Professor d'Aisonval as honorary President and Professor Abram as Chairman. There is a national European committee with members representing various European countries.

An abstract of the papers will be published in the volume of the transactions in English, German and French. Information regarding the conference may be obtained from the Secretary, Dr William Bierman, 471 Park Avenue, New York N. Y.

Dr William Nimeh (Fellow), Mexico, D. F., has been elected President of the Mexican Chapter of the National Society for the Advancement of Gastro-enterology.

Dr Nimeh also was recently and unanimously elected a member of the National Academy of Science.

Dr Archibald L. Hoyne (Fellow), Clinical Professor of Pediatrics, Rush Medical College, and Associate Clinical Professor of Pediatrics, School of Medicine of the Division of the Biological Sciences, University of Chicago, addressed the Northern Ten-State Medical Meeting at Fort Wayne, Ind., in April on "Progress in the Management of Contagious Diseases."

He also addressed the Nebraska State Medical Meeting at Lincoln, during April, on "The Treatment of Meningococcic Meningitis Without Intraspinal Therapy," and the Iowa Public Health Association's meeting at Des Moines, on April 28, on "Diphtheria." On May 29 he addressed the Iowa State Medical Meeting at Des Moines on "Meningococcic Meningitis."

Dr C. C. Burlingame (Fellow), Hartford, Conn., as Chairman of the Committee on Public Education of the American Psychiatric Association, recently announced the election by the Board of Examiners of that organization, of Dr Kenneth Appel (Associate), Philadelphia, Pa.

Dr Howard M. Jamieson (Fellow), Wilkes-Barre, Pa., has accepted a Public Health appointment in Great Britain.

Newly elected Fellows of the American College of Physicians of Puerto Rico gave a dinner on April 28 in honor of the College Governor of the Island, Dr R. M. Suarez. Dr Suarez presented a report upon the Twentieth Annual Session of the College held in Detroit, at which he was in attendance. There was a round table discussion in regard to the College, its policies and the further development of its membership in Puerto Rico. Action was taken toward organizing a local unit with the purpose of furthering the aims and objects of the College and its scientific activities in the Island.

Under the Presidency of Dr F. M. Pottenger (Fellow), Monrovia, the Twentieth Annual Scientific Session of the Association for the Study of Internal Secretions was held in Kansas City, May 11 to 12. Among members taking part in the program were

- Dr E L Sevringhaus (Fellow), Madison, Wis (with R K Meyer)—“Gonadotropic Inhibitory Substances in Blood of Women and Monkeys After Anterior Pituitary Therapy”,
- Dr J B Collip (Fellow), Montreal, Que (with Hector Mortimer, Percy Wright, Carl Bachman)—“The Hormone Relationship Between the Female Organs of Sex and the Nasal Mucous Membrane” and “Further Studies in Anterior Pituitary Physiology”,
- Dr Henry J John (Fellow), Cleveland, Ohio—“The Interrelationship Between the Pancreas and Other Endocrine Organs in Diabetes”
- Dr Hans Lissner (Fellow), San Francisco, Calif—“Two and One-Half Years' Observation of a Patient with Cushing's Disease, Following Removal of a Pars Intermedia Adenoma”,
- Dr W O Thompson (Fellow), Chicago, Ill (with N J Heckel, A D Bevan, E R McCarthy and P K Thompson)—“The Treatment of Undescended Testicles with an Anterior Pituitary-Like Substance”,
- Dr L G Rowntree (Fellow), Dr J H Clark (Fellow) and Dr N H Einhorn (Fellow), all of Philadelphia (with Arthur Steinberg, Philadelphia, and A M Hanson, Faribault, Minn)—“The Role of the Thymus Gland in Growth and Development”,
- Dr Homer P Rush (Fellow), Portland, Ore—“Three Cases of Macrogenitosomia”,
- Dr Daniel L Sexton (Fellow), St Louis, Mo—“Treatment of Sexual Underdevelopment in the Human Male with Pregnancy Urine Extract Further Report”,
- Dr Matthew Molitch (Associate), Jamesburg, N J (with Sam Poliakoff)—“Hypothyroidism in Behavior Problems”

Dr Joseph C Doane (Fellow), Medical Director of the Jewish Hospital of Philadelphia, will give a short course in hospital operation in the Summer School of Hotel Administration at Cornell University, June 29 to July 11. The course, planned as a “refresher” course for those already engaged in hospital work is a “unit” course, which means that students enrolled will devote all their study time exclusively to the study of hospital problems

The Philadelphia County Medical Society, during the week of April 20 1936, conducted its First Annual Postgraduate Institute. Authorities in their respective fields offered postgraduate lectures relating especially to cardiovascular and renal diseases. Admission was open to all interested physicians not only locally but throughout the eastern portion of the country. The following Fellows of the College were members of the Committee on the Postgraduate Institute: Dr E J G Beardsley, Dr Edward L Bortz, Dr Willis F Manges, Dr H K Mohler and Dr William D Stroud

Dr David P Barr (Fellow) and Dr Sinclair Luton (Fellow) both of St Louis, addressed the annual meeting of the Missouri State Medical Association at Columbia, Mo on “Nature and Treatment of Obesity” and “The Clinical Use of Digitalis Variables Encountered,” respectively

Dr William Devitt (Fellow) Allenwood Pa, is President of the Pennsylvania Tuberculosis Society, succeeding Dr Charles Howard Marcu (Fellow), Pittsburgh

Under the Presidency of Dr Herbert L Bryans (Fellow), Pensacola, the 63rd Annual Meeting of the Florida Medical Association was held on the S S Florida, April 27 to 29, on a cruise to Havana

Dr Willis F Manges (Fellow), Philadelphia, presented the Russell D Carman Memorial Lecture, sponsored by the Minnesota Radiological Society, during the annual session of the Minnesota State Medical Association at Rochester, Minn, early in May. Dr Manges' title was "Foreign Bodies and the Use of X-Ray Examination in Their Localization and Removal"

Dr James Alex Miller (Fellow) has been appointed Administrative Consultant in Tuberculosis to the New York City Department of Hospitals

A reception and testimonial dinner was tendered to Dr Andrew P Biddle (Fellow), Detroit, on April 1 by the Wayne County Medical Society and the Detroit Dermatological Society in recognition of his completion of fifty years in the practice of medicine. Dr Biddle is Emeritus Professor of Dermatology at Wayne University, College of Medicine. He was President of the Detroit Board of Education in 1925, President of the Detroit Library Commission in 1931, Charter member of the Wayne County Medical Society and was the first Editor of the Journal of the Michigan State Medical Society. He has also acted as President of the State Society, President of the Detroit Academy of Medicine and President of the American Dermatological Society

Dr Robinson Bosworth (Fellow), Rockford, has been elected President of the Illinois Tuberculosis Society

Dr Andrew C Ivy (Fellow), Chicago, has been named Secretary of the American Physiological Society.

Under the Presidency of Dr Robert A Peers (Fellow), Colfax, Calif, the 65th annual meeting of the California Medical Association was held at Coronado, May 25 to 28. Dr Jacob J Singer, St Louis, Dr Harry H Wilson, Los Angeles, Dr F M Pottenger, Monrovia, Dr Philip H Pierson, San Francisco, all Fellows of the College, were among the speakers on the program

Dr Ralph A Kinsella (Fellow), St Louis, delivered the annual oration in medicine before the Illinois State Medical Society at its meeting in Springfield, May 19, his title being "The Career of a Heart"

Dr George W Covey (Fellow), Lincoln, Nebr, was installed as President of the Nebraska Medical Association at its 68th annual meeting during April

Dr Peter Irving (Fellow), New York City, is Secretary of the Medical Society of the State of New York

Dr Earl B McKinley (Fellow), Washington, D C, has been named Vice-President of the American Association of Pathologists and Bacteriologists

Dr Charles F Martin (Master) for many years Dean of the Faculty of Medicine of McGill University, Montreal, will retire August 31, having reached the retirement age in effect at that institution

Dr Albert Grant Fleming, Professor of Public Health and Preventive Medicine and Director of the Department, has been appointed Dean to succeed Dr Martin

A newly established position of Associate Dean will be filled by J C Simpson, LL D, Secretary of the Faculty of Medicine and Chairman of the Committee on Physical Education

OBITUARIES

DR CLARENCE EUGENE SIMONDS

Clarence E Simonds was born February 13, 1874, in the town of Mansfield, Conn, a son of William E and Mary (Lee) Simonds

He was educated in the common schools of Mansfield and graduated from Willimantic High School in 1893 After teaching for a year he entered the medical school of New York University, finishing the course there in 1897 Following this he did postgraduate work at New York Post-graduate Medical School and Hospital

He practised his profession in Danielson and South Coventry, Conn, before beginning to practice in Willimantic in 1903, where he has remained until about a year ago when failing health caused him to give up all active work He served as health officer of the town of Windham and was medical examiner for the towns of Windham, Scotland and Hampton for many years until ill health compelled him to resign

He was formerly Attending Physician, St Joseph's Hospital, Chief Physician and President of the Medical and Surgical Staffs, Windham Community Memorial Hospital, ex-president and ex-secretary of Willimantic City Medical Society, ex-president of Windham County Medical Society, a member of the Connecticut State Medical Society and of the American Medical Association He was also a member of the Willimantic Chamber of Commerce and past president of the Exchange Club He became a Fellow of the American College of Physicians in 1930

At the time of his death he was president of the professional staff of the Windham Community Memorial Hospital

HENRY F STOLL, M D, F A C P,
Governor for Connecticut

DR ARTHUR D HOLMES

Arthur David Holmes, M D, C M, Detroit, Michigan, died after a short illness, February 20, 1936

Dr Holmes was born in Chatham, Ontario, in 1863 He graduated from McGill University, Faculty of Medicine, in 1889, and then started practice in Detroit Very early he confined his work to pediatrics He spent the year 1902-1903 in London and Vienna doing graduate work in the diseases of children

He held numerous teaching and hospital appointments Attending Physician, Children's Free Hospital, 1905-1916, Attending Physician, Woman's

Hospital and Infants' Home, 1907-1916, Consultant to both of these institutions to the time of his death, Clinical Professor of Pediatrics, Detroit College of Medicine, 1913-1916. He held membership and office in many medical societies: Wayne County Medical Society (President in 1910, and a Trustee from 1910 to 1930), Michigan State Medical Society, American Medical Association, Detroit Academy of Medicine (President, 1901), Mississippi Valley Medical Association (Vice-President, 1912), Central States Pediatric Society. Dr. Holmes was one of the very early members of the American College of Physicians, having taken Fellowship in 1917. He was also a Director of the Equitable Trust Company, Charles W. Warren Company, and the Central West Casualty Company. In social organizations he held membership in the Detroit Club, the Witenagemote Club, and the Detroit Country Club.

Dr. Holmes had been a widower for many years, and is survived by two daughters, Mrs. Ernest G. Davis and Miss Agnes Holmes of Detroit.

Dr. Holmes' death is a great loss to the medical profession of the city and state. He was one of the earliest to confine his work to pediatrics, and for many years was an active teacher in the college and hospitals of the city. As an able clinical teacher, his work became the inspiration for many of our younger pediatricians. A gentleman of broad culture and great personal charm, he enjoyed a wide social acquaintanceship in the city. Organized medicine also owes a great debt to Dr. Holmes, for it was during his presidency in 1910 and under his inspiring guidance, that the Wayne County Medical Society first purchased and became quartered in a building of its own, marking an important step in the growth and prosperity of the Society. The profession will miss greatly his genial friendship, and his able professional counsel.

HENRY R. CARSTENS, M.D., F.A.C.P.,

Governor for Michigan

DR. WEBSTER STANLEY SMITH

Dr. Webster Stanley Smith (Associate), Dayton, Ohio, died January 30, 1936, of arteriosclerosis, at the age of 79. Dr. Smith was born in Dayton, November 13, 1856. He attended the public schools and graduated from the Medical College of Ohio in 1880. For many years he was connected with the Miami Valley Hospital as a member of the department of medicine and as instructor to nurses in diseases of the chest. He was a member and past president of the Montgomery County Medical Society, a member of the Ohio State Medical Society, the Mississippi Valley Medical Society, the American Medical Association, and had been an Associate of the American College of Physicians since 1925.

MINUTES OF THE BOARD OF REGENTS

DETROIT, MICH

March 1, 1936

A regular meeting of the Board of Regents was held at the Book-Cadillac Hotel, Detroit, March 1, 1936, with the following present James Alex Miller, President, Ernest B Bradley, President-Elect, David P Barr, Second Vice-President, William Gerry Morgan, Secretary-General, William D Stroud, Treasurer, Walter L Biering, John H Musser, O H Perry Pepper, Francis M Pottenger, Luther F Warren, William J Kerr, Roger I Lee, Sydney R Miller, George Morris Piersol, G Gill Richards, James B Herrick, Jonathan C Meakins, James H Means, James E Paullin, Maurice C Pincoffs, Charles H Cocke, and Dr Alfred Stengel, Chairman, College Headquarters Committee, and Mr E R Loveland, Executive Secretary, acting as secretary of the meeting, with Dr James Alex Miller, of New York City, President of the College, presiding

The Executive Secretary read abstracted Minutes of the meeting of the Board of Regents held in Philadelphia December 15, 1935, which were approved as read

President Miller in preliminary remarks referred with regret to the death of Dr Charles G Jennings General Chairman of the Twentieth Annual Session, to two main subjects to be discussed later in the meeting, namely, the matter of a permanent home for the College and the certification of internists by the American Board of Internal Medicine, and to the remarkably satisfactory manner in which the Executive Offices had functioned during the past year

The Executive Secretary then presented a communication from Professor M Fernan-Núñez of Marquette University School of Medicine, Milwaukee, inviting, on behalf of Prof Dr Gustavo Pittaluga, Madrid, Spain, President of the III International Congress on Malaria to be held there October 12 to 18, 1936, some representative of the College to attend the Congress

On motion by Dr Biering, seconded by Dr Pepper, and regularly carried, it was

RESOLVED, that the incoming President, Dr Ernest B Bradley, may designate any Fellow of the College whom he finds is going to attend this Congress to act as the official delegate of the American College of Physicians

Dr Ernest B Bradley, Chairman of the Committee on Public Relations presented the following resignations, which were acted upon by resolution

Associates

Bernard G Efron	New Orleans, La
Walter S Lucas	Wynnewood, Pa
Jenaro Suarez	San Juan, P R

Fellows

W L Holman	Toronto Ont
Lester J Williams	Baton Rouge, La

RESOLVED, that the resignations of the three above named Associates and two Fellows be accepted

Dr William Gerry Morgan, Secretary-General, presented the following resolution, which was unanimously adopted, on the death of Dr Charles G Jennings (Master), including its being spread upon the Minutes of this meeting and a copy of it being sent to Dr Jennings' son, Dr Alpheus Jennings

IN MEMORIAM

CHARLES GODWIN JENNINGS

WHEREAS Through the death of Charles Godwin Jennings on January 9th, 1936, the American College of Physicians has lost one of its earliest and most distinguished members

Dr Jennings was elected to Fellowship in 1916 at the first annual meeting of the College held in New York City He was the second Fellow to be elected Master

During the twenty years of his membership as Fellow and Master, Dr Jennings took an active part in shaping the development of the College

He was President of the American Congress on Internal Medicine 1925 to 1926, at that time an integral part of the College He served for many years as Governor of the College for the State of Michigan, and as such built up a large and enthusiastic State membership On his retirement from the office of Governor, he was elected to the Board of Regents and served in this capacity until 1930 He was elected Second Vice-President of the College in 1931 and served until 1933, when he was made First Vice-President Dr Jennings was returned to the Board of Regents in 1935 for a term of three years

At the time of his death, Dr Jennings was General Chairman for the Twentieth Annual Meeting of the College

Dr Jennings by his broad vision, keen judgment and wise counsel had won the confidence and esteem of those with whom he had worked for so many years

THEREFORE BE IT RESOLVED that we express our deep sorrow for the loss of this true physician and wise counselor

The Executive Secretary, Mr Loveland, presented cases of failure to take up election, delinquency, and failures to qualify for Fellowship Two names were discontinued on the Fellowship Roster for failure to take up election, 14 Associates were dropped from the roll for failure to qualify for Fellowship within five years of their election to Associateship, as required by the By-Laws, 7 Fellows and 5 Associates were dropped from the roll because of delinquency of two years or more

Reporting upon the candidates elected to Associateship in 1931 and whose term of Associateship expires with the 1936 Annual Session, the Executive Secretary presented the following analysis

78 Qualified for Fellowship
2 Died
4 Resigned
1 Failed to take up election
16 Were rejected or dropped

101 Total elected 1931

77.2% qualified for Fellowship, 22.8% failed ever to become Fellows

Dr Wilham Gerry Moigan, Secretary-General, reported the deaths of the following members since the last meeting of the Board of Regents

Master

Charles Godwin Jennings	Detroit, Mich	January 9, 1936
-------------------------	---------------	-----------------

Fellows

Henry Wald Bettmann	Cincinnati, Ohio	December 5, 1935
Thomas C Chalmers	Forest Hills, N Y	November 16, 1935
William Krauss	Meridian, Miss	December 21, 1935
George Washington McCaskey	Fort Wayne, Ind	December 30, 1935
Stephen Roman Pietrowicz	Chicago, Ill	January 12, 1936
Hubert Schoonmaker	Clifton Springs, N Y	October 21, 1935
Charles D Steinwinder	San Antonio, Tex	

Associates

John Leonard Eckel	Buffalo, N Y	November 26, 1935
Henry Finlay Hyndman	Wichita, Kan	October 31, 1935

Dr Morgan also reported the following list of Fellows who have become Life Members since the last meeting of the Board of Regents This made a total of sixty-one Life Members, including the late Dr John Phillips

Lewis Beals Bates	Ancon, Canal Zone
Casper H Benson	Columbus, Ohio
Donald Gregg	Wellesley, Mass
James Rae Arneill	Denver, Colo
Thomas Fitz-Hugh, Jr	Philadelphia, Pa
C Charles Burlingame	Hartford, Conn
Noble Wiley Jones	Portland, Ore
Cecil M Jack	Decatur, Ill
Anna Weld	Rockford, Ill
Roy M Van Wart	Descanso, Calif (formerly of New Orleans)
Estes Nichols	Portland, Maine
Wilham Henry Watters	Coconut Grove, Miami, Fla

Dr George Morris Piersol, Chairman of the Committee on Credentials reported that the Committee had held two meetings, one at the College Headquarters in Philadelphia on February 2 and one at Detroit on March 1 He distributed to the Board of Regents a mimeographed list of the recommendations for election both to Fellowship and Associateship from the meeting of February 2 An analysis of this list follows

Recommended for election to Fellowship	
Advancement for Associateship	39
Direct election to Fellowship	15
	<hr/> 54
Recommended for election to Associateship first	1
Deferred for further investigation, maturity etc	10
Rejected	1
	<hr/> 66

Of those recommended for election directly to Fellowship, the majority were members of the Medical Corps of the U S Army and U S Navy

An analysis of the recommendations of the Committee on the Associate candidates considered February 2 was as follows

Recommended for election to Associateship	
From regular list	48
From Fellowship list	1
	<hr/>
	49
Deferred for further consideration	11
Rejected	6
	<hr/>
	66

Dr Piersol having insufficient time to mimeograph the recommendations of March 1, read the list of recommendations to the Board. His analysis of the candidates considered on March 1 was as follows:

Recommended for election to Fellowship	
Advancement from Associateship	40
Direct elections to Fellowship	11
	<hr/>
	51
Recommended for election to Associateship first	1
Deferred for further investigation maturity, etc	4
Rejected	3
	<hr/>
	59

An analysis of the candidates considered for Associateship on March 1, follows:

Recommended for election to Associateship	41
Recommended for election directly to Fellowship	2
Deferred for further consideration	2
Rejected	7
	<hr/>
	52

The combined lists of recommendations from the meetings of February 2 and March 1, both for Fellowship and Associateship, follow. On motion by Dr Piersol seconded by Dr Bradley and regularly carried, it was

RESOLVED, that the following 105 candidates for Fellowship and 92 candidates for Associateship shall be and are hereby elected to membership in the respective classes indicated:

The complete list of elections was published in the March, 1936, issue of this journal.

Dr Piersol, on behalf of the Committee on Credentials, presented two cases for advice and direction from the Board of Regents: (1) the case of a Fellow who resigned some years ago and who now is interested in being reinstated, but at a minimum of expenditure. After thorough discussion of the case, the Board of Regents, by resolution, directed that it shall be the policy in such cases to require the payment of all delinquent dues and to have the support and recommendation of the Governor of the district for reinstatement. The Board expressed itself as unfavorable to establishing a precedent of permitting members to leave and reenter the College at will without any obligation in the meantime. The only other method of regaining membership would be through an original proposal and reentry according to the present requirements, (2) the case of a former Fellow who subsequently became a Fellow of the American College of Surgeons and who specialized thereafter particularly in Obstetrics, although he is highly accomplished also in Internal Medicine. This member had resigned his Fellowship in the American College of Physicians because he understood it was the policy of the College not to include in its membership those engaged in obstetrical practice, or those who had become members also of the American College of Surgeons. This case was presented to determine whether the Board of Regents would consider reinstatement to active Fellowship in this College. A resolution was adopted re-

iterating the fact that the policy of the American College of Physicians remains the same in this respect as in the past, and that consequently as long as the candidate in question remains a Fellow of the American College of Surgeons and is not confining his work mainly if not exclusively, to Internal Medicine, the case cannot be reopened.

Dr Alfred Stengel, Chairman of the temporary Committee on the College Headquarters, reported that after his Committee had considered the matter, it had come to the conclusion that it was of such importance that the broad question of principle should be passed upon by the Regents before the Committee engaged anyone to draw up detailed plans. Therefore, he reported only upon the general proposition of a College Headquarters. There were two problems: first, whether the College wishes or requires a building for its headquarters, leaving rental considerations altogether out of mind, and, second, if they do feel that they should have such a building or headquarters, how far the Board of Regents of the College would like to go in the matter of expenditure. In regard to the question of the desirability, it has been the feeling of all the members of the Committee perhaps with some slight amendment in the way it was presented that it seems desirable that the College should have a dignified place wherever the headquarters of the College will be located, where Fellows of the College, as they may perhaps be going through that center, would find occasion to make visits either to obtain information, to arrange programs or to stop casually. He had obtained information from the Executive Secretary that aside from the meetings of the Regents and Governors at the College Headquarters, from time to time, there are perhaps one hundred and fifty or more visitors from the membership of the College every year who come to the headquarters for one purpose or another. The universal comment of visitors is that the College Headquarters is inadequate and inferior. He said there are all kinds of reasons that may be advanced as to why the College should have a central headquarters, but that he was passing over those to consider the question of finances. The Committee had determined that the cost of operating its headquarters including the loss of interest on the investment, maintenance, light, heat, taxes, etc., would total about \$8,000.00 per annum. This was all predicated on the erection of a building that would cost approximately \$100,000.00. Calculating the amount of space that the Executive Offices reasonably would require in the building where they are now located, the cost would be approximately \$7,800.00 per annum, or a difference only of \$200.00 between offices in an ordinary office building and headquarters in a dignified, individual home.

Dr Stengel reported that his Committee had surveyed many properties in the vicinity of the present College Headquarters, and had found one location, a vacant lot in a very desirable neighborhood, convenient to one of the large academic medical centers, to a first-class hotel and to transportation, which could be obtained for about \$30,000.00. The Committee felt that an appropriate headquarters could be erected and furnished for an additional \$70,000.00, as an outside figure. An architect, without charge to the College, had made several sketches and submitted different kinds of plans, making the estimate within the amount indicated above, and providing for materials of the best quality and a fireproof structure. Dr Stengel described the architect's plans, which were presented purely as a working basis and a theoretical possibility, that called for a Georgian building of two stories with an unfinished third floor, of construction permitting for adding additional floors if in future years such would be required. The type of architecture was in keeping with the surrounding buildings.

The Committee recommended to the Board of Regents favorable consideration of a permanent headquarters building erected and furnished in Philadelphia at a cost not to exceed \$100,000.00.

After wide discussion, a resolution was adopted to the effect that it was the sense of the Board of Regents that they approve in principle the program outlined by the Committee, but that final action be deferred until after a conference with the Board of Governors and until further and more specific details can be obtained.

Even after the adoption of this resolution, there was extended discussion in which it was brought out that the location considered was not far removed from the new mun station.

of the Pennsylvania Railroad and the new U S Post Office. The location was thought by some to be one that would be definitely appreciating in value as years go by.

The consensus of opinion was that the College should be conservative, should not expend an unnecessary amount, other than reasonably required, that it should take into consideration various uses for the College funds, but that if an appropriate College Headquarters of dignified character and adequate facilities could be provided, it would be a tangible evidence of its existence, that it would be a convenience to its members, and would provide better facilities for the proper functioning of the Executive Offices.

The discussion led also to a consideration of the initiation fee for Fellowship, it being suggested that as soon as possible, the Board should take under consideration a reduction of the present initiation fee of \$80.00. There has been an erroneous idea that the initiation fee was \$100.00, to which the annual dues have to be added. As a matter of fact, the initiation fee is but \$80.00 a year for practicing clinicians, with a gradual reduction, according to salary, for those employed as medical teachers or research workers in non-profit institutions.

At the end of the discussion, Dr Stengel concluded with the following remarks:

"I have tried to present this matter as objectively as possible, without going into some of the details that have been brought forward. The College has accumulated funds at a fairly rapid rate, due in great measure to its careful administration. If you can now invest some of that money to house yourself and pay your own headquarters rent instead of leaving it invested in funds producing income which you might be spending in other ways, your situation will be exactly the same. You are going to spend the same amount of money for rental as you will be spending upon this new building. It leaves you just where you are.

"The second proposition that immediately suggests itself is that the College could afford to reduce its present initiation fee. One of my fears is, and I am speaking as an 'ex-', is that the College will get too many members, which will kill it, and at present you are either right on the edge of or you have already accomplished a stricter method of surveillance of those who are candidates, which will keep out undesirables. If you had eliminated your initiation fee five years ago and persons could have come into the College without an initiation fee, but by merely paying \$15.00 a year dues, you would have had a much louder outcry at your door for admission on the part of undesirables. Your Committee on Credentials would have had a much harder job, and no matter how hard they worked, they would have let in a lot more undesirables than they did let in. Your initiation fee, in a sense, has stood as a guardian for the College. Now, with the proposition of a strict examination for admission to the College, that reason for an initiation fee will no longer exist in the same manner, and I think that this proposition makes it entirely possible to take some of your surplus and put it into a building which will make for a sense of stability and a sense of dignity, rather than to be merely a showplace.

"In my earlier report I mentioned the number of people who stop at the headquarters. Although that is a very unimportant thing and no one, I would think, would regard it otherwise, yet when one hundred and fifty men come along and say with disappointment, 'Is this where you live?'—well, that is one hundred and fifty men in an organization who go away and tell a sundry other one hundred and fifty men what they think of it. There is no strong argument for putting up a palace, but I think a dignified building that lends a sense of stability to an organization is a very important thing, and I think that financially you can well afford to do it, and, after you have got it, you can well afford to reduce your initiation fee and, perhaps, other fees as well."

Dr Walter L. Bierring, as Chairman of the joint Committee on the Certification of Internists, distributed copies of his report, which was as follows:

REPORT OF JOINT COMMITTEE

(American Board of Internal Medicine)

DETROIT, MICH.,
March 1, 1936

TO PRESIDENT JAMES ALLEN MILLER

AND

MEMBERS OF THE BOARD OF REGENTS,
AMERICAN COLLEGE OF PHYSICIANS

Since the report of this Joint Committee presented to the Regents at the meeting in Philadelphia, December 15, 1935, the further developments in the formation of the American Board of Internal Medicine are reported herewith

1 An application in due form was submitted to the Advisory Board for Medical Specialties, which functions in connection with the Council on Medical Education and Hospitals of the American Medical Association, for approval of the organization of the American Board of Internal Medicine

This application was accompanied by a copy of the proposed Articles of Incorporation which embodied the Constitution, a copy of the By-Laws, which includes the requirements and methods of Certification of Specialists in Internal Medicine and a copy of the application blank

Within a short time, advice was received from Dr Paul Titus, the Secretary of the Advisory Board for Medical Specialties, that its Committee on Credentials and Qualifications had reported favorably on the application and so recommended to the Executive Committee of the Advisory Board for its meeting in Chicago on February 16, 1936

2 The Joint Committee met in Chicago on Sunday, February 16, 1936, at which time certain minor changes were made in the Articles of Incorporation and the By-Laws, which were then submitted in corrected form to the Executive Committee of the Advisory Board of Medical Specialties, members Irons, Middleton and Bierring appearing for the Joint Committee

The Executive Committee of the Advisory Board approved the formation of the American Board of Internal Medicine and transmitted its action to the Council on Medical Education and Hospitals of the American Medical Association at its meeting on Monday, February 17, 1936, which Council endorsed the action of the Advisory Board

It was stated by both of the above bodies that final official action and approval would be withheld until a meeting of the entire Advisory Board for Medical Specialties and that of the Council on Medical Education and Hospitals in Kansas City, Mo, May 10 to 15, 1936, during the annual session of the American Medical Association

If the Regents of the American College of Physicians, during this session, can approve the steps thus far taken in the formation of the American Board of Internal Medicine, the further official approval of the Section on Practice of Medicine of the American Medical Association can be obtained at its executive meeting on May 15, 1936, at Kansas City. After this has been accomplished, all the requirements of organization will have been complied with and the American Board of Internal Medicine will then be ready to begin operations

At the meetings in Chicago, February 16 and 17, 1936, the Advisory Board for Medical Specialties and the Council directed that the Articles of Incorporation be filed in a Court of Record and this was accordingly done at Des Moines (Polk County), Iowa, on Friday, February 28, 1936

The three required witnesses to the document, residents of Des Moines, were Dr Tom B Throckmorton, Governor for Iowa of the American College of Physicians, Dr Fred Moore, Member, Council on Medical Education and Hospitals of the American Medical Association, and Dr Walter L Bierring, Member of the Joint Committee

The purpose of filing these Articles in Iowa seemed advisable because of more favorable regulations in this State for non-profit sharing corporations. A special filing fee, an annual report and registration are not required as is the custom in some of the other States

Because the Articles are filed in Iowa does not imply that the place of business of the Board shall necessarily be in Iowa

It will be noted by the accompanying copy of the Articles of Incorporation (Constitution), that the American Board of Internal Medicine is composed of nine members, five of which shall be Fellows of the American College of Physicians, and four shall be representative of the Section on Practice of Medicine of the American Medical Association

Previous to the meeting of the Advisory Board for Medical Specialties in Chicago on February 16, 1936, Dr James Alex Miller, by virtue of his authority as President of the American College of Physicians, submitted to the secretary of the Advisory Board, Dr Paul Titus, the names of Drs Meakins, Pepper, Middleton, Barr and Richards to represent the American College of Physicians, and in like manner, Dr William J Kerr, as Chairman of the Section on Practice of Medicine of the American Medical Association, the names of Drs Fitz, Irons, Musser and Bierring to be members of the first American Board of Internal Medicine

The By-Laws include the requirements for special training in Internal Medicine and procedure of Certification, which incorporate the report of the special committee appointed at the meeting on December 14, 1935—Drs Meakins, Fitz, Irons and Middleton

The Founders Group or Charter Members which are to be certified without examination within the period until July 1, 1937, will be more limited in number than at first proposed

The Joint Committee expects to hold a meeting tomorrow, Monday, March 2, 1936, at 4 00 p m, at which time further details of organization of the American Board of Internal Medicine, as well as Examination and Certificate procedure, will be considered

It now seems probable that the first (Part I) Written Examination will be held in December, 1936, and the first (Part II) Practical or Clinical Examination will be conducted at or near the time and place of the Annual Session of the American College of Physicians in 1937

The Joint Committee at this time desires to record its appreciation of the constant encouragement and valuable advice given so freely at all times by Dr James Alex Miller, President of the American College of Physicians, Dr William J Kerr, Chairman of the Section on Practice of Medicine of the American Medical Association, and particularly Mr E R Loveland, Executive Secretary of the American College of Physicians, for many important suggestions and faithful cooperation during the formative period of the American Board of Internal Medicine

Respectfully submitted—WALTER L BIERRING, *Chairman*

JONATHAN C MEAKINS	} <i>American College of Physicians</i>	ERNEST E IRONS	} <i>Section on Practice of Medicine, American Medical Association</i>
O H PERRY PEPPER		REGINALD FITZ	
WM S MIDDLETON		WALTER L BIERRING	
DAVID P BARR			
JOHN H MUSSER			
G GILL RICHARDS			

In submitting this report, Dr Bierring asked members of the Board to read the material over carefully in preparation for a further discussion of the matter at the next meeting Dr Bierring's report was received with applause and a resolution adopted accepting the report with the profound thanks of the Board of Regents Thereupon, Dr Bierring stated that the formation of this Board has gone forward in stages, and that his Committee feels that at this time the steps that have been taken thus far should have the sanction of the Board of Regents of this College It was suggested, however, that action be deferred until after the reports might be further studied and also examined by the Board of Governors

Adjournment

Attest E R LOVELAND,
Executive Secretary

MINUTES OF THE BOARD OF REGENTS

DETROIT, MICH

March 3, 1936

The second meeting of the Board of Regents, during the Twentieth Annual Session at Detroit, was held Tuesday, March 3, 1936, at the Book-Cadillac Hotel, convening at 12 15 o'clock, with Dr James Alex Miller, President, presiding, with the following present James Alex Miller, President, Ernest B Bradley, President-Elect, Arthur R Elliott, First Vice-President, David P Barr, Second Vice-President, William Gerry Morgan, Secretary-General, William D Stroud, Treasurer, Walter L Bierring, John H Musser, O H Perry Pepper, Luther F Warren, William J Kerr, Roger I Lee, Sydney R Miller, George Morris Piersol, G Gill Richards, James B Herrick, Jonathan C Meakins, James H Means, James E Paullin, Maurice C Pincoffs, Charles H Cocke, and with Mr E R Loveland, Executive Secretary, acting as secretary of the meeting

The reading of abstracted Minutes of the previous meeting was dispensed with

Dr Charles H Cocke, Chairman of the Board of Governors, reported the following resolutions received from the Board of Governors at their meeting the day previous

RESOLVED, that the Board of Governors recommend to the Board of Regents, and such other Officers as may be concerned in the selection of the time for the Annual Meeting, to hold future Annual Sessions at as late a date in April as consistent with the convenience of those in the City in which the meeting will be held

Chairman Miller ruled that this resolution merely will be entered on the Minutes as a record of a communication to be considered by those in charge of setting the date of the next meeting

RESOLVED, that the Board of Governors suggests to the Board of Regents the desirability of having the By-Laws amended to provide for the appointment of alternates for Governors who cannot attend the Annual Sessions

It was explained by Dr Cocke that there were three proxies allowed to sit by unanimous vote of the Board of Governors at the meeting of that Board the preceding day He felt that every constituency has a right to representation, and since there is no constitutional provision for it, the Board of Regents should take under consideration proper amendments providing for the same

On motion by Dr Piersol, seconded by Dr Bradley, and regularly carried, it was

RESOLVED, that the Board of Regents instruct the Committee on Constitution and By-Laws to draw up proper amendments providing for alternates for Governors who cannot attend the Annual Sessions, and that the proposed amendments be presented in accordance with present provisions of the Constitution and By-Laws

RESOLVED, that the Board of Governors shall express to the Board of Regents their approval of the project for the acquisition of a permanent College home and headquarters, and, further, recommend that the Board of Regents proceed immediately on the project

Chairman Miller reported that he had been present at the meeting of the Board of Governors at which the matter of the College Headquarters was discussed, and that it was quite impressive, since it was unanimous, with the exception of one Governor, in revealing what the general fellowship of the College feels about it There had not been a single vote from the Board of Governors in the negative, although in the discussion at least one had indicated some opposition

RESOLVED, that the Board of Governors express to the members of the Board of Regents their keen appreciation and thanks for the Dinner tendered them on March 1

It should here be recorded that the members of the Board of Regents, as individuals, tendered a Dinner to all members of the Board of Governors who could be present on the evening preceding the opening of the Annual Session Matters of general interest to the College and to each Board were freely discussed

Chairman Miller reviewed the present status of the situation regarding the College

Headquarters, explaining that to date the Board had had only a committee headed by Dr Stengel who had reported informally upon preliminary possibilities. Now, with this resolution from the Board of Governors, one of the possible obstacles to this serious project had been removed. He asked for the judgment of the Board as to how best to proceed in the matter. He stated that he would make reference to it in his annual address at the Convocation and that the matter could be further mentioned at the Annual Business Meeting on March 5.

Dr O H Perry Pepper expressed the opinion that it would be proper to appoint a new committee to study the matter in detail, outlining it, get actual plans and actual estimates, but that that committee should not be empowered to proceed with the purchase of land or the erection of a building without further action by the Regents.

Chairman Miller explained that the committee that had been functioning thus far was appointed purely for a preliminary survey, that its work had probably been completed and that it might now be discharged with thanks.

Dr Stroud, Treasurer of the College, being asked for comments, expressed his approval of the idea of appointing a new committee, but suggested further that there should be included within the motion authorization for any financial outlay from the College funds as may be necessary for the services of an architect, etc.

Upon motion by Dr Bierring, seconded by Dr Lee and regularly carried, it was

RESOLVED, that the temporary Committee on the College Headquarters be discharged with an expression of the deep thanks and appreciation of the Board of Regents for their general survey of the situation.

Chairman Miller pointed out that if it be the wish of the Board of Regents, the Board might proceed to definite plans for the acquisition of a new home and authorize the appointment of a definite committee for making concrete plans, and also to inform the Treasurer of such plans, because that might materially influence the disposition of funds that are now idle awaiting reinvestment.

In the discussion that followed, it was brought out that this might mean that the new committee would be authorized, if they felt wise, to employ an architect and to prepare definite plans. The committee would look into the particular proposition presented by the previous committee in Philadelphia and would also consider other suggestions concerning Washington, or any other city, but the Board of Governors were unanimous in expressing a preference for Philadelphia. The report of the new committee at the next meeting of the Board of Regents would have to be a very businesslike affair, not informal and not indefinite.

On motion by Dr Bierring, seconded by Dr Bradley and regularly carried, it was

RESOLVED, that the incoming President shall appoint a Committee on College Headquarters which shall be authorized by the Board of Regents to proceed actively at once with detailed plans for the acquisition, or the construction, of a new College Headquarters, including the selection of a suitable site, the selection of the proper city, and, further, with authorization for preliminary expenditures for an architect, and with instructions to report to the Treasurer as to any financial arrangements entered into, so that proper funds may be available.

The report of this committee shall be presented to the Board of Regents as soon as feasible—a special meeting of the Board of Regents or the Executive Committee may be called if deemed advisable.

Dr Maurice C Pincoffs, Editor of the ANNALS OF INTERNAL MEDICINE, made a brief report to the effect that his work had been greatly aided by the temporary appointment of Dr Clough. Before another meeting he expressed the hope that that appointment may become permanent. He had been receiving a satisfactory number of manuscripts. The papers presented at the Annual Meeting remained the backbone of the publications in the ANNALS, and probably always will. He reported that unfortunately his office had gotten behind some weeks in getting out the journal recently. He expressed the assurance that the condition would be corrected.

In the absence of Dr Charles F Martin, Chairman of the Committee on Finance, Dr Roger I Lee presented the following report, which, upon motion, was accepted and filed

"Your Finance Committee beg to report a very satisfactory condition of the annual budget Detailed statement of this will be given by the Treasurer at the appropriate time

"They would draw attention to the fact that more than half of the gross income of \$72,000 is derived not from dues from members (which represents only \$31,000), but from the exhibits, subscriptions to the ANNALS, advertisements in the ANNALS and other minor sources of income

"Attention has been directed from time to time, to the substantial annual surplus of the organization in recent years On the other hand, your Committee would remind the Board of Regents that the income from the ANNALS and its advertisements is always a variable quantity according to the size of the ANNALS, the price of paper and printing, the cost of labor and the amount of advertising obtained,—that furthermore, an urgent need exists for more space in the executive offices, perhaps an increase in the personnel of the central office and an expense to be incurred through underwriting the Certification Board,—in all of which instances, increased demands will be made on the annual budget

"Your Committee approves the budget for 1936 as presented in the financial report of 1935

"Initiation Fees and Annual Dues In order to correct false impressions, they would remind the Regents, as well as the Fellows generally, that the initiation fee has been reduced to \$80, and that the annual dues of \$15 include the Journal

"They would recommend that an entertainment allowance for the President of \$200 be set aside in the budget to be drawn upon if, as and when required for special occasions

"It will be of interest to the Regents to know that the book value of securities today, in comparison with that of the original cost, will bring an enhancement of the values of securities and equities equivalent to approximately \$7,000

"The Finance Committee feels a responsibility with respect to your investments and suggests that a Trust Company, to be selected after due consideration by the President and Treasurer, be employed to act as agent to supervise the accounts of the College and advise with regard to investments, giving such suggestions to the Finance Committee as is dictated by their expert judgment They recommend that such a service be obtained from the best Trust Company in Philadelphia at a figure commensurate with the amount of capital involved—this service not to exceed, perhaps, \$300 per year

"Respectfully submitted,

" (Signed) C F MARTIN,

" *Chairman, Committee on Finance* "

Dr Stroud, Treasurer, explained that the handling of the investments is a heavy responsibility, and that it is difficult for the Committee on Finance to keep up with the rapidly changing ideas in investment principles College funds could be better and more safely invested if such counsel were available The responsibility for purchases and sales would still be with the Finance Committee, the investment counsel merely being an assistant agency in helping the Committee

Upon motion by Dr Pepper, seconded by Dr Lee, and regularly carried, it was

RESOLVED, that an appropriation of \$300 00 be added to the 1936 budget in accordance with the recommendation embodied in the last paragraph of the Finance Committee's report

Another item in the report requiring special consideration was the recommendation of the establishment of a fund of \$200 00 for the President's Entertainment Fund Dr Lee, in commenting upon the matter, pointed out that it is a very modest sum and the financial responsibilities that are indirectly put upon the President may in some instances be very large, and it seemed to the Finance Committee, despite the opposition of the President, that a moderate allowance was fitting for such an organization as the College to provide Dr Pepper, another member of the Committee, pointed out that the word "special" in the

report does not mean occasions other than those which may arise and always do arise at the Annual Meeting. In other words, it refers only to the usual entertainment incident to the Annual Meeting.

Upon motion by Dr. Piersol, seconded by Dr. Herrick, and regularly carried, it was

RESOLVED, that the sum of \$200.00 be appropriated for the year 1936-37, in accordance with the sixth paragraph of the Finance Committee's report.

Dr. William D. Stroud, Treasurer, distributed mimeographed copies of the annual report, which hereafter follow, and commented as follows:

"The annual report now in your hands explains the financial situation of the College. Mr. Loveland's report on page 1 shows that we have an Endowment Fund of \$58,281.72 and a General Fund of \$99,047.47, total assets of \$157,329.19. On our investments the total purchase price of our bonds is \$111,844.82, while an estimate of their sale value on February 28, 1936, taken from quoted prices, was \$116,130.15, an appreciation of more than \$4,000.00. The purchase price of our stock was \$14,811.00, which are now worth at current prices, \$17,902.00, therefore with an appreciation of over \$3,000.00. The total appreciation on bonds and stocks is therefore in excess of \$7,000.00."

Upon motion by Dr. Cocke, seconded by Dr. Lee, and regularly carried, it was

RESOLVED, that the report of the Treasurer be accepted and filed.

Chairman Miller pointed out that the budgets for the year 1936 had already been presented and passed upon by the Board of Regents at their meeting in Philadelphia, December 15, 1935, except for the two additions authorized at this meeting.

The report from the Committee on Fellowships and Awards, headed by Dr. David P. Barr as Chairman, was deferred for a later meeting.

Dr. Walter L. Biering, Chairman of the joint Committee on the Certification of Internists, reported that the Committee had held one meeting during this Session, and, in a tentative way, had added a few facts to what was reported previously. No special meeting of the Committee is planned at the Kansas City Session of the American Medical Association, except of those members who are required to bring the matter before the Section on the Practice of Medicine. It was contemplated that the first meeting of the American Board of Internal Medicine will be held during the first week in June for the purpose of working out further details (henceforth the joint Committee on the Certification of Internists will be referred to as the "American Board of Internal Medicine"). The Committee felt that one of its great problems will be the determination and selection of the Founders' Group.

Dr. O. H. Perry Pepper, a member of the Committee, expressed the suggestion that the Founders' Group might be built up very slowly. The determination of the Founders' Group must be based upon definite principles yet to be developed. Those selected must be men about whom there could be no question or criticism. Other opinions and plans were suggested by Dr. Meakins, also a member of the Committee.

On motion by Dr. Herrick, seconded by Dr. Pepper, and regularly carried, it was

RESOLVED, that the Board of Regents of the American College of Physicians approves of the plan of the Committee on the Certification of Internists as outlined for the American Board of Internal Medicine, and the Board of Regents authorizes its representatives on said Board to proceed, using their best judgment.

There was general discussion about any appropriations needed for the operation of the Committee before the next meeting of the Board of Regents. It had been pointed out that the Board of Regents had originally authorized the financing of this project to the limit of \$10,000.00, but that only \$1,000.00 specifically has been budgeted.

Upon motion by Dr. Pepper, seconded by Dr. Bradley, and regularly adopted it was

RESOLVED, that the Board of Regents shall appropriate a sum of \$4,000.00 additional, total \$5,000.00, on the 1936 budget to be made available, if necessary, for the American Board of Internal Medicine.

There was some discussion about a special meeting of the Board of Regents to be held for a final report from the Committee on College Headquarters and also from the American Board of Internal Medicine. The matter was left open, subject to the call of the President when such reports are ready and action necessary.

Dr John H Musser stated that he could not be present for the meeting of the Board of Regents on Friday, March 6, but wished to present to the Board an invitation for the Annual Session of 1938 to be held in New Orleans. An official invitation is being prepared by New Orleans, and will be sent to the Executive Secretary. He pointed out that just as the Twentieth Annual Session has been held in Detroit ten years following its previous meeting, the Twenty-second Annual Session, if held in New Orleans, would also be ten years after the previous meeting.

Chairman Miller asked Dr Musser if it would make any difference particularly to New Orleans whether the College came in 1938 or 1939, inasmuch as New York City also had been planning for sometime to present an invitation for 1938. Dr Musser replied that it will not, except for reasons of sentiment.

Dr William J Kerr at this point presented a memorial prepared by Dr C E Watts, Governor of the College for the State of Washington, on the death of Dr Frederick Epplen, for many years the College Governor for Washington.

On motion by Dr Kerr, seconded by Dr Bierring, and regularly adopted, by rising vote, it was

RESOLVED, that the following tribute be recorded in the Minutes of the Board of Regents, that a copy be transmitted to Mrs Epplen, and that this memorial be published in the ANNALS OF INTERNAL MEDICINE

IN TRIBUTE TO DR FREDERICK EPPLEN

"The Philadelphia Session last year was attended by Dr Frederick Epplen, who had been a member of the Board of Governors for many years. The question of his attending that last Session had been carefully considered and debated. He knew well that the trip to Philadelphia would cost him a large proportion of the myocardial compensation he possessed, but he felt sure that it would be the last opportunity of his lifetime. He elected to exchange most of his remaining strength and probably a part of the days left to him for the joy of association, the renewal of friendship, the revival of memories, in the College. Within the month he died, suddenly as he wished it, because he dreaded a lingering death.

"And thus passed one who was loved by all of us. He was not a prolific author, and yet he was well known the country over. By birth, training at home and abroad, and life long habit, his approach to medicine was intensely scientific rather than artful. He was rewarded with an unusually large practice for many years. The pressure of this professional work did not prevent him from maintaining his contacts and friendships in various organizations, especially in the College.

"The elevation of the level of medical practice in the Pacific Northwest was his constant desire. He gave much time and effort to the Pacific Northwest Medical Association, and the success of this adventure in postgraduate training stands as a tribute to him. A

firm believer in the County Medical Society as a disseminator of facts and ideas, he attended its meetings regularly, and he organized special societies in internal medicine, study clubs and discussion groups where needed

"As a means for the advancement of internal medicine and for improvement of all medicine, he believed thoroughly in the College of Physicians. His best efforts were given in its behalf. He acted as Governor for Washington for many years, and worked diligently in that capacity. He rarely failed to attend the Annual Sessions, and his friendships in the College were cherished as none other.

"During the last four years it was distressing to his friends to see him failing, and to have a cessation of activity in one who had been so energetic. Yet it was inspiring that his enthusiasm never waned, and his final effort to participate in the activities of the College was so characteristic of him and of what he held in highest esteem, that the memory of him will be with us always."

Adjournment

Attest E R LOVELAND,
Executive Secretary

MINUTES OF THE BOARD OF REGENTS

DETROIT, MICH

March 6, 1936

The third meeting of the Board of Regents during the Twentieth Annual Session was held on March 6, 1936, at the Book-Cadillac Hotel, Detroit, convening at 12 20 o'clock, with President Ernest B Bradley presiding, and with the following present: Ernest B Bradley, President, James H Means, President-Elect, David P Barr, Second Vice-President, William D Stroud, Treasurer, William Gerry Morgan, Secretary-General, James Alex Miller, Francis M Pottenger, Luther F Warren, William J Kerr, Roger I Lee, George Morris Piersol, G Gill Richards, Jonathan C Meakins, Maurice C Pincoffs, James D Bruce, and with Mr E R Loveland, Executive Secretary, acting as secretary of the meeting.

Upon motion, seconded and regularly carried, the reading of the Minutes of the previous meeting was dispensed with.

On motion by Dr J A Miller, seconded by Dr Stroud and regularly carried, it was

RESOLVED, that the President appoint a committee to revise and rewrite the present Fellowship Pledge of the College.

President Bradley appointed Dr James H Means, of Boston, a committee of one, to carry out the resolution.

President Bradley next brought up the matter of constitutional provisions for the endorsement of candidates either by a Governor, an Officer or a Regent. Although none of these may propose a candidate, some members of the Board of Governors have felt that it should be the policy of Officers and Regents to refrain from endorsing a candidate, so that all candidates may pass through their hands for investigation and final endorsement. Furthermore, President Bradley suggested that it might be more acceptable to the Committee on Credentials to have candidates endorsed by their respective Governors rather than Officers and Regents.

After general discussion, during which it was brought out that whether or not a proposal is endorsed by the Governor, it is always referred to the Governor by the Executive

Secretary, and the Governor given an opportunity to file his report before action by the Committee on Credentials, on motion by Dr James Alex Miller, seconded by Dr Means and regularly carried, it was

RESOLVED, that it is the sense of the Board of Regents that for the present at least it be considered desirable for no Officer or Regent to act as endorser of candidates, but rather that all proposals be referred to the Governor for the district from which the candidate comes

This resolution did not carry with it a recommendation of the changing of the By-Laws, which provide that an Officer or Regent may endorse a candidate as well as a Governor. The purpose of the resolution was merely to try out the plan of having all candidates endorsed officially by the Governor, so that in no case would the Governor be overlooked

The Executive Secretary, Mr Loveland, presented two communications from Dr James D Bruce, Governor for Michigan, recommending the reinstatement to Fellowship in the College of Dr Eva Finn and Dr William Clift, who had resigned five or six years ago. Their reinstatement was recommended by Dr Bruce in accordance with their desire to pay up past dues rather than being repropose as new cases

On motion by Dr Pottenger, seconded by Dr Lee and regularly carried, it was

RESOLVED, that Dr Eva Finn and Dr William Clift be reinstated as Fellows of the College subject to the payment of the dues from the time of their resignations to date

President Bradley at this time pointed out that the Constitution of the College permits specialists in other lines than Internal Medicine to become Fellows, such as roentgenologists, pathologists, pediatricians, neurologists, psychiatrists and others. There has been a growing tendency toward limitation of membership to those engaged in Internal Medicine. However, if such limitation shall be carried out, it will be plainly necessary to amend the Constitution and By-Laws. This could not affect those who are already members of the College, but would change the policy in connection with the election of new members in following the specialty of Internal Medicine

The Executive Secretary then presented the following communication and resolution from the Board of Governors, as adopted at their meeting on March 5

RESOLVED, that the Board of Governors suggest to the Board of Regents that each year the Executive Secretary send out appropriate questionnaires to obtain information as to the status and work that the members of the College have done during the preceding year, and that these records should be kept on file in the headquarters office

Later in the Minutes of the Board of Governors particular reference is made to Associates. The motion was intended to include all members of the College, but particularly Associates. The Board of Governors, in their discussion felt that there should be available up-to-date information about every member of the College, what he has done during the past year, his contributions, his new appointments, etc., they also felt that it would be a stimulus to Associates who are attempting to qualify for Fellowship for the College office to be following them up concerning these data each year

The Executive Secretary explained that this motion was initiated by some Governors of the College who had inquired for specific information concerning what certain physicians had done during the last two or three years. It not only was not available in the College, but could not be procured through the American Medical Association, or elsewhere. These men feel it desirable to have this information available in the College office about every man

Dr Bruce, speaking to the question, explained that a plan of this character had been employed at the University of Michigan with reference to postgraduate work for the past six years, and that he now has at his office in Ann Arbor the records of over three thousand of the Michigan State members concerning their attendance on various postgraduate activities, both within and out of the State. The plan has had a stimulating effect on the men. He recommended the idea as a very excellent one for the stimulation of Associates particularly

Dr James Alex Miller made inquiry as to the amount of work such a plan would entail in the Executive Offices, whether it would require additional clerical service, filing equipment, etc. The Executive Secretary replied that the present staff could take care of the work without excessive burden, but that additional space and files would be required. The volume of

material on file grows tremendously in an organization of this character. Mr. Loveland further explained that there is an individual folder for every Fellow and Associate of the College. The records, however, are often meagre for those members who have been in the College for many years, for in many instances no original application forms, or, for that matter, any other relevant records were received from the early executives of the College. However, records are fairly complete for all members from about 1920 forward, and wholly complete from 1926 forward.

On motion by Dr. Lee, seconded by Dr. Pincoffs and regularly carried, it was

RESOLVED, that a committee be appointed to draw up a plan for the sending out of blanks which will keep the College records up to date concerning the accomplishments of its Fellows and Associates, the committee to report back at the next meeting.

President Bradley subsequently appointed the following committee:

James D. Bruce, Chairman

Jonathan C. Meakins

Maurice C. Pincoffs

In the discussion, it was brought out that these blanks are intended primarily to keep the College records up to date as to the accomplishments of our Fellows and Associates, that the first records at least shall be complete for a man's entire history, and that the annual form sent out thereafter shall be intended merely to supplement the original record.

Dr. James Alex. Miller proposed that inasmuch as the formation of the American Board of Internal Medicine and the activities of other committees, such as that of the Committee on Credentials, will affect the constitutional requirements for admission to the College, that the Committee on Constitution and By-Laws review and, perhaps, present proper amendments at the next meeting of the Board of Regents. He pointed out that our Constitution says that Fellows shall be members of the medical profession engaged as practitioners, teachers or research workers in Internal Medicine or in an allied specialty. Perhaps the last clause should be deleted.

President Bradley pointed out that in the appointment of new committees due consideration will be given to overlapping certain appointments, so that the Committee on Constitution and By-Laws will have a better appreciation of any amendments that may be necessary.

On motion by Dr. J. A. Miller, seconded by Dr. Richards and regularly carried, it was

RESOLVED, that there be referred to the Committee on Constitution and By-Laws a request for a report and suggested changes in the Constitution and By-Laws to meet the new demands of the College standards for qualification for Internal Medicine.

Dr. Miller's motion had in mind the preparation of such amendments as may be made necessary by the further restriction of the College membership to internists, as may be occasioned particularly by the operation of the new American Board of Internal Medicine.

The next matter of business was the election of a Secretary-General and of a Treasurer for 1936-37.

Dr. George Morris Piersol nominated Dr. William Gerry Morgan for reelection, Dr. Luther F. Warren seconded the nomination.

President Bradley called for other nominations, of which there were none.

Dr. William Gerry Morgan was unanimously elected Secretary-General for the year 1936-37.

Dr. George Morris Piersol nominated Dr. William D. Stroud for reelection as Treasurer, Dr. J. A. Miller seconded the nomination.

By motion seconded and regularly carried, nominations for Treasurer were closed.

Dr. William D. Stroud was unanimously elected Treasurer for the year 1936-37.

On inquiry by a member of the Board, it was disclosed that the Treasurer is bonded in the amount of \$50,000.00.

Dr. David P. Barr, Chairman of the Committee on Fellowships and Awards, reported for that Committee, reading a letter from Dr. John P. Peters concerning Dr. Michael J. Lepore, who is the American College of Physicians Research Fellow at Yale University for

1935-36 Dr Peters' letter revealed that he considers the granting of these fellowships as the most worthy thing the College carries on Dr Lepore's work was reported on in detail, with most favorable comment

Dr Barr then reported that the Committee recommends to the Board of Regents the appointment of Myron Prinzmetal as Research Fellow for 1936-37 Dr Prinzmetal was graduated in 1932 from the University of California His record in school was extraordinary He worked in the Department of Pharmacology, the Department of Pathology and the Department of Medicine as a student and in each of these did investigative work of high order Two years ago he was appointed National Research Fellow, letters from his former teachers were of the most enthusiastic kind Dr Barr stated that his Committee believed that Dr Prinzmetal was considered the outstanding graduate not only of his year, but, perhaps, for five years He later went to the Barnes Hospital, St Louis, for a year as Assistant Resident, where he took part in some of the researches conducted by Dr Kountz He then went to the Boston City Hospital under Dr Soma Weiss As a result of the work with Dr Weiss, he published a paper, "The Nature of the Peripheral Resistance to Arterial Hypertension, with Special Reference to the Vasomotor System" Dr Barr passed a reprint of this publication around for examination by the Board Dr Prinzmetal had published about twenty-four papers even preceding the one in question, most of his publications in association with men from the various schools in which he had worked

Dr Barr stated that he was familiar with most of Dr Prinzmetal's publications, and stated that he (Dr Prinzmetal) had contributed much more than the ordinary assistant does contribute to researches with older men The Committee is informed Dr Prinzmetal wishes to pursue further work with Sir Thomas Lewis in London, especially to continue research on hypertension The Committee, therefore, recommended to the Board of Regents Dr Prinzmetal's selection for the Research Fellowship for the year 1936-37

Upon motion by Dr Lee, seconded by Dr Meakins and regularly carried, it was

RESOLVED, that Dr Myron Prinzmetal be awarded the Research Fellowship of the American College of Physicians, amounting to \$150.00 per month for twelve months, beginning July 1, 1936

Dr Stroud inquired whether in view of the fact that some felt there should be additional fellowships, Dr Michael J Lepore now working at Yale University and whose fellowship expires in June might not be considered for an additional year

Dr Barr, for the Committee on Fellowships and Awards, reported that Dr Lepore had not requested a continuation of his fellowship, and expressed the belief that Dr Lepore might be provided for directly in the budget at Yale Dr Barr expressed a doubt as to there being any necessity the present year to consider the extension of his fellowship He said further that in appointing a Fellow the College assumes at least a great interest in that man and a certain degree of responsibility for seeing that he has the opportunity to develop from this grant, and when and if the College funds permit the extension of fellowships in this form or in other forms, the matter should be actively considered by the Regents

Dr Barr was informally authorized by President Bradley to write Dr Peters, thanking him for his report on the work of Dr Michael J Lepore, and to convey to Dr Peters the very great interest of the College in Dr Lepore's work, also to find out, without in any way committing the College, what provision is being made for Dr Lepore next year

Dr Richards inquired from Dr Barr whether in his opinion the College would accomplish more good by extending a fellowship for two years, or to award separate fellowships to different men

Dr Barr's reply was that he feels that one year is preferable, because each one of these fellowships is, to a degree, a gamble, it cannot be determined how the one selected will succeed, in one year he has an opportunity of showing how good he is, if he is very good, the College, perhaps, should consider him for a second year

Dr James Alex Miller "Mr President, in this connection, following up the line on which I spoke at the General Business Meeting yesterday, it does seem to me that we ought to be thinking over, in connection with our plans for a new home, also the question of a

program for possibilities of using surplus funds for the advancement of Internal Medicine. This granting of Fellowships would be one method, there may be others. It seems to me that it would be very helpful if, in addition to your specific committee that has already been authorized for the consideration of specific plans and estimates for our new home, we had at the same meeting a report from another committee that might consider other possibilities for a program of funds, with some estimate of what that would involve, which would help us to determine another thing, that is, this question as to in what way, if any, we should reduce the financial obligations of the new Fellows. It seems to me that it might help in this whole matter if we at this meeting authorize the appointment of another committee to report at the same time that the House Committee does, in connection with the possibility of a future program for the use of available funds of the College for the promotion of Internal Medicine, leaving it open to more fellowships or something else.

"Dr. Pincoffs made the suggestion of some sort of revolving fund and some of us have been discussing a revolving fund that might be given to young men, that would be turned back. If it was similar to other revolving funds, it might be of great value to this organization. That money would very likely come back, come back to us with interest.

"In other words, there is quite a field there and I think that while we are considering this new home, the Fellowship of the College would be very much interested to know how much we have been considering other possible programs for the use of our money and, if they could consider them altogether, it would seem to me it would be very helpful."

In the discussion that followed, Dr. Miller indicated that this additional program would not be limited to fellowships and awards alone, but that there should be some committee to take up a composite program that would include everything that the College might consider.

Dr. Kerr said that as soon as the American Board of Internal Medicine is established and begins to function, queries will probably begin to come in as to facilities for training as internists in this country. The College should be prepared to furnish such information about these facilities both in this country and abroad. He suggested that the College might definitely consider the investment of some of its funds in assisting young men who cannot afford to continue their training as they should. But, the College should be well informed and be well prepared, through a survey, before launching on any particular project.

On motion by Dr. Pincoffs, seconded by Dr. Barr and regularly carried, the following resolution was adopted:

RESOLVED, that a Committee on Future Policy for the development of Internal Medicine be appointed by the President for the purpose of considering a program of possibilities for using surplus funds for the advancement of Internal Medicine. This committee shall take under consideration all matters outside of that of the College Headquarters, such as fellowships, awards, postgraduate education, initiation fees of new Fellows, revolving funds for the aid of research, etc.

President Bradley subsequently appointed the following Committee:

James Alex. Miller, *Chairman*
Walter L. Bierring
Roger I. Lee
Maurice C. Pincoffs
Francis M. Pottenger

The following Executive Committee of the Board of Regents was elected for the year 1936-37:

Ernest B. Bradley, *Chairman*
James H. Means
William Gerry Morgan
William D. Stroud
Walter L. Bierring
Roger I. Lee
James Alex. Miller
Maurice C. Pincoffs
Francis M. Pottenger

President Bradley proceeded to the appointment of committees in accordance with the Constitution and By-Laws or special regulations previously adopted by resolution by the Board of Regents (asterisk indicates new appointment, \ indicates reappointment)

Committee on Advertisements and Commercial Exhibits

\E J G Beardsley, *Chairman*
 \George Morris Piersol
 \William D Stroud

* * * * *

Committee on Annals of Internal Medicine

\James H Means, *Chairman* (1939)
 David P Barr (1938)
 *Egerton L Crispin (1937—taking the place of O H
 Perry Pepper, resigned)

* * * * *

Committee on Fellowships and Awards

xDavid P Barr, *Chairman*
 *Jonathan C Meakins

Committee on College Headquarters

Roger I Lee, *Chairman*
 O H Perry Pepper
 William D Stroud
 James Alex Miller
 David P Barr

The Executive Secretary then presented invitations for the 1937 Annual Session from the Cities of Columbus, Buffalo, Cleveland, Toledo, Memphis and St Louis, including one for 1938 from New Orleans. The two most complete invitations were from Memphis and St Louis, and were read in detail. They contained official invitations from all the medical organizations, the medical school, civic bodies, hotels, Chamber of Commerce, the Governor for the State, the local Regent and Fellows, and others.

On motion by Dr J A Miller, seconded by Dr Piersol and regularly carried it was RESOLVED, that the Twenty-First Annual Session of the American College of Physicians be held in St Louis during 1937

On motion by Dr Barr, seconded by Dr Richards and regularly carried, it was RESOLVED, that the date of the meeting shall be during the third week of April, namely, April 19-23, 1937

Dr James Alex Miller reported that he has been discussing with keymen in New York City the possibility of the College coming to New York in 1938, and expressed the opinion that there will undoubtedly be a complete invitation laid before the College for the 1938 Session

On motion by Dr Meakins, seconded by Dr J A Miller and regularly carried, it was RESOLVED, that Dr David P Barr shall act as the General Chairman of the 1937 Session in St Louis

Dr G Gill Richards inquired why the Daily Bulletin had been discontinued at the 1936 Session, saying that several inquiries had come to him from members in attendance who missed the Bulletin

The Executive Secretary, Mr Loveland, reported that the Daily Bulletin had never been officially established by the Board of Regents, but had been published by him primarily for the exhibitors. It had entailed a tremendous amount of work because each issue had to be published over night with a great deal of work in preparing copy, proof reading, etc. Furthermore, its publication had entailed an expense of from three to four hundred dollars. He said that the bulletin was not serving any valuable purpose so far as exhibitors were concerned. The daily registration of attendants at the Session is of some value, but will be furnished to exhibitors after the meeting. He reported that the Editor of the ANNALS had preferred not to act as editor of the Daily Bulletin, and it had been discontinued at the Detroit meeting purely because of the burden of work entailed by its publication

President Bradley asked for the opinion of the Board of Regents, saying that if they felt it worth while, the Executive Secretary would be glad to publish it

On motion by Dr Piersol, seconded by Dr J A Miller and regularly carried, it was RESOLVED, that the publication of the Daily Bulletin at the Annual Sessions be discontinued because of the amount of work and the expense attached

President Bradley, speaking about the present Session and the one for 1937, informed the Board of Regents that he would like to have a free expression of recommendations and suggestions for the program next year. He stated he had talked with many of the members of the College about the program of the Detroit Session, and without a dissenting voice, the opinions had been that the program was excellently arranged. Sometimes addresses were considered too numerous for the time available at former meetings, but there had been no such criticism at the current meeting. He had also talked with the exhibitors, who expressed their appreciation of the forty-five minute intermissions in the General Sessions. Some of them felt that the program ran too late in the afternoon, and expressed the desire to have a little more time open for the inspection of exhibits. Exhibitors had expressed some question as to the desirability of his suggestion that the intermissions might be shorter with earlier closing in the afternoon. President Bradley stated that he felt it should be announced by every presiding officer on the afternoon session before intermission that this time is given attendants solely for their visit to and inspection of the exhibits, and suggested that this announcement be placed on the afternoon agenda in the future

Dr David P Barr inquired if it were the feeling of the Board that it is necessary to have a considerable competition of clinical programs or a greater number of clinical programs each morning. He suggested the possibility that at St Louis he might be able to arrange two, or at the most three, programs of high excellence, with halls sufficiently large to accommodate the people who wish to come, and inquired whether the Board felt that at the same time there should be a larger number of programs in other places. At some of the Sessions there are about twenty different clinics going on simultaneously

President Bradley, referring to the didactic morning lectures at the Philadelphia Session, reported that the chairman of the clinics, Dr Pepper, had found that they were rather popular among some of the men who did not wish to go hither and yon to various hospitals and laboratories for clinics. It was offered as a suggestion for consideration at the St Louis meeting again. President Bradley said that he saw no particular reason why men should be sent to hospitals unless patients were to be shown and real clinics given.

Dr Stroud inquired whether by doing this there might not be some danger of curtailing the attendance at the various clinics.

Dr Lee expressed the opinion that it is merely a question of competing against one's self in either event. He personally had a strong feeling that the mornings are clinical sessions, but that there has been a strong drift against the clinical session in the hospital, yet these clinics are the real keynotes of the meetings and the members ought to be encouraged to go to the hospitals, otherwise the actual purpose of the College is defeated. He said further that the only criticisms he had heard were that the standard of both the clinics and the lectures should be raised, getting them out of the district medical society level to which they have drifted and getting them on the level of internists.

Dr Meakins said that he had been very much impressed for quite a few years with the fact that the morning sessions, while they are supposed to be clinical, seldom provide patients. There have been lantern slides and x-rays. At his clinic that morning he had been the only one who had presented patients. The other patients were there, but were not used, they were left in the background and the speakers talked from slides, etc. The previous morning he had been at a dermatological clinic, and it had been most illuminating because they had something one can see. If the patient is not going to be used, if it is not going to be a real clinical program, why should the members of the College be put to the bother and trouble of going off to a distant hospital several miles away? Why should such presentations not be given at the headquarters?

Dr Means stated that he heartily endorsed the sentiments of Dr Meakins. He thought it very necessary to get back to the presentation of patients.

Dr Pincoffs stated that he thought there are other features that could be developed that have been present at some of our meetings, one of which is the mornings at home for people in the laboratories. He referred especially to the Thorndike Laboratory in Boston, where this idea was well carried out. It was also carried out by a number of men in Philadelphia. Many men visiting those laboratories spoke highly of that feature.

Dr Meakins further pointed out that if the College is to have real clinics it cannot have them in a place that seats two hundred people, because they can't see anything. Real clinics must be conducted in smaller groups.

President Bradley, in discussing the date of the next meeting of the Board of Regents, suggested that it might be necessary to call a meeting during the summer or the very early autumn, in order to receive reports from the Committee on the College Headquarters, the American Board of Internal Medicine and the Committee on Future Policy for the Development of Internal Medicine.

Adjournment

Attest E. R. LOVELAND,
Executive Secretary
